Foreword

While there has been significant scientific study into the ignition of fires and explosions, the results of this research have not been utilized to their maximum potential. This book is a significant step towards correcting the under-utilization of this body of knowledge.

Vytenis Babrauskas has a reputation for the thoroughness of his literature searches, and this book demonstrates that that reputation is well deserved. Dr. Babrauskas left no stone unturned, and the result is arguably the most comprehensive work on a single subject in the area of fire science or fire protection engineering.

This book is written for a broad audience, ranging from beginners who are new to the scientific study of ignitions to experts who have a well developed scientific background. The author presents fundamental science relating to combustion, which is presented in a manner suitable for beginners with only a rudimentary understanding of chemistry, then expands upon this treatment at a level that would be suitable for most advanced experts in areas relating to ignitions of fires and explosions. For each topic covered, this book thoroughly presents the relevant underlying science, then uses this science to explore the strengths and weaknesses of typical applications such as regulatory requirements and test methods.

While the author states that the primary use of this book will be in the investigation and understanding of past fires, there is another important application of this information: the design of buildings and facilities. In any design where the prevention of ignition is an objective, the concepts presented in this book provide an invaluable resource for the design engineer.

Morgan J. Hurley
Technical Director
Society of Fire Protection Engineers

Preface

The present work is the first book attempting to cover the entire subject of ignition of unwanted fires. The only areas where coverage has been intentionally limited are:

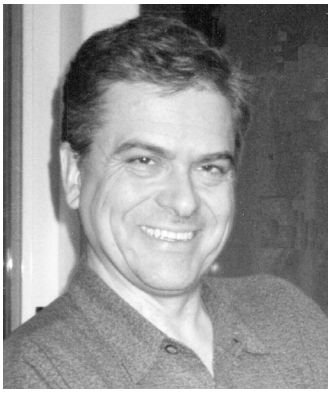
(1) Fundamental theory of reacting flows. A number of modern ignition theories are simply specialized applications of general computational fluid dynamics (CFD) models. The CFD field has become highly developed in recent years and an assortment of good textbooks already exists.

(2) Preventive measures. Chapter 12 presents material in several, selected areas where systematic, research-based studies exist. But the field is vast and hundreds of codes, standards, and handbooks dealing with preventive issues involved in design, installation, and maintenance of facilities have been published by NFPA and other organizations. The reader should consult these for their detailed recommendations.

(3) Flash point compilations. Chapter 15 contains information on a wide variety of pure and 'practical' fuels where, apart from flash points, additional data, e.g., flammability limits or minimum ignition energies, exist. For an authoritative compilation of flash point data on roughly 2000 substances, NFPA 325 is recommended.

(4) Brand-name listings of defective or recalled products. This is ephemeral information and should be obtained from CPSC or from specialty periodicals.

Even with the limitation #1 stated above, some readers may find that much less space is devoted to coverage of theory than to coverage of practical applications. This, however, is due to availability of material. The author believes that a theory is valuable only if:



(a) it leads to a conceptual understanding of the problem; or

(b) it provides a framework for making useful practical calculations.

The author reviewed a very large number of theory papers which did not meet either of these objectives and, consequently, are not covered in this Handbook. Typically, such theoretical studies did not lead to physical insights and either (a) produced only wholly-numeric solutions, which were illustrated with a few example problems but with no means for users to apply to their own cases, or (b) were so ambitious that a huge number of input constants is required, but there exists no practical means by which users can obtain such constants for their problems. If such theories had been included, the size of the Handbook would likely have doubled, but it is hard to see that its value would have increased.

Several of the author's friends have suggested that coverage should also be limited in the areas where information might prove of value to lawless individuals. Apart from the fact that he doubts a book can be made useful for technical specialists, yet devoid of value to the criminal, the author believes in the wisdom of Isaac Bonewits: *"Evil acts cannot be prevented by keeping the public ignorant."*

About the author

Vyto Babrauskas was the first person to ever earn a doctoral degree in Fire Protection Engineering (University of California, Berkeley), where he studied fire endurance of buildings and created the first computer room fire model to be released in the US. Subsequently, he conducted fire research at the National Institute of Standards and Technology for 16 years, where he developed the Cone Calorimeter, the large-scale open calorimeter, and other test methods. He also developed various fire safety engineering design methods and models and has written extensively on fire safety topics, which includes more than 200 articles and reports. Since 1993 he has headed Fire Science and Technology Inc., a firm providing consulting, contract R&D services to manufacturers and laboratories, and fire science support to fire investigations and litigations.

.

Acknowledgements

Writing this book proved to be a bigger undertaking than I envisioned at the start. Thus, the decision by the Society of Fire Protection Engineers' Education and Scientific Foundation to provide some support for the effort has been much appreciated.

Many individuals graciously provided various materials helpful towards preparing this book, with special thanks due to: Marty Ahrens, Kathleen Almand, John Amerongen, Ralph Anthenien, Jesse Aronstein, Kiyomi Ashizawa, Arlene Barnhart, Chris Bloom, Joe Bloom, Regina Burgess, Mary Cahill, Monica Carnesi, Kenneth Cashdollar, Judd Clayton, Hugh Council, Michel Curtat, John D. DeHaan, Fred Dryer, Dougal Drysdale, David Edenburn, Ulf Erlandsson, Charley Fleischmann, Ross F. Firestone, Michael Fitz, Mario Fontana, Mark E. Goodson, Cecile Grant, Yasuaki Hagimoto, John R. Hall jr., Yuji Hasemi, David Higday, Irma M. Hill, David B. Hirsch, Marcelo Hirschler, Donald Hoffmann, Blake Holt, Ron Hrynchuk, Morgan Hurley, David Icove, Nora Jason, Mohammed Khan, Richard Kithil, jr., Ingolf Kotthoff, Ulrich Krause, Christian Kubainsky, Peter Lambrineas, John Lentini, Neville McArthur, Roy Merrifield, Keith Moodie, Steven Nowlen, Jack Olsen, Birgit Östman, Roger Parker, David Peace, Ulrich von Pidoll, Chris M. Pietersen, Albert Reed, David Reiter, Terry A. Roberts, Kuma Sumathipala, Takeshi Suzuki, Ken Swan, Russell Thomas, Robert J. Tuchman, Kathy Whisner, Robert H. White, Ulf Wickström, Fred Williams, and R. Brady Williamson.

Sincere thanks is due the reviewers whose comments were greatly valued and helped to make this a better book: Norman Alvares, Andrew Armstrong, Larry Arnold, Robert Barker, Bruce Ettling, Irvin Glassman, Mark Goodson, Brian Gray, Yasuaki Hagimoto, Martin Hertzberg, Robin Holleyhead, Gordon Jones, Takashi Kashiwagi, Ronald Kilgore, Ulrich Krause, Graeme Leiper, Bob Levine, Keith Moodie, Howard Needles, Thomas Ohlemiller, Thomas Peacock, Albert Reed, John Rockett, Jack Sanderson, Eckart Schmidt, Thomas Shefchick, Joel Stoltzfus, Hugh Talley, Craig Tarver, Elizabeth Weckman, and Robert Witter. I am especially grateful to those reviewers—Michael Fitz (who read the book's manuscript as a graduate-student assignment for a course I was teaching at Worcester Polytechnic Institute) and John Staggs (and anonymous reviewers recruited by him)—who undertook to review the entire manuscript.

Ross F. Firestone wrote the section on Arc-discharge lamps; Michael M. Fitz wrote the section on Welding and portions of the sections on Chimneys and flues and on Coffeemakers and teapots.

Thanks to Carol Heywood-Babrauskas and Doris Heywood for proofreading the book, and to Viki Mason and David Heywood for designing the cover and the titlepage. Chau Nguyen and Noel Putaansuu helped prepare some of the figures for this book.

Chapter 1. Introduction

Background **1**
Fire ignition statistics **2**
The fire triangle and taxonomy of ignitions **6**
Some complications of definition *8*
Types of combustion and combustion-like reactions *8*
Apparatus-dependent nature of ignition **9**
The probabilistic nature of ignition and negative proof **9**
Comments to the fire investigator **10**
Computer methods **11**
References **12**

Background

All fires start with ignition. In olden times, by the way, ignition used to be called *inflammation*, and that term is still occasionally found in some literature. When a fire is investigated, many things may be checked, but one of the essential ones is an attempt (it is not always successful!) to determine the cause of the fire. To determine the cause, it is important to know the ignition characteristics of combustibles. Can a material have undergone self-heating and spontaneous combustion? Is the radiant heat output of a certain malfunctioning device sufficient to ignite a hypothesized first-ignited material? Often, when one of these questions arises, the issue of testing and analysis must then be handled. How shall the material be tested? and how shall the results be presented so that a hypothesis could properly be accepted or disproved? Conversely, the fire protection engineer and the chemical engineer must have knowledge about ignition characteristics so that environments could be designed which minimize the possibility of unwanted ignition.

The present book is the first ever to attempt to encompass the total field of ignition of unwanted fires. (We will generally not deal with *desired* ignitions, such as the ignition of gasoline vapors in an engine cylinder, although in some cases wanted ignitions have to be studied due to their potential for leading to further ignitions that are unwanted.) Because ignition is of concern both to fire investigators and to engineers, the needs of two different groups must be addressed and the intended readership of this tome encompasses both these groups. This is an experiment, since very few publications have been written which attempt to be useful to both. However, the author feels that this is possible. The more theoretical or mathematical sections can be skipped by those without a science background and continuity will not be lost. Most of the chapters which contain heavy doses of theory also contain a section entitled *Highlights and summary of practical guidance*; this can be the first recourse to the fire investigator, who can then use it as a basis to explore other sections of particular relevance in that chapter. Additionally, Chapters 14 and 15 function as a mini-encyclopedia of practical information on substances and devices commonly encountered in fires.

While it is true that ignition begins a fire, this book is not an introduction to fire science, nor to the investigation of fires. While the reader is not expected to have a background both in fire science/engineering and in fire investigation, he or she is expected to have a background in *one* of these. Individuals from scientific fields would be expected to have first studied Dougal Drysdale's **An Introduction to Fire Dynamics**[1]; this is a unique introduction to fire science and there is currently no 'or-equal.' In the fire investigation area, the two most essential prerequisites are John DeHaan's **Kirk's Fire Investigation**[2] and NFPA 921—Guide for Fire and Explosion Investigations[3]. Also valuable is a British fire investigation textbook issued by The Institution of Fire Engineers[4].

While much here may be useful to the researcher, nonetheless the book is primarily addressed to the practitioner. Thus, even in the theory sections, lengthy or highly complex mathematical solutions have not been presented in detail. Instead, ample references are given to those researchers who will want to look up (and maybe improve upon!) various lengthy mathematical procedures reported in the literature. The summaries of theoretical proofs and conclusions given in this book, however, should suffice in most cases even for the advanced practitioner.

Much of the literature of this field was developed quite a few years ago. Thus, the best way of presenting numeric guidance was generally by means of graphs. Today, however, it is reasonable to assume that any engineer or investigator will have access to spreadsheet programs on the computer. Thus, the author has taken many such older results which were given only in graphical form and, by digitizing and curve-fitting them, converted them into simple equations which can readily be set up in a spreadsheet. It is also worthwhile to point out that some old solutions are only available as trial-and-error equations, commonly ones where the unknown quantity appears on both sides of the equation. Such equations were laborious to evaluate in slide-rule days, but by setting up an expression for each side of the equation into two cells of a spreadsheet, iterations can be made almost as fast as evaluating a simple algebraic expression.

Fire ignition statistics

In many countries, death rates due to fire improved remarkably over the course of the 20th century, as illustrated by US data[5, 6] in Figure 1. Reliable national statistics are not available prior to 1913, but fire losses in the 19th century were evidently very large. For example, in 1875 it was estimated

Table 1 Causes of US structure fires (average per annum over the years 1994-1998)

Cause	Fires	Civilian deaths	Civilian injuries	Direct property damage (in Millions)
Cooking equipment	107,500 (19.0%)	339 (9.0%)	4,928 (23.1%)	$514.7 (7.1%)
Stove	71,000 (12.5%)	248 (6.6%)	3,645 (17.1%)	$282.9 (3.9%)
Oven	15,800 (2.8%)	25 (0.7%)	488 (2.3%)	$71.4 (1.0%)
Incendiary or suspicious	90,300 (15.9%)	628 (16.8%)	2,468 (11.6%)	$1,598.1 (22.1%)
Match	16,000 (2.8%)	70 (1.9%)	362 (1.7%)	$168.5 (2.3%)
Unknown-type open flame	8,600 (1.5%)	46 (1.2%)	263 (1.2%)	$162.2 (2.2%)
Heating equipment	70,100 (12.4%)	486 (13.0%)	1,828 (8.6%)	$778.5 (10.8%)
Fixed space heater	18,300 (3.2%)	145 (3.9%)	402 (1.9%)	$192.1 (2.7%)
Central heating unit	11,500 (2.0%)	50 (1.3%)	259 (1.2%)	$111.1 (1.5%)
Chimney or flue	10,500 (1.8%)	13 (0.3%)	46 (0.2%)	$65.3 (0.9%)
Water heater	8,400 (1.5%)	37 (1.0%)	379 (1.8%)	$92.1 (1.3%)
Fireplace	7,800 (1.4%)	28 (0.7%)	114 (0.5%)	$85.3 (1.2%)
Portable space heater	6,100 (1.1%)	178 (4.7%)	492 (2.3%)	$135.6 (1.9%)
Other equipment	64,000 (11.3%)	298 (8.0%)	2,164 (10.2%)	$1,045.8 (14.4%)
Electrical distribution	54,700 (9.6%)	372 (9.9%)	1,664 (7.8%)	$971.4 (13.4%)
Fixed wiring	17,400 (3.1%)	138 (3.7%)	400 (1.9%)	$359.0 (5.0%)
Light fixture or sign	8,700 (1.5%)	33 (0.9%)	162 (0.8%)	$101.4 (1.4%)
Cord or plug	8,100 (1.4%)	99 (2.6%)	450 (2.1%)	$149.2 (2.1%)
Appliances, tools, or air conditioning	39,200 (6.9%)	136 (3.6%)	1,223 (5.7%)	$352.7 (4.9%)
Clothes dryer	18,100 (3.2%)	17 (0.5%)	418 (2.0%)	$92.5 (1.3%)
Open flame, ember or torch	34,300 (6.0%)	138 (3.7%)	1,014 (4.8%)	$456.0 (6.3%)
Torch	8,300 (1.5%)	15 (0.4%)	283 (1.3%)	$190.6 (2.6%)
Open fire	6,200 (1.1%)	18 (0.5%)	93 (0.4%)	$45.2 (0.6%)
Rekindle or reignition	5,800 (1.0%)	1 (0.0%)	5 (0.0%)	$47.8 (0.7%)
Hot ember or ash	5,400 (1.0%)	16 (0.4%)	108 (0.5%)	$66.2 (0.9%)
Smoking material	29,000 (5.1%)	850 (22.7%)	2,256 (10.6%)	$341.0 (4.7%)
Cigarette	25,700 (4.5%)	735 (19.6%)	2,025 (9.5%)	$292.6 (4.0%)
Exposure (to other hostile fire)	25,200 (4.4%)	35 (0.9%)	190 (0.9%)	$358.1 (4.9%)
Convection or direct flame	9,400 (1.7%)	17 (0.5%)	77 (0.4%)	$148.3 (2.0%)
Radiated heat	7,100 (1.3%)	10 (0.3%)	47 (0.2%)	$57.5 (0.8%)
Child playing with fire	22,600 (4.0%)	296 (7.9%)	2,119 (10.0%)	$271.2 (3.7%)
Match	8,700 (1.5%)	84 (2.2%)	634 (3.0%)	$96.0 (1.3%)
Lighter	7,700 (1.4%)	140 (3.7%)	1,039 (4.9%)	$110.2 (1.5%)
Other heat, flame, or spark	16,800 (3.0%)	152 (4.1%)	1,196 (5.6%)	$263.1 (3.6%)
Candle	8,000 (1.4%)	95 (2.5%)	838 (3.9%)	$112.7 (1.6%)
Natural causes	13,400 (2.4%)	16 (0.4%)	243 (1.1%)	$291.4 (4.0%)
Lightning	7,700 (1.4%)	10 (0.3%)	63 (0.3%)	$179.0 (2.5%)
Total	**567,100**	**3,744**	**21,293**	**$7,241.9**

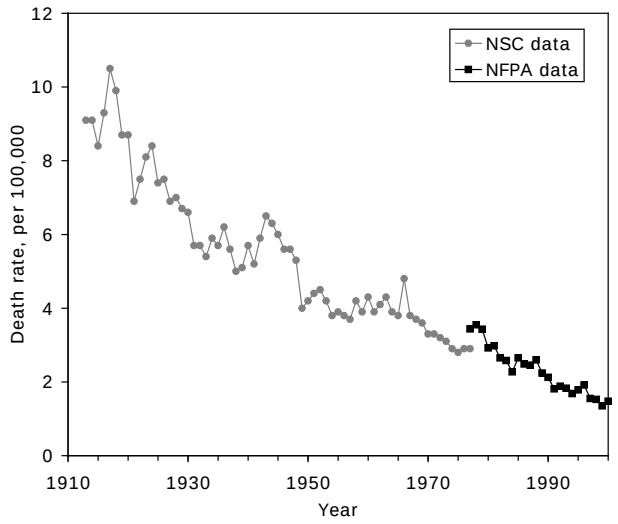

Figure 1 Death rate due to fire in the United States

(but possibly overestimated) that 5,000 to 6,000 deaths[7] were occurring annually in the US due to kerosene ignition accidents alone. Today, there are around 4,000 deaths annually from *all* fire causes. No single factor accounts for this impressive record of improvement. Smoke detectors are perhaps the modern invention that has had the most significant impact on fire deaths. The fraction of households equipped with smoke detectors in the US[8] jumped from 10% in 1974 to 67% in 1982 and is currently over 90%; yet the statistics show a relatively smooth decline, without a sharp downward jump during that period. A number of ignition sources which were notorious in earlier years became insignificant a century later. As an example, gas and kerosene lighting were very prominent fire sources in the 19th century but are rare today. But it is not entirely clear that sufficient categories of this type exist to account for the steady improvement. Two factors which may account for a steady improvement are (1) increased education among the population, and (2) more strict codes, standards, and regulations, although their effects are hard to quantify.

Detailed causes of US structure fires are given in Table 1, as provided by NFPA[9]. These are fires reported to U.S. municipal fire departments and so exclude fires reported only to Federal or state agencies or industrial fire brigades. The table presents fires in *all* buildings and is not restricted to homes. First-level cause categories are based on a hierarchical sorting developed by the US Fire Administration. Hierarchical sorting means the numbers tend to be lower than those calculated if a cause is considered in isolation. Second-level causes are calculated within the first-level categories and are shown only if they accounted for at least 1.0% of fires. Also, second-level causes that are totally lacking in detail (e.g., unknown form of heat) are omitted. Most fires classified as "Other equipment" lack all detail on the equipment involved. Fires are shown to the nearest hundred, civilian deaths and injuries to the nearest one, and direct property damage to the nearest hundred thousand dollars. Sums may not equal totals because of rounding errors. Fires with first-level cause category of "unknown" have been proportionally allocated.

Table 2 Fraction of US fires that are incendiary or suspicious

Location of fire	1980	1998
structure fires	23.4	19.2
vehicle fires	8.7	14.9
outdoor and other	67.9	65.9

Two things must be kept in mind in connection with the US national statistics, such as given in Table 1:

(1) The only fires counted are those reported to the local fire departments, but *most* fires are unreported. The majority of these are small nuisance fires which are successfully extinguished by individuals who do not subsequently feel a need to contact the fire department. A 1974 study in one city found that only about 11% of the total residential fires were reported[10]. A much larger, more recent study of US households[11] found that only 4% of the total residential fires were reported. The study also identified that many householders tend to forget events that occurred as recently as a year ago, and it was necessary to restrict surveying to just the most recent 3-month period. On the basis of all, rather than just reported, fires, the conclusion was that nearly 30% of US households experience a fire in any one year. Of *all* residential fires, 69.1% were due to human carelessness, 21.3% due to failure of products or equipment, 0.1% due to children playing with fire, and the remainder due to miscellaneous or unknown causes. The majority (76.4%) of *unreported* fires took place in the kitchen.

(2) The determination of cause is made by the local fire department. Their primary obligation with regards to

Table 3 Deaths due to fire for 1993, per year, per 100,000 population

investigation of fires is to determine if a crime has been committed. If no crime is found, then the resources in many communities do not permit a detailed investigation. Private investigators working for insurance companies may have greater resources to investigate fires, but there is no mechanism whereby their findings would enter into the national statistics.

In the US, incendiary and suspicious fires declined in structures over the last two decades[12], but rose for vehicles (Table 2).

The statistics of other countries are significantly different. Annual death rates due to fire in selected countries[13] is shown in Table 3. Such wide discrepancies have been studied, but a clear rationale does not always emerge; the topmost reasons are, perhaps: cultural differences, building construction differences, quantities and types of occupant goods, widely disparate rates of utilizing energy, effectiveness of firefighting forces and occupant devices (smoke detectors), and—perhaps most important of all—incompatible schemes for collecting statistical data. Table 5 shows the breakdown of fire causes in Sweden[14]; clearly lightning is a large problem in that country.

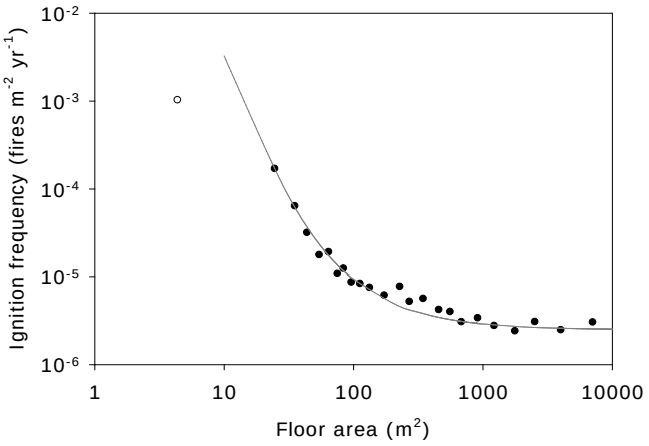

Figure 2 Ignition frequency in Finnish buildings, normalized per unit floor area

Fire statistics in developing countries tend to be quite different from those in industrialized countries. For example, some recent statistics from Brazil[15] are shown in Table 4. It is also interesting to note the focus on blame, which is generally absent in Western statistics.

To a first approximation, one might expect that the frequency of ignition per unit floor area is constant. Few countries publish fire statistics on that basis, but data from Finland[16] indicate something else. Figure 3 shows that for buildings larger than about 100 m^2, the frequency of ignition does increase with increasing floor area. But the increase is not linear, as made clear in Figure 2, except for buildings of floor area greater than 10,000 m^2. It is also not immediately evident why very small structures (< 100 m^2) have a disproportionately high incidence of ignitions, but some of these would evidently be outbuildings, not occupied structures.

Not all ignitions have the same probability of leading to a large fire, as shown in Table 7, compiled by NFPA[6]. Apart from the obvious case of exposure fires, it is clear that in-

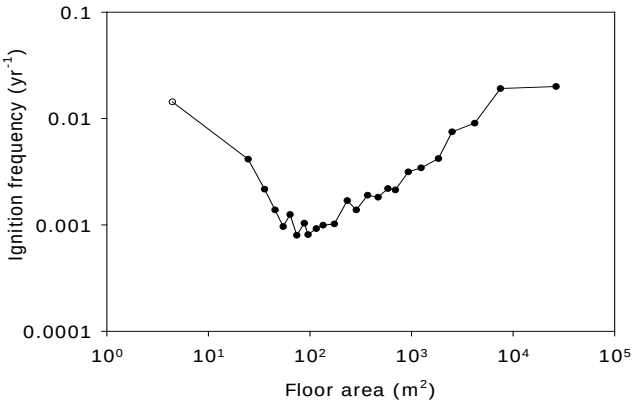

Figure 3 Ignition frequency in Finnish buildings, as a function of floor area of building

tentional ignitions are disproportionately likely to lead to large fires; conversely cooking-equipment fires are likely to be confined to the kitchen. Generally, the results suggest that open-flame ignitions cause the probability of fire extension to be high. It should also be noted that the top six include three causes – exposure, natural causes, electrical distribution equipment – where fire origin often is not inside a room and so flame spread beyond the room of origin may be hard to define. The effect of children playing with matches on causing large fires is especially extreme judging from another set of statistics. In the nationwide US study on unreported fires referred to above[11], it was found that while only 4% of the total fires were reported, 47% of the fires started by children playing with fire were reported. This is evidently because these fires are much more likely to overwhelm the householders' personal ability to extinguish.

Similar UK statistics[17], but more detailed and restricted to dwelling fires are shown in Table 6. Cox et al.[18] reported the results of a 1977 survey of fires and explosions in the chemical industry; these are given in Table 8; the study is also of significant interest in that it is one of the few ambitious efforts to analyze ignitions as part of an overall effort to quantify risk in a particular industry. The authors also reported the results of a British survey covering 1987/88, these results are given in Table 9.

More recent, but less specific data have been published in a world-wide survey[19] encompassing hydrocarbon/chemical industry losses during 1970 – 1999 that exceeded a $10,000,00 loss. These are given in Table 10 through Table 12.

The fire triangle and taxonomy of ignitions

The fire triangle should already be well-known to any reader coming to this book. It says that fuel, an oxidant, and heat are necessary for combustion. Ignition is, of course, *the initiation of combustion*, but it may be surprising that, among the many available combustion textbooks, most do not provide any definition of combustion! There are a few that do. Demidov[21] defines it as: "Any chemical reaction accompanied by liberation of heat and emission of light." Lewis and von Elbe, in their classical textbook[22] define it as: "A spontaneously accelerating chemical reaction with large energy release." Fristrom[23] considers it to be: "Any relatively fast exothermic gas-phase chemical reaction." Griffiths and Barnard[24] define it as: "A self-supporting exothermic reaction."

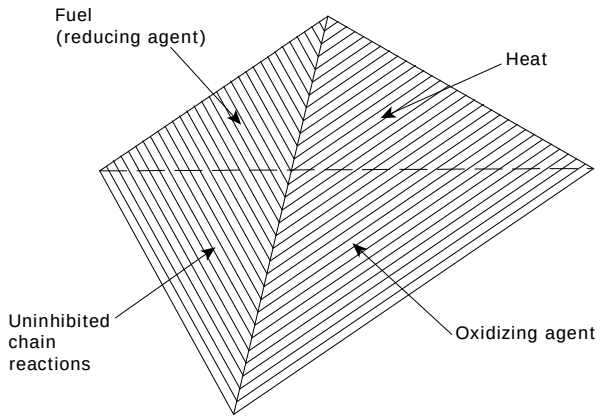

Figure 4 The tetrahedron of fire
(Copyright NFPA, used by permission)

For our purposes, it is best to define combustion as "**A self-sustained, high-temperature oxidation reaction**," a definition very close to that adopted by Turns[25]. Now, we can consider what the implications of this definition are. First, "reaction" identifies that the process is one where a chemical reaction occurs. Next, "high-temperature" excludes phenomena such as rusting, which is self-sustained oxidation, but one occurring at low temperatures. "Self-sustained" means that the process can occur without the continued presence of external energy. The opposite phenomenon is called "oxidative pyrolysis." If a material requires continued external heating for it to sustain an oxidation reaction, then it is being pyrolyzed rather than combusted. Finally, "oxidation" means that there are two participants to the reaction, with one substance being oxidized (losing electrons, or increasing in oxidation number), the other being reduced (acquiring electrons, or decreasing in oxidation number). It may be noted that while a combustion reaction is indeed exothermic, this does not need to be separately included in the definition since it is encompassed within "self-sustained."

Thus, for the fire triangle, we have explained the need for fuel and oxidant. The need for heat must be understood in a broad sense. Something must bring the system to a self-sustained, high-temperature condition. Commonly, it will be an external source of energy, with the system being able to continue reacting once a small area has been raised in temperature. But in other circumstances (spontaneous combustion), the material itself generates enough heat due to a chemical reaction occurring in it, that no external energy source is needed. Thus, a source of heat *is* present, but it is internal.

Based on this, it would be possible to divide ignitions into the form of fuel (gas, liquid, or solid), then into the form of heat used (internal or external). This type of taxonomy would be simple, but not comprehensive. A number of real-world complications exist. Some substances are mixed-phase, e.g., oil-soaked rags. Dust clouds are composed of solid particles, but their ignition behavior is specialized, and much more resembles that of gases. The oxidizer is usually gaseous air. But it may be a liquid or, in certain cases, a solid substance.

The definition of combustion we have adopted is appropriate, since it is consistent with other NFPA definitions. What it does, however, is exclude rapid, high-temperature events which are not an oxidation reaction. These include primarily decomposition reactions. A decomposition reaction is where a single molecule splits up into two pieces. These are common in pyrotechnics and explosives, also in chemical manufacturing accidents. Such will fall outside of our narrow definition of combustion. Nonetheless, initiation of these types of non-oxidative reactions will be considered in this work. The reason is that a very similar theory is used for their analysis, and many practical strategies for measuring, quantifying, or preventing them are also similar to those pertinent to oxidation reaction.

Finally, as explained in NFPA 921, modern textbooks usually invoke the fire tetrahedron (Figure 4), where uninhibited chain reactions are also considered[*]. The reason that the tetrahedron concept is introduced has to do with halogenated fire extinguishing agents. These work largely by terminating chain reactions, not by cooling or removing fuel or oxygen. Thus, if the nature of chain reactions were not considered (see Chapter 3 for a further discussion of combustion chemistry), then it would not be possible to explain the high effectiveness of halogenated fire extinguishing agents. In terms of our definition of combustion, this leg of the tetrahedron assures that the reaction *is* self-sustaining.

The reader will note that, in due accordance with their practical importance, the four sides of the tetrahedron are not equally represented in this handbook. In the vast majority of fires, it is evident that fuel, oxygen, and chain reactions are available. Thus, the largest emphasis is placed on ignition sources—examination of all aspects that make or do not make a potential ignition source a *competent ignition source* in a given situation. Conversely, chain reactions only become crucial to consider when chemical extinguishing media are involved or flame-retardant materials are being developed. Extinguishment is outside the scope of this Handbook. FR materials are considered only in the context that a certain amount of experimental ignition data on FR materials is presented, otherwise, as indicated in the Preface, the Handbook also does not delve into the topic of designing FR formulations.

[*] The present author does not think that it is a useful idea to teach the fire tetrahedron. For students at an elementary level, the additional concepts introduced can be needlessly confusing, while for more advanced students the tetrahedron concept does not provide any needed chemistry tools.

Table 14 Primary types of combustion and combustion-like reactions (and corresponding ignition types)

Combustion type	Reaction zone temp.	Fuel	Oxidizer	Where reactions occur	External ignition energy needed	Notes
normal flame	H	G	G	G	Y/N	
cool flame	M	G	G	G	Y/N	
catalytic	M	G	G	surface	Y	a
glowing	M/H	S	G	surface	Y	
smoldering	M	S	G	surface	N	b
condensed-phase				S/L	Y/N	c

G – gas
H – high
L – liquid
M – medium
N – no
S – solid
Y – yes

a – catalytic surface is needed
b – porous, char-forming fuel is needed
c – reactions are not limited to oxidation and may be decomposition, polymerization, isomerization, etc.

SOME COMPLICATIONS OF DEFINITION

In the majority of cases, the ignition event is clear when it occurs. If a piece of newspaper is lit, or a match is thrown into a gasoline pool, there is no doubt when ignition has occurred. In some cases, however, things are not so clear. The three main cases of difficulties concern:

(1) Flashing, or transient ignition, even with sustained source of heat. If visible flaming occurs, but very quickly dies out, leaving most of the fuel unburnt, the event is clearly different from one where ignition leads to nearly-complete consumption of combustibles.
(2) Cessation of burning upon removal of heat source. A number of substances can exhibit a behavior whereby combustion stops as soon as the external source of heat is removed. Is this "self-extinguishment" indicative of the fact that the product will be nearly non-participating in a fire?
(3) Cool flames. We have agreed above to only consider high-temperature reactions. Cool flames can be considered intermediate-temperature (a few hundred ºC). They are not common to most fire scenarios, but in certain situations need to be recognized. Cool flames are considered in Chapter 4. The initiation of cool flames is termed *sub-ignition*.

Issues #1 and #2 have troubled standards-makers for years, with no clear solution being at hand. Arbitrary divisions of ignition into "sustained flaming," "transient ignition," and "flashing" have sometimes been made, as seen in the next Chapter. In many cases, a substance which only exhibits transient ignition or flashing *in the full-scale fire* would qualify as relatively safe. Yet, the difficulties arise because such properties are normally measured in bench-scale tests, and the extrapolation to much larger scales is uncertain, especially for borderline phenomena. In some cases, even flashing can be problematic, for instance in burns to exposed skin. The vivid term "self-extinguishment" has a history of mis-use, and this is explored further in Chapter 7.

From the definition of combustion, it immediately follows why fuel and oxidizer need to be present to have an ignition. It is not an entirely trivial question to ask why heat or other form of energy must be added. The explanation for this requires that the concept of activation energy be considered. Chapter 3 presents some rudiments of combustion theory and provides a brief introduction to chemical kinetics.

TYPES OF COMBUSTION AND COMBUSTION-LIKE REACTIONS

Since ignition is the initiation of combustion, it is important to be aware that several types of combustion (or combustion-like) reactions exist. For our purposes, the primary combustion types can be divided into 6 main types, as shown in Table 14. Normal flames are, of course, the most commonly known form of combustion. A flame is a gas-phase manifestation and the proximate fuel and oxidizer are both gaseous. The ultimate source of the fuel, however, may be a vaporizing liquid or a solid which is degrading (pyrolyzing) and releasing combustible gases. Cool flames are rarely observed outside a laboratory environment, but for many substances the manifestation of a normal (hot) flame is preceded by a cool flame. Catalytic combustion can occur on the surface of certain substances, especially platinum, which are only mildly heated. It is not a common cause of accidental ignitions, apart from certain industrial accidents. Glowing ignition is seen when a surface which is receiving some heat suddenly exhibits a jump in temperature and begins to glow. When exposed to modest heating conditions, wood and cotton fabric sometimes ignite initially in a glowing mode, possibly changing to flaming combustion later. Glowing combustion differs from catalytic combustion in that the surface itself acts as fuel and is consumed; in catalytic combustion, the surface is not consumed and fuel and oxidizer molecules merely combine while on the surface. Smoldering also involves a glowing, but by definition, it is a self-sustained process—external heating is not needed to sustain it, although it may be needed to start the process. Combustion-like exothermic reactions in con-

densed-phase (i.e., solid or liquid) substances can show a wide variety of behaviors. These are most common in explosives, pyrotechnics, and as runaway reactions in chemical processing plants.

Normal-flame ignitions are considered throughout the book. Cool flame ignitions are covered in Chapter 4. Catalytic combustion is treated in Chapters 3 and 4. Apart from ignitions which are due to self-heating, glowing and smoldering combustion modes have not been extensively studied; the basic principles are treated in Chapter 7, while specific substances are discussed in Chapter 14. Self-heating and spontaneous combustion are covered in Chapter 9. Some metals and certain other non-metallic elements ignite and burn in a glowing mode. The ignition of these substances is covered in Chapter 8, with additional details given in Chapter 14. Condensed-phase ignitions are covered in Chapter 10.

Explosions can be physical or chemical. Chemical explosions are due to combustion or combustion-like reactions considered above. Physical explosions are forceful pressure disturbances not caused by a chemical reaction, for example, caused by dropping a large hot piece of metal into water. Physical explosions are outside the scope of this book, for an introduction, see Leiber and Doherty[26].

The definition of ignition is often a source of rich controversy to theoreticians, and some of this is alluded to in Chapters 7 and 9. Experimentalists generally do not face this difficulty, it being usually visually clear whether a substance is ignited or not. Thus, we shall be content to use the simple definitions of ignition and related concepts as given in Chapter 2.

Apparatus-dependent nature of ignition

Many physical or chemical properties can be measured in a way which is independent, or at least almost independent, of the measuring apparatus. In many practical cases, the complications introduced by the measuring apparatus are but a minor nuisance. This may lead the casual observer to feel that ignition must also be an intrinsic property. Since heat losses in a particular system are clearly an apparatus-dependent feature, maybe these losses should be eliminated? But some thought will serve to reveal that if two substances which can interact exothermically—a fuel and an oxidizer—are put together in an adiabatic system, they will always ignite and will reach the adiabatic flame temperature. In real life, of course, we know that ignitions occur in some circumstances and not in others. What prevents the potential occurrence of ignition is the presence of heat losses. In any experiment, these heat losses, which are wholly an artifice of the experimental rig are, in fact, the crucial variable which determines ignition. Thus, it becomes important to design measuring rigs which reflect some real-life characteristic which we wish to embody, since striving for the 'ideal' would lead trivial results. This will become

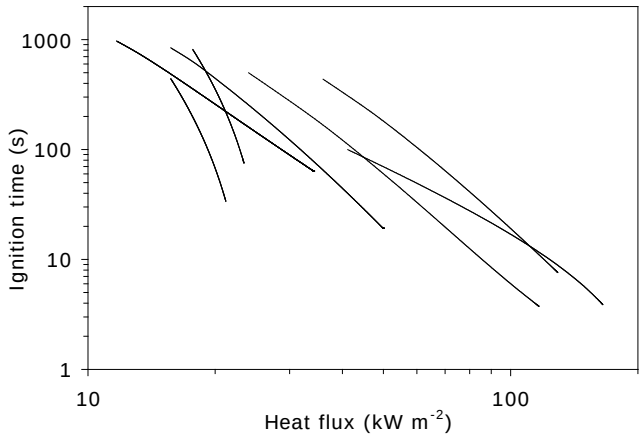

Figure 5 Piloted ignition of wood, as measured by various investigators prior to 1970

clear throughout this book, in that most of the chapters include a lengthy section on test methods. Without the availability of test methods—credible and applicable test methods—it would not be possible to say anything useful on the ignition topic.

In many important cases for ignition, for example, the ignition of solids from an applied heat flux, progress has been rather slow. As late as 1970, Ulrich and Sasine[27] examined the available data for the piloted ignition of wood. Figure 5 shows the results they found by reviewing the literature. A small part of the scatter is accounted for by genuine differences—wood species, thickness, moisture content, etc. The major differences, though, stem from the fact that the investigators all used different apparatuses and different calibration techniques, without the benefit of standardization. For this specific problem, it turned out that accurate calibration of heat flux meters is a crucial requirement, but concerted efforts to establish a minimum quality for heat flux meter calibrations did not take place until the 1980s.

The probabilistic nature of ignition and negative proof

The fire safety engineer and the risk manager involved in designing or assessing facilities can generally work with existing data and common scenarios. However, when investigations are made to find why a particular fire occurred, questions often arise as to whether *X* could have ignited *Y*, under certain circumstances. The question can be tackled by basic science principles, by data correlations, or by wholly-specific testing. In any of these approaches, the individual must exercise great care if an attempt is made at negative proof, that is, proving that something cannot happen. In the world of science, many things can happen which are unexpected or not intuitive. If one performs only a few experiments and obtains a negative result, this can mean that (1) the event is indeed impossible; or (2) the investigator was either not smart enough or not patient enough in order to discover the rare circumstances under which the event actu-

ally occurs. Many ignition phenomena have a strong probabilistic aspect to them—if the event is rare and only a few experiments were done, a wrong conclusions can be arrived at.

Can a cigarette dropped into a wastepaper basket start a flaming fire? In a study on this question[28], the experimenter had to conduct 132 trials before obtaining the first positive result. At the end of the study, 5 positive results from 300 trials were found. Had he stopped at 100 trials—a large number, already—the conclusion would have been reported that "dropped cigarettes cannot start flaming wastepaper baskets."

The issue is especially germane for electrical fires. The failure rate of electrical outlets has been estimated as 2×10^{-6}/year, as based on an estimated 1.62 billion outlets that are in use and are carrying current[29]. This is a very low failure rate, lower than that for most products whose failure rates are known. But this low failure actually corresponds to 3290 fires/year from this cause. This is a significant number and worthy of attention, yet to re-create the fires may be very difficult. The only way that this might feasibly be done is by over-stressing the device, in comparison to its typical use condition. Such studies are discussed in Chapter 14, but are always open to challenge that the over-stressing protocol may not fully simulate reality.

Patience may simply be required in waiting during a single test, apart from the issue of needing to run many trials. Most published values show that somewhere over 20 kW m^{-2} radiant heat flux must be applied to a wood surface to cause autoignition. These experiments are typically concluded in 10 – 30 minutes. But in one case[30], the experimentalists waited for over 3 hours and discovered that wood can autoignite at a heat flux of 5 kW m^{-2}. An even more extreme example has been presented by Cawley[31]. He conducted tests to determine the probability of igniting a methane/air mixture from an electric 'break-spark.' His results (Figure 6) show that, at low enough currents, probabilities on the order of 10^{-6} are found. It requires some highly automated experimental equipment to be able to generate enough trials to determine such low probabilities. Even if 1000 trials were made—which is an enormous number for most conventional experiments—a notably higher minimum igniting current would have been reported than was actually found at the $P = 10^{-6}$ level.

For risk managers, it is especially important to appreciate the probabilistic nature of the entire fire triangle. The probability P of a fire or an explosion occurring can be expressed as:

$$P = P_f P_o P_s$$

where P_f = probability of ignitable fuel being present; P_o = probability of necessary oxidizer being present; and P_s = probability of an ignition source being present. P_o will commonly be ≈ 1, but an inerting atmosphere may turn out to be practical. But the other two terms can vary widely. The role of the risk manager has to be to minimize P, and all too often this is misunderstood and focus is placed only on reducing P_s. Hertzberg has given some good examples of improving the overall level of safety by carefully evaluating the possibility of reducing each of the three factors[32].

Redundancy is an important concept in safety systems. In many areas of product design, it is accepted practice (or a legal requirement) that any single failure should not result in a grievous consequence. For example, design of electrical appliances against electric shock hazard is often done on that basis. If a metal enclosure is used, two failures must occur before a user will be subject to active endangerment: (1) a short from the phase conductor to the cabinet must occur; (2) a failure must take place in the grounding arrangement for the enclosure. But in the majority of situations, redundancy is not provided against the hazard of ignition—it generally takes only one failure or one thoughtless action for fire to be started. There are, however, a few areas of fire safety where redundancy is provided, for example, in the design of electric equipment to be used in potentially flammable atmospheres; this topic is covered in Chapter 12.

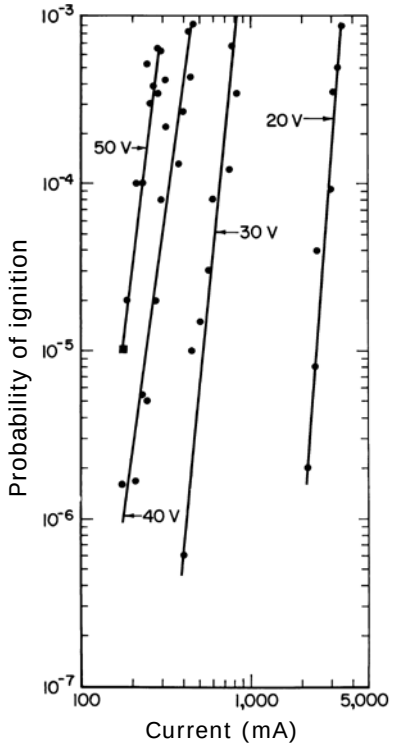

Figure 6 Probability of igniting methane/air mixtures with a break-spark from a resistive circuit

Comments to the fire investigator

A fire is investigated by first determining the area of origin, and then establishing the cause. To establish the cause, it is necessary to consider all combustibles that could have been located in the area of the origin, and then determined that

there was an ignition source capable of igniting one of the combustibles. It is also necessary to rule out other causes by determining that available ignition sources were not capable of igniting other combustibles. Thus, once the origin area has been found, much of the work of the investigator consists of trying to match various possible ignition sources against various fuels, and determining which pairs can and which cannot lead to ignition. This book has been organized to facilitate being used for this purpose.

This Handbook contains much material dealing with theory or mathematical aspects of fire. These will be of importance to fire science and fire engineering specialists, but will not be of main interest to fire investigators. Consequently, even though a great deal of mathematical material is presented, the book has been organized so that schooling in mathematics or science is not necessary in order to obtain practical guidance. The information of greatest importance to the investigator will be found in Chapters 14 and 15, which contain alphabetically organized material on various combustibles and on ignition sources. This information is given largely in non-mathematical terms and emphasizes the qualitative aspects of ignition. In some cases, quantitative data are also given, for example, E and P values for describing the temperature-versus-size relation of self-heating solids. The reader wishing to make computations by using these variables will have to consult Chapter 9, where the theory of self-heating is developed. To understand the theory requires a fair bit of mathematical background. Lacking this, the reader can simply be aware that the substance discussed has been known to self-heat, and that calculational formulas are available for estimating the minimum size of material needed for spontaneous combustion.

The fire investigator may want to know why science is useful at all to his or her task. This is an important question and deserves a serious answer. The reasons are the following:

- by studying the science, an improved qualitative understanding can be achieved of the phenomena involved, even if no quantitative calculations are undertaken;
- if testing is required, guiding principles will be known which will allow selection of the most appropriate tests and minimize unfruitful explorations;
- when data are collected, knowledge of the scientific principles will enable sensible plots to be made and errors to be avoided in making extrapolation or interpolations.

It must also be mentioned that the status of the science underlying ignition phenomena is such that it will rarely be possible to compute desired answers from first principles alone, unless the individual is willing to expend a dissertation's worth of effort. Instead, recourse to tests will almost always be needed.

Chapter 11 presents extensive general information on ignition sources. It should be used in conjunction with material in Chapter 14 on specific ignition sources. Chapters 4 through 10 contain a systematic presentation of ignition principles, theory, and test methods, as pertains to each of the various classes of combustibles. Each of these chapters begins with a section on *Highlights and summary of practical guidance*. This gives a brief overview of the substance of the chapter and sets out the basic principles in non-mathematical terms. These chapters do contain extensive mathematical developments, but the investigator can skip over those sections, while still getting benefits from the rest of the material. Sections of special interest to investigators will include those dealing with effects of various variables on the ignition process and on test methods used.

Computer methods

The reader may note that no review is made in this book of computer programs for ignition problems. This is not due to an oversight but, rather, due to an absence of material to review. Problem-solving in engineering and applied sciences can be viewed as falling into three procedural categories:

(1) looking up data in tables and using simple formulas;
(2) using computer programs which have been set up to solve well-known categories of problems for which systematic procedures had been developed;
(3) conducting research by setting up conservation equations, expressing them in the form of differential equations (commonly partial differential equations, with possibly three spatial dimensions) and solving them by advanced mathematical techniques.

Category #3 describes how Ph.D. dissertation research is commonly pursued in science and engineering, but the present work is not intended as a primer towards that purpose. Category #1 generally only requires that equations be typed into a spreadsheet, and there is a great deal of material in the present handbook compiled for this purpose. A few computer programs are also available for solving simple formulas in the ignition field (e.g., ignition of building façades from radiant heat of a neighboring building). Category #2 can best be illustrated in fire science by room fire models. These have been developed since the 1970s and have become a highly valuable engineering tool. A survey identified several dozen of those[33], and a number of them are available at low cost or gratis from the developers. These tools require some science background to use intelligently, but are a far cry from the 'Ph.D. candidate with a white sheet of paper' of Category #3. To this author's knowledge, no Category #2 tools have become available in the ignition area. But there are a number of aspects of ignition (self-heating of geometrically non-simple shapes is one that immediately comes to mind) that could benefit from the availability of competent, affordable computer programs.

Concerning Category #3, the utility is often less than meets the eye. The literature contains a wide proliferation of theoretical studies (all categories of engineering, not just fire-safety-related) that are accompanied by numerical solutions to example problems but, regrettably, only occasionally

accompanied by validation. This scheme is of little value to a potential user, unless his company can sponsor a Ph.D. candidate. The reason is because the solutions are typically published only for example problems which will generally be unrelated to the user's need.

Chapter 2. Terminology

Terms used in this book **13**
Definitions **13**
Abbreviations and acronyms **20**
References **22**

Terms used in this book

Many of the terms discussed in this book do not have an absolute meaning. Instead, they refer to the findings from certain tests or procedures. Thus, when using ignition-related terms it becomes very important to know the specifically-applicable definitions. In some cases, there are conflicting definitions issued by standards-making bodies; the reader must be aware of such discrepancies. Thus, in this Chapter, a collection of definitions is presented that are useful to the study of ignition. A number of them may not be intuitively obvious to the reader and they all deserve careful study if misconceptions are to be avoided.

Abbreviations of names for various explosive compounds are given in Chapter 14 under *Explosives*.

Following modern practice, units are written without the use of the solidus ("/") symbol. Thus, for example, instead of writing kg/m^3, the notation kg m^{-3} is used.

Definitions

Adiabatic flame temperature. The temperature of a flame in the absence of any heat losses.

Aerosol. A colloidal suspension of liquids or solids in a gaseous medium.

Afterflame. ISO 13493[1] defines it as: "Flame which persists after the ignition source has been removed."

Afterglow. ASTM E 176[2] defines it as: "Emission of light, usually subsiding, from a material undergoing combustion, but occurring after flaming has ceased."

Air terminal. A lightning rod.

Arc. See: *electric arc.*

Arc tracking. A phenomenon whereby an arc between two or more wires, on initiation, will sustain itself through a conductive path provided by degradation of the insulation for a measurable length[3]. See also: *Tracking*.

Autocatalytic reaction. A reaction which is accelerated by an accumulation of the reaction products.

Autogenous ignition temperature. Archaic variant of *autoignition temperature*.

Autoignition. The sudden inflammation of a gaseous charge when it is exposed to a particular temperature and pressure[4]. NFPA 921[5] defines it as: "Initiation of combustion by heat but without a spark or flame." It is also normally understood that the heat is to be applied uniformly; thus, ignition facilitated by localized hot surfaces is a form of piloted ignition, not autoignition.

Autoignition temperature. NFPA 325[6] defines it as: "The ignition temperature of a substance, whether solid, liquid, or gas, is the minimum temperature required to cause self-sustained combustion, independently of the heating or heated element."

Backdraft. NFPA 921[5] defines it as "An explosion occurring from the sudden introduction of air into a confined space containing oxygen-deficient superheated products of incomplete combustion."

Basis weight. The mass of a thin material expressed per unit area; customary units are g m^{-2}. This quantity is used since thickness of fabric, paper, etc. is not a quantity that can be reliably determined, thus density (kg m^{-3}) is not appropriate as a quantitative descriptor for these materials.

Bead. NFPA 921[5] defines it as "A rounded globule of resolidified metal at the end of the remains of an electrical conductor that was caused by arcing and is characterized by a sharp line of demarcation between the melted and unmelted conductor surfaces."

BLEVE. Boiling liquid, expanding vapor explosion. It is the explosive release of expanding vapor and boiling liquid when a container holding a pressure-liquefied gas fails catastrophically[7].

Bolted short. An electrical short circuit where good metal-to-metal contact is made and arcing does not occur at the location of the short.

Catalyst. A substance which promotes chemical reaction without itself being significantly consumed.

Combustible liquid. According to NFPA 30[8], a combustible liquid is any liquid that has a closed-cup flash point at or above 100ºF (37.8ºC). Combustible liquids are further subdivided as:

- Class II liquids have a flash point at or above 100°F (37.8ºC) and below 140ºF (60ºC).
- Class IIIA liquids have a flash point at or above 140ºF (60ºC), but below 200ºF (93ºC).
- Class IIIB liquids have a flash point at or above 200ºF (93ºC).

Liquids having lower flash points are identified as *flammable liquids*. The NFPA system is being made obsolete by UN/DOT regulations, which define 60.5°C as the limit, not 37.8ºC See also: *flammable liquid*; *ignitable liquid*.

Combustion. A self-sustained, high-temperature oxidation reaction.

Condensed phase. The term refers to substances which are liquids or solids, but not gases.

Cookoff. Explosion of weapons due to external flames or fire.

Cool flames. Slow combustion reactions which occur only under limited conditions and produce temperatures of only 200 – 300ºC.

Critical diameter. Minimum diameter of an explosive charge capable of maintaining detonation.

Deflagration. A subsonic wave supported by combustion[18]. Also defined as the propagation of a combustion zone at velocity that is less than the speed of sound in the unreacted medium[9]. The flame front and the reaction products travel in opposite directions. If within a gaseous medium, a deflagration is the same as a *flame*.

Detonation. A reaction propagating at a velocity greater than the local speed of sound in the unreacted material. In a detonation, the shock front and the reaction products travel in the same direction.

Detonator. The US government[10] defines it as: "Blasting caps, electric blasting caps, delay electric blasting caps, and nonelectric delay blasting caps."

Diathermancy. Partial transparency. Diathermanous solids absorb radiant energy in-depth, while opaque substances absorb it only at the surface.

Ease of ignition. ISO 13943[1] declares this to be: "Deprecated term, see *ignitability*." However, on a practical basis, since *ignitability* is just as imprecise a term as *ease of ignition*, declaring a preference for one term over the other would seem unnecessary.

Electric arc. A continuous, luminous discharge of electric current crossing a gap or an insulating surface between two conductors. It has been more precisely defined as[11]: "A stable discharge between two electrodes in which thermionic emission is the feedback mechanism for sustaining the discharge." An arc is distinguished from an electric spark by being a continuous discharge, whereas a spark is a transient discharge.

Electric contact. Holm[12] defines it as: "A releasable junction between two conductors which is apt to carry current."

Electric spark. See: *spark (electric)*.

Emissive power. The radiant flux received from a source object if the view factor is unity. The units are kW m^{-2}.

Endothermic reaction. A chemical reaction which requires that energy be supplied to the system from an external source for the reaction to occur.

Energy fluence. Flow of energy per unit area. Typically reported in units of kJ m^{-2}, the term is most commonly used in the munitions field.

Enthalpy. The thermodynamic quantity that is the sum of the internal energy of the system and the product of its volume multiplied by its pressure.

Equicylinder. A cylinder having a height equal to its diameter.

Equivalence ratio. The fuel/air ratio, divided by the fuel/air ratio for a stoichiometric mixture.

Exothermic reaction. A chemical reaction which releases energy. The opposite is *endothermic reaction*, which denotes that the reaction requires an external heat source in order to take place. It must be borne in mind that, if the temperature of a substance is progressively raised, many substances will show both endothermic and exothermic reactions. Exothermic reactions encountered in self-heating problems may be oxidative, that is, needing oxygen. But they may also be decomposition reactions that do not require oxygen.

Explosion. As Stecher[13] points out, "The term 'explosion' has no fixed and definite meaning either in ordinary speech or in law." Cook[14] defines explosion as "A release of energy creating a sudden outburst of gas." This broad definition includes chemical, atomic, and physical explosions. Physical explosions can occur due to overpressures of boilers or pressure vessels. They also include steam explosions, which occur when a large, hot body is quickly inserted into water*. In combustion science, an explosion is any rapid, high-temperature combustion. It excludes such low-temperature phenomena such as *cool flames*. Thus, in the broadest sense, a sound is not necessary as part of an explosion, and explosions are considered to encompass normal *flames*[15]. Confusingly, some detonation experts consider 'explosion' and 'detonation' to be mutually-exclusive terms, with 'ex-

* The largest known steam explosion was the underwater volcano eruption which demolished the island Krakatoa in 1883. Its shock waves in air and water circled the entire planet several times.

plosion' referring only to deflagrations. The term 'thermal explosion' denotes the self ignition of self-heating materials[16]. The latter phenomenon is normally not accompanied by any sudden outburst of gas, nor by any sound or appreciable pressure rise. Definitions of 'explosion' have been reviewed by Martin et al.[17]

Explosion limits. In colloquial speech, *explosion limit* is taken to be a synonym for *flammability limit*. In combustion science, however, the meanings are different. The flammability limits for a given temperature and pressure are the lean and rich fuel concentration values beyond which no flame will propagate. Explosion limits, by contrast, are[18]: "the pressure-temperature boundaries for a specific fuel-oxidizer ratio that separate regions of slow and fast reaction." Thus, explosion limits are presented as a line on a graph where temperature is plotted on the x-axis, pressure is plotted on the y-axis, and the fuel/air ratio is specified (typically, the stoichiometric value).

Explosive substance. The UN definition is[19]: "Explosive substance is a solid or liquid substance (or a mixture of substances) which is in itself capable by chemical reaction of producing gas at such a temperature and pressure and at such a speed as to cause damage to surroundings. Pyrotechnic substances are included even when they do not evolve gases."

Fire. ASTM E 176[2] defines it as: "Destructive burning as manifested by any of all of the following: light, flame, heat, smoke." Another definition is[20]: "Any incident that results in flames or smoke and can cause damage to life or property if left unchecked."

Fire point. NFPA 850[21] defines it as: "The lowest temperature at which a liquid in an open container will give off sufficient vapors to burn once ignited. It generally is slightly above the flash point." Taking a more narrow approach, NFPA 30[22] defines it as: "The lowest temperature at which a liquid will ignite and achieve sustained burning when exposed to a test flame in accordance with ASTM D 92, Standard Test Method for Flash and Fire Points by Cleveland Open Cup." ISO[1] defines it much more generally as: "The minimum temperature at which material ignites and continues to burn for a specified time after a standardized small flame has been applied to its surface under specified conditions." Perhaps the best definition is from BSI[23]: "The lowest temperature at which a liquid gives off sufficient flammable vapours in air to produce sustained combustion after removal of the ignition source." In addition to ISO, some authorities consider fire point to be a general term, also applicable to solids, not just liquids.

Firedamp. Natural gas. The term refers to gas found in mines. It consists mostly of methane, with small amounts of ethane and other hydrocarbons and possibly of carbon monoxide or carbon dioxide.

Flame. A rapid, self-sustaining propagation of a localized combustion zone at subsonic velocities through a gaseous medium. Since they are rapid, flames also represent high-temperature combustion. In a gaseous medium a flame is identical to a *deflagration*. A slow form of combustion which can exist under certain conditions is differentiated as a *cool flame*.

Flame kernel. The initial gaseous breakdown zone during spark ignition of a fuel/oxidizer mixture.

Flammable. NFPA 921[5] defines it as: "Capable of burning with a flame."

Flammable liquid. According to NFPA 30[8], a flammable liquid is any liquid that has a closed-cup flash point below 100ºF (37.8ºC) and a *Reid vapor pressure* not exceeding 276 kPa at 100ºF (37.8ºC) Flammable liquids are further subdivided as:

- Class IA liquids have flash points below 73ºF (22.8ºC) and boiling points below 100ºF (37.8ºC).
- Class IB liquids have flash points below 73ºF (22.8ºC) and boiling points at or above 100ºF (37.8ºC).
- Class IC liquids have flash points at or above 73ºF (22.8ºC), but below 100ºF (37.8ºC).

Liquids having higher flash points are identified as *combustible liquids*. See also: *ignitable liquid*.

The UN defines[19] liquids as 'flammable' if their closed-cup flash point is less than or equal to 60.5ºC (141ºF) or their open-cup flash point at or below 65.6ºC (150ºF). The UN system has been adopted by the US Dept. of Transportation[24] and is expected to eventually make the NFPA definitions obsolete.

Flammable solid. This definition is problematic because standards bodies have adopted definitions which conflict with both combustion science and everyday understanding of fire. In combustion science, a flammable solid is merely any solid substance which can burn; this includes newspapers, wood, fabrics, etc. The standards bodies, however, effectively consider "highly hazardous flammable solids," but omit the "highly hazardous" phrase. The UN definition is[19]: "Solids which, under conditions encountered in transport, are readily combustible or may cause or contribute to fire through friction; self-reactive and related substances which are liable to undergo a strongly exothermic reaction; desensitized explosives which may explode if not diluted sufficiently." Substances having a heat of decomposition $\geq$ 300 kJ kg^{-1} or an SADT $\leq$ 75ºC for a 50 kg specimen are construed to be self-reactive. UN excludes from the definition substances which fall into other, more specific classifications: Class 1 explosives, oxidizing substances, and organic peroxides.

Flash ignition temperature. Piloted ignition temperature. There is only one common test which uses this definition, ASTM D 1929. This test method does not distinguish between flashing and sustained-flaming ignition, and many substances do not show flashing prior to initiation of sustained flaming, but the nomenclature unfortunately implies that flashing and not sustained-flaming is being recorded.

Flash fire. Rapid combustion of a flammable gas cloud which does not result in a significant overpressure.

Flash point. The NFPA 325[6] definition is: "The flash point of a liquid is the minimum temperature at which the liquid gives off sufficient vapor to form an ignitable mixture with air near the surface of the liquid or within the test vessel used. By 'ignitable mixture' it is meant a mixture that is within the flammable range (between the upper and lower limits) and, thus, is capable of propagation of flame away from the source of ignition. Some evaporation takes place below the flash point, but not in quantities sufficient to form an ignitable mixture." ISO[1] defines it as: "The minimum temperature to which a material or product must be heated for the vapours emitted to ignite momentarily in the presence of flame under specified test conditions." For completeness, the definitions must be understood to include the requirement that the test conditions involve air at a pressure of 1 atm. The actual value of the flash point is dependent on the type of test equipment that is used for its determination. Flash point differs from *fire point* in that at the flash point temperature the vapors are only required to flash and not to continue burning.

Flashover. This term is used in two different, unrelated contexts. In fire safety science, it means the full involvement in flames of a room or other enclosed volume. In electrical engineering, it means the electrical breakdown of insulation along a surface.

Forced ignition. See *piloted ignition*.

Gas discharge. Gas discharges refers to a group of phenomena which accompany the flow of current through a gas under the influence of an applied electric field. Such discharges may be classified as self-sustaining (e.g. arc) or non-self-sustaining (e.g., photoionization discharge), a transition from the latter to the former occurring via an electrical breakdown (e.g., spark). In the case of a non self-sustaining discharge, the current flow ceases as soon as the external ionizing source is removed even though the electric field remains. Conversely a self-sustaining discharge persists as long as the driving electric field persists.

Glow. ASTM E 176[2] defines it as: "(1) the visible light emitted by a substance because of its high temperature; (2) visible light, other than flaming, emitted by a solid undergoing combustion."

Glowing combustion. NFPA 921[5] defines it as: "Luminous burning of solid material without a visible flame."

Ground fault. NFPA 921[5] defines it as: "A current that flows outside the normal circuit path, such as (a) through the equipment grounding conductor, (b) through conductive material other than the electrical system ground…, (c) through a person, or (d) through a combination of these ground return paths.

Halogenated. Containing atoms from one of the halogen-series elements (fluorine, chlorine, bromine, etc.).

Heat flux. The rate at which energy flows across an imaginary plane of 1 m^2. The units are power/area, or kW m^{-2}. This is the definition normally used in engineering; in physics, the quantity is termed *heat flux density*.

Heat flux density. See *heat flux*.

Heterogeneous reaction. A reaction in which the reactants are not all in one phase, for instance, a gas and a solid. In combustion systems, this is often illustrated by a reaction at a surface, e.g., air + charcoal. This type of combustion exhibits a glow or a bright light, but not flames.

Homogeneous reaction. A reaction in which the reactants are all in the same phase. An example is homogeneous combustion in the gas-phase, where flaming combustion occurs throughout a volume of space.

Hypergolic. A reaction is hypergolic if two substances ignite directly upon contact.

Ignitability. ISO[1] defines it as a: "measure of the ease with which an item can be ignited, under specified conditions." This is clearly a very loose term, and it can be used in various different ways. In recent years, it is most typically used in describing the response of a solid material to a flame or a radiant heat source.

Ignitable. ISO[1] defines it as: "capable of being ignited."

Ignitable liquid. An ignitable liquid is a liquid which is either a *flammable liquid* or a *combustible liquid*.

Ignite. ISO[1] defines it two ways: "(Intransitive verb). To catch fire with or without the application of an external heat source. (Transitive verb). To initiate combustion."

Ignited. ISO[1] defines it as: "The state of a body undergoing combustion."

Ignition. ISO[1] defines ignition as: "Initiation of combustion."

Ignition source. ISO[1] defines it as "Source of energy that initiates combustion."

Ignition temperature. ISO[1] defines "ignition temperature (minimum): (Minimum) temperature at which combustion can be initiated under specified test conditions."

NFPA 921[5] defines it as: "Minimum temperature a substance must attain in order to ignite under specific test conditions. Reported values are obtained under specific test conditions and may not reflect a measurement at the substance's surface. Ignition by application of a pilot flame above the heated surface is referred to as piloted ignition temperature. Ignition without a pilot energy source has been referred to as autoignition temperature, self-ignition temperature, or spontaneous ignition temperature."

Note that NFPA limits the definition to the material surface temperature, while the ISO definition is broad and can encompass criteria based on either surface temperature or test-furnace temperature.

Ignition time. The time from beginning of exposure to heat, until ignition occurs. The ignition time is highly dependent on the conditions of the test or the experiment.

ISO[1] declares it to be: "Deprecated term; see *minimum ignition time*." This is an unfortunate stance, since *ignition time* (**not** minimum) is an essential term in describing the results of radiant-heating tests for ignition of solid materials. In such tests specimens of the material are presented with various radiant heat flux values, and the ignition times corresponding to each are tabulated. Furthermore, at any particular heat flux value, if multiple test runs are made, the report should sensibly document the average time for ignition and not just the minimum from the runs.

Incendive. Able to cause ignition. The NFPA 77[25] definition is: "A spark that has enough energy to ignite an ignitable mixture is said to be incendive. Thus an incendive spark can ignite an ignitable mixture and cause a fire or explosion. A nonincendive spark does not possess the energy required to cause ignition even if it occurs within an ignitable mixture."

Incendivity. The ability to cause ignition. The NFPA 77[25] definition is: "The ability of a spark to ignite an ignitable mixture." Morgan[26], who coined the term, felt that the term was needed to clearly differentiate the concept from 'inflammability.' Morgan, however did not restrict it to sparks and defined it as: "That property of an igniting agent (such as a spark, flame, or hot solid) whereby it is able to cause ignition." It is sometimes viewed that incendivity is a property of a heat source, while ignitability is a property of a fuel but, in fact, the two are not independent.

Induction period. This term is mainly used in combustion chemistry studies, and generally means *ignition time*.

Initiation. The start of detonation, as applied to explosives.

Intrinsically safe circuit. NFPA 70, the National Electrical Code[27] defines this as: "A circuit in which any spark or thermal effect is incapable of causing ignition of a mixture of flammable or combustible material in air under prescribed test conditions." It then refers to UL 913[28] for test requirements.

Intrinsically safe system. NFPA 70 defines this as: "An assembly of interconnected intrinsically safe apparatus, associated apparatus, and interconnecting cables in that those parts of the system that may be used in hazardous (classified) locations are intrinsically safe circuits."

Laminar flame speed. Glassman[18] defines it as: "The velocity at which unburned gases move through the combustion wave in the direction normal to the wave surface." Also called burning velocity, flame velocity, normal combustion velocity, and fundamental flame speed.

Layer ignition temperature. For a layer of dust upon a hot surface, this is the lowest temperature of the hot surface that can cause ignition.

Lightning. A transient, high-current electric discharge whose path length is measured in kilometers[29].

Liquid. In chemistry, a liquid is defined as[30]: "An amorphous form of matter intermediate between gases and solids in which the molecules are much more highly concentrated than in gases, but much less concentrated than in solids." In practice, it is often necessary to distinguish between gases and low-boiling point liquids. For this purpose, a substance is a liquid and not a gas if its boiling point at 1 atm is 25ºC or higher; other slightly different reference temperatures are also sometimes used. The NFPA 30[22] definition of a flammable liquid requires that it have a Reid vapor pressure not over 276 kPa at 37.8ºC; substances with a higher vapor pressure are flammable gases. This definition is not identical to the preceding. In some cases, liquids must be distinguished from highly viscous substances; see NFPA 30 for details of a definition of liquids that is used to exclude highly viscous substances. Note that a particular substance may be in a gaseous, liquid, or solid state, depending on its pressure and temperature.

Limit flame temperature. The flame temperature at the lower flammability limit.

Lower explosive limit; **lower explosion limit**. See *explosion limits*.

Lower flammability limit. The lowest concentration of a gas or vapor that will just support the propagation of flame away from a pilot ignition source. The LEL is commonly measured in volume percent, which is the same as mole percent, but *not* the same as mass percent. Occasionally it is reported in mass concentration units (g m^{-3}). The value of the LFL also depends on the atmosphere: its composition, temperature, and pressure. By convention, the LFL values are reported for a normal atmosphere of 21% (by volume) oxygen, at 25ºC (77ºF) and a pressure of 1 atmosphere (760 mm Hg) unless specified otherwise. Sometimes called *lean limit of flammability*.

Lower temperature limit. It is the minimum temperature to which a saturated fuel vapor-air mixture must be heated for flame propagation to be possible. It differs from the flash point only in that different test equipment is used for its measurement and a different criterion is prescribed for interpreting the results.

Maximum experimental safe gap. The maximum permissible gap, between flanges of defined geometry, separating the internal volume of a vessel from an external explosive atmosphere. A gap larger than this figure may allow an internal ignition in the vessel to propagate to the external atmosphere[31].

Minimum explosible concentration. ASTM E 1515[32] defines it as: "The minimum concentration of a combustible dust cloud that is capable of propagating a deflagration through a uniform mixture of the dust and air under specified conditions of test." The units are g m^{-3}, and the term is identical to LFL, if the latter is expressed in mass concen-

tration units. For consistency, in this book 'LFL' is generally used, irrespective of whether the substance is a gas or a dust cloud.

Nonincendive circuit. NFPA 70 defines this as: "A circuit in which any arc or thermal effect produced, under intended operating conditions of the equipment or due to opening, shorting, or grounding of field wiring, is not capable, under specified test conditions, of igniting the flammable gas, vapor, or dust-air mixture." It then refers to ISA-S12.12[33] for test requirements.

Ohmic heating. Heating created by an electrical current, as determined by Ohm's Law. The power dissipated is expressed as $P = I^2R$, where P = power, I = current, and R = resistance.

Overcurrent. NFPA 921[5] defines it as: "Any current in excess of the rated current of equipment or the ampacity of a conductor. It may result from an overload (see definition), short circuit, or ground fault."

Overload. NFPA 921[5] defines it as: "Operation of equipment in excess of normal, full-load rating, or of a conductor in excess of rated ampacity, which, when it persists for a sufficient length of time, would cause damage or dangerous overheating. A fault, such as a short circuit or ground fault, is not an overload."

Oxidation. A chemical reaction in which a compound or a radical loses electrons. The opposite reaction, in which electrons are gained, is called "reduction."

Oxygen index. The ratio of moles of oxygen to moles of oxygen + diluent; it is usually expressed as a percentage.

Pilot source of ignition. ASTM E 176[2] defines it as: "A discrete source of energy, such as, for example, a flame, spark, electrical arc, or glowing wire."

Piloted ignition. ISO[1] defines it as: "Ignition of combustible gases or vapours by a secondary source of energy, as by, for example, a flame, spark, electrical arc or glowing wire." Sometimes referred to as 'forced ignition' or 'induced ignition.' Piloted ignition occurs when a localized heat source is present; if a substance ignites due to being raised uniformly in temperature, then *autoignition* occurs.

Piloted ignition temperature. The surface temperature of a substance that occurs at the moment that ignition is observed, under conditions that a pilot is used for ignition. The term is applied primarily to solids; see also *fire point*.

Plosophoric materials. NFPA 495[34] defines them as: Two or more unmixed, commercially manufactured prepackaged chemical ingredients (including oxidizers, flammable liquids or solids, or similar ingredients) that are *not* classified as explosives but that, where mixed or combined, form a blasting explosive.

Porosity. The volume of void spaces, divided by the gross volume. The definition is used in connection with substances having internal voids.

Pressure limit. The pressure below which a combustion or decomposition reaction cannot take place.

Pressure piling. MSHA[35] defines it as: The development of abnormal pressure as a result of accelerated rate of burning of a gas-air mixture (frequently caused by restricted configurations within enclosures).

Primer. The US government[10] defines it as: A cartridge or container of explosives into which a detonator or detonating cord is inserted or attached.

Propellant. An explosive material that normally burns but not detonates and is used for propulsion purposes.

Pyrolysis. The chemical degradation of a substance by the action of heat. In fire science, sometimes *pyrolysis* is used to refer to a stage of fire before flaming combustion has occurred. In gas chromatography, *pyrolysis* is sometimes restricted to the heating of a substance without oxygen, but in fire science no implications of presence or absence of oxygen are made.

Pyrophoric. Following the recommendations of UN[19], the US Dept. of Transportation[36] classifies pyrophoric substances into its Division 4.2 and defines them as: "A pyrophoric material is a liquid or solid that, even in small quantities and without an external ignition source, can ignite within 5 minutes after coming in contact with air when tested according to UN Manual of Tests and Criteria." NFPA 471[37] uses the identical definition, but omits mention of the UN tests. NFPA 49[38] defines pyrophoric material as "A substance capable of self-ignition upon short exposure to air under ordinary atmospheric conditions," thereby omitting both a quantitative time element and a test method. Another meaning of the word *pyrophoric*, now obsolete, used to be "producing sparks when ground or abraded."

The temperature comprising "ordinary atmospheric conditions" is made more precise in certain other definitions. According to the Chemical Manufacturers Association, a pyrophoric substance is one which will ignite spontaneously in dry or moist air at or below 130ºF (54ºC). NFPA 318[39] uses essentially the same definition: "A chemical with an autoignition temperature in air at or below 130°F (54.4°C)."

Pyrotechnic substance. The UN definition[19] is: "Pyrotechnic substance is a substance or mixture of substances designed to produce an effect by heat, light, sound, gas or smoke or a combination of these as a result of non-detonative self-sustaining exothermic chemical reactions."

Quenching distance. Minimum dimension that a flame kernel must acquire in order to establish a freely propagating flame. Below this minimum size, heat losses exceed heat gain from the chemical reaction and the kernel will self-extinguish[31].

Reid vapor pressure. The vapor pressure as determined by the ASTM D 323 test method[40]. Note that real vapor pressures are generally not identical to the Reid vapor pressure, because the measurement is affected by the vapor/liquid

volume ratio, and generally the real situation will not entail a ratio of 4:1.

Rekindle. NFPA 921[5] defines it as: "A return to flaming combustion after apparent but incomplete extinguishment."

Self-accelerating decomposition temperature. This term does not have a specific scientific meaning, but is used in UN Regulations[19] is different contexts, depending on which test method is being described. It generally connotes a temperature at which a self-heating reaction either surpasses a criterion value or becomes critical.

Self-heating. ISO[1] defines it as: "A rise in temperature in a material resulting from an exothermic reaction within the material." The US Dept. of Transportation[36] classifies self-heating materials into the same division as pyrophoric ones, Division 4.2, and defines them as: "A self-heating material is a material that, when in contact with air and without an energy supply, is liable to self-heat. A material of this type which exhibits spontaneous ignition or if the temperature of the sample exceeds 200ºC (392ºF) during the 24-hour test period when tested in accordance with the UN Manual of Tests and Criteria, is classed as a Division 4.2 material."

NFPA provides several definitions. NFPA 471[41]: "Self-heating material — a material that, when in contact with air and without an energy supply, is liable to self-heat." NFPA 921[5]: "Self-Heating. The result of exothermic reactions, occurring spontaneously in some materials under certain conditions, whereby heat is liberated at a rate sufficient to raise the temperature of the material."

An entirely different meaning of the term exists in electrical engineering[1]: "Heat generated by a powered electrotechnical product resulting in a rise in temperature of the product."

Self-ignition. This term is ambiguous and can be understood two different ways: as *autoignition* or as *spontaneous combustion*. NFPA 921[5] defines it as: "Ignition resulting from self-heating. Synonymous with spontaneous ignition." ISO[1] defines it as: "Spontaneous ignition resulting from self-heating."

Self-ignition temperature. This term is usually understood to mean *autoignition* temperature. Because it is prone to being interpreted in various ways, ISO[1] declares it as: "Deprecated term (see *spontaneous ignition temperature*)." NFPA 921[5] defines it as: "The minimum temperature at which the *self-heating* properties of a material lead to ignition." This is needlessly narrowing the scope of the term, since it is often taken to mean an unpiloted ignition due to any cause, which could include radiant heating just as well as self-heating. NFPA 53[42] more appropriately treats self-ignition temperature as a synonym for *autoignition temperature*.

Sensitivity. The sensitivity of an explosive is the minimum stimulus that must be imparted to the explosive, within limited time and space, to detonate it. The term can only be used in a qualitative way, since the results are highly dependent both on the mode in which the energy is supplied, and on the details of the test apparatus.

Short circuit. IEEE[43] defines it as: "An abnormal connection (including an arc) of relatively low impedance, whether made accidentally or intentionally, between two points of different potential." NFPA 921[5] defines it as: "An abnormal connection of low resistance between normal circuit conductors where the resistance is normally much greater. This is an overcurrent situation but it is not an overload."

Smoldering. A propagating, self-sustained exothermic reaction wave deriving its principal heat from heterogeneous oxidation of a solid fuel. The term does not apply to situations where an external source of heat drives the exothermic reaction. See: *pyrolysis*.

ISO[1] defines "smouldering: The combustion of a material without flame and without light being visible. NOTE: smouldering is generally evidenced by an increase in temperature and/or by effluent." ASTM E 176[2] defines it as: "Combustion of a solid without flame, often evidenced by visible smoke."

Spark. The term is used in connection with two different phenomena. **Electric spark**: Dielectric breakdown of a gas between two electrodes in which the liberation of secondary electrons from one of the electrodes is the major feedback mechanism necessary to sustain the discharge[11]. NFPA 77[25] defines it as: "A short-duration electric discharge due to a sudden breakdown of air or some other insulating material separating two conductors at different electric potentials, accompanied by a momentary flash of light." A *spark* is a transient event, while an *electric arc* is a sustained event. **Mechanical spark**: A small, incandescent particle.

Inconsistent with NFPA 77 and general scientific usage, NFPA 921[5] uses the term *arc* to encompass both arcs and electrical sparks, and defines *spark* solely as "a small incandescent particle," excluding electric breakdown phenomena.

Spontaneous combustion. Visible smoldering or flaming caused by thermal runaway. ISO[1] declares it to be: "Deprecated term; see *self-ignition*." Despite ISO's stance, the term is useful and properly descriptive.

Spontaneous ignition. This term is commonly used interchangeably with *spontaneous combustion.* The latter term is preferred, however. *Spontaneous ignition* has another meaning: the ignition of an object due to external heating, without the use of a pilot flame. To avoid confusion, *autoignition* is the preferred term for the latter.

ISO[1] defines it as: "Ignition resulting from a rise of temperature without a separate ignition source." This definition is notably ambiguous, and it is not clear whether *autoignition* of all sorts is contemplated, or solely that due to self-heating.

Spontaneous ignition temperature. ISO[1] defines it as: The minimum temperature at which ignition is obtained under specified test conditions without any source of pilot ignition. NOTE: This temperature may be caused either by self-heating or by induced heating." Thus, unlike its definition of *spontaneous ignition* itself, here ISO is including all forms of *unpiloted ignition*.

Stoichiometric mixture. A stoichiometric mixture of chemical reactants (more correctly referred to as a stoichiometrically balanced mixture) is one in which the proportion of reactants is such that there is no surplus of any reactant after the reaction is completed. The reaction products must be known (or defined) for the concept to be applicable. In systems which are capable of partial reaction, the ultimate reaction products are normally used (example: carbon is taken as oxidizing to CO_2, not to CO).

Stray current. Current flowing through paths other than the intended circuit.

Subcritical. In self-heating theory, denotes conditions that will not lead to thermal runaway.

Supercritical. In self-heating theory, denotes conditions that will lead to thermal runaway.

Surface flash. ISO[1] defines it as: "Movement of transient flame over the surface of a material without ignition of its basic structure." It also states in a note that "This period of time is usually shorter than 1 s.

Surface ignition. Ignition caused by an imposed heat flux accompanied by a pilot flame placed directly onto the surface of a specimen. The term is rarely used.

Sustained flaming. ISO[1] defines it as: "Persistence of flame on or over a surface for a minimum period of time. NOTE: the period of time required will vary across different standards, but it is usually of the order of 10 s." In the military research community, this term is sometimes understood to mean that flaming persists after the source of heating is removed, which is a fundamentally different definition from the one given by ISO.

Thermal explosion. Runaway self-heating of a substance, the exothermicity of which can be represented as a single chemical reaction of the Arrhenius form. Runaway self-heating may not cause any detectable pressure rise nor make a noise that is commonly considered a trait of explosions. If the reaction is a chain reaction, rather than a single-step reaction, then ignition is referred to as a "chain-reaction explosion."

Thermal runaway. Self-heating which rapidly accelerates to high temperatures. Under many practical conditions of organic substances stored in air, thermal run-away will lead to ignition. Under some conditions, a stable elevated temperature is reached rather than a runaway condition. Note that self-heating does *not* need to result in a thermal runaway and may simply result in a moderate temperature rise.

Thermally-thick solid. A solid which, while heated from one face, shows a negligible temperature rise at its opposite face. This characteristic is not simply a property of a material, but also depends on the time of exposure and the heat flux.

Thermally-thin solid. A solid which, while heated from one face, shows a back-face temperature which is nearly identical to the temperature of the heated face. This characteristic is not simply a property of a material, but also depends on the time of exposure and the heat flux.

Tracking. IEC[44] defines it as: "Progressive formation of conducting paths, which are produced on the surface and/or within a solid material, due to the combined effects of electric stress and electrolytic contamination." The phenomenon is also referred to as *arc tracking*.

Tracking resistance. ISO[1] defines it as: "The ability of a material to withstand a test voltage, under specified conditions, without creating conducting paths on the surface of the specimen and without the occurrence of flame."

Tramp metal. Loose metal objects present in places where they should not be, for example, among pulverized agricultural products.

Transient flaming. Flaming ignition which does not exhibit *sustained flaming*. ISO uses the variant term *transitory flaming*.

Transitory flaming. ISO[1] defines it as: "Existence of flame on or over the surface of the specimen for a period of time longer than that of *surface flash*, but shorter than that of *sustained flaming*."

Triboelectrification. The generation of static electricity by friction between two dissimilar materials.

Unpiloted ignition. ASTM E 176[2] defines it as: Ignition caused by one or more sources of energy without the presence of a pilot source of ignition." *Autoignition* is the preferred synonym.

Upper explosive limit; **upper explosion limit**. See *explosion limits*.

Upper flammability limit. The highest concentration of a vapor or gas that will ignite and burn with a flame in a given atmosphere (air, pure oxygen, etc.).

Upper temperature limit. The maximum temperature for which a saturated fuel vapor-air mixture can show flame propagation.

Abbreviations and acronyms

A. amperes.
abs. absolute.
ABS. acrylonitrile-butadiene-styrene.
AES. Auger electron spectroscopy.
AIChE. American Institute of Chemical Engineers.
ARC. Accelerating Rate Calorimeter.

ASTM. American Society for Testing and Materials, now called ASTM International.

Introduction

In this Chapter, a brief review is made of some simple fundamentals of combustion theory. Here, we present some of the basic ideas of the chemical reactions involved in oxidation of materials. A *chemical reaction*, by the way, is simply a rearrangement of atoms into a different configuration. In other words, it occurs when molecules split up, and new molecules are formed out of the original collection of atoms. A *change of state*, however, is a physical change, not a chemical reaction. Thus, ice melting and becoming water, then being boiled off and becoming steam does not comprise any chemical reaction, only a change of state of matter. The molecules at all times continue to remain H_2O.

The branch of science which is concerned only with the state of the initial reactants and the final products is termed *thermochemistry*. The study of how fast the reactions take place is termed *reaction kinetics*.

Rapid, high-temperature oxidation is referred to as *combustion*. There is sometimes a distinction made between fire and explosion. According to one author[1], an *explosion* is a gas-dynamic process by which a marked increase in system pressure generates destructive forces. By contrast, he considers *fire* to be slower combustion process in which the overall rate of fuel oxidation is limited by its rate of mixing with the surrounding air. Definitions something of this nature are commonly used both by scientists and by laymen. However, these terms are not intended to be highly precise, and all manner of subtle difficulties can arise. For example, the process leading to spontaneous combustion is often termed a *thermal explosion*, yet gas-dynamics plays a negligible role in it. *Detonation* is a unique, narrowly defined form of explosion (a reaction propagating at a velocity greater than the local speed of sound in the unreacted material), but apart from that, explosion and fire should be viewed simply as points of emphasis on a continuum.

Thermochemistry

Fuels and oxidizers, when combined, cause heat to be liberated. If the heat is sufficient, visible flames can be seen. Why are, then, all fuels not spontaneously igniting? In other words, why is the "heat" side of the fire triangle needed? To understand the answer to this simple-seeming question, we must examine some chemistry of combustion. In such study, we will learn that the fuel + oxidizer reaction usually* has an energy hump: external energy must be put into

* Some pairs of substances do not need energy input in order to ignite. Such pairs of substances which ignite directly upon being mixed are termed *hypergolic*. In many hypergolic reactions, the oxidizer needed for such ignition is not oxygen, thus the more general concept of "pairs of substances" is used for clarity.

the system, before fuel and oxidizer molecules can actually combine and form products. To understand this process, some concepts of combustion thermochemistry and kinetics must be understood. This will be the theme of the present chapter.

HEAT OF COMBUSTION

The heat of combustion is actually more precisely defined as the *enthalpy of combustion* and sometimes casually denoted as *calorific value*. Thus, it is essential that the concept of *enthalpy* be briefly reviewed from thermodynamics. The First Law of Thermodynamics states that:

$$\Delta E = Q - W$$

where ΔE = change in the internal energy of a system; Q = heat added to the system; and W = work done by the system. The units for all of these quantities are joules, although in fire studies it is more convenient to use kJ (1000 J) or MJ (10^6 J). The internal energy can be understood as the energy stored in the molecules themselves. As it turns out, in thermodynamics we do not try to determine the absolute value of this energy, but are only interested in changes which occur when the system interacts with the outside world. This is why the First Law is couched in terms of the change, ΔE. The reason for the minus sign is that due to the definition of W, whereby a positive W means work is done by the system. Since work done *by* the system lowers its energy, whereas heat added to the system raises the energy, there is a minus sign in front of W, but not in front of Q.

We must now consider some details of the work term. We will mainly be concerned with work due to expansion of gases. Suppose a reaction occurs which causes the volume of the system to expand from V_1 to V_2. Then the work that is done *by* the system *on* the atmosphere surrounding it is

$$W = P(V_2 - V_1) = P\Delta V$$

In SI units, pressure is measured in Pascals (Pa), where 1 Pa = 1 N m^{-2}. The Newton (N) is basic SI unit of force. It can be expressed as 1 N = 1 kg m s^{-2}. The work term is *absent* if the reaction occurs in a constant-volume vessel, since then $\Delta V \equiv 0$; otherwise, an expansion that occurs corresponds to a positive ΔV and therefore to a positive W term. Chemical reactions taking place under constant-pressure conditions are very common. If the only work involved is that due to the expansion of the gases and the pressure P is constant throughout the process, then the First Law becomes:

$$\Delta E = Q - P\Delta V$$

We now define enthalpy H as:

$$H = E + PV$$

The heat added to the constant-pressure system in going from state 1 to state 2 is:

$$Q = (E_2 - E_1) + P(V_2 - V_1) = (E_2 + PV_2) - (E_1 + PV_1)$$

But by the definition of H, this becomes:

$$Q = H_2 - H_1 = \Delta H$$

In other words, in a constant-pressure process, the heat added to the system is equal to the change in its enthalpy. Since in thermochemistry the main task is to account for the heat absorbed or eliminated from a system, the use of the enthalpy concept simplifies things by developing expressions for heat that do not require accounting for volume changes. The units of enthalpy are the same as energy, e.g., J, kJ or MJ.

Now, consider a general reaction where:

$$(\text{reactants}) \rightarrow (\text{products})$$

Using the concept of enthalpy, the *heat of reaction*, h_r, is the heat which must be *added* to the system to produce the products from the reactants:

$$\Delta H_r = \sum n\Delta H_f^o\Big|_{\text{products}} - \sum n\Delta H_f^o\Big|_{\text{reactants}}$$

where the n is the number of moles of a particular reactant or product species, ΔH_f^o is the *standard heat of formation* for the species, and the summation is taken over all products and all reactants. The heat of formation of any chemical species, in turn, is defined as the heat which is required to be added in order to form that species out of its constituent elements, with the elements being in their standard state. By convention, the standard state is defined to be at a temperature of 298 K and a pressure of 1 atm, and the "o" superscript reminds us of that. To fully specify the standard state, the state of aggregation must also be specified. This is taken to the be normal or common state at 298 K. For example, the normal state for oxygen at 298 K is as the molecule O_2, not as the atom O; thus, the standard state for oxygen is defined as $O_2(g)$, where the "g" denotes the gas state. The standard heat of formation is sometimes written as ΔH_{f298}^o, where the "298" denotes the standard temperature of 298 K. There are several other slight permutations of this symbol that will be found in the literature. The reason for establishing such conventions is to facilitate making published tables of values; if the conditions were not standardized, it would be very difficult to collect the needed data for solving problems.

A simple example of the arithmetic of heats of formation will make this clear. Suppose we combine hydrogen and carbon to form methane:

$$C(s) + 2H_2(g) \rightarrow CH_4(g)$$

If the process takes place at room temperature, the hydrogen will be gaseous, but the carbon will be solid (graphite); this is reflected in the equation written above. Since the (s) state for carbon and the (g) state for H_2 are the standard states for both of these substances, the heats of formation are $\equiv 0$ for both. Gaseous methane is not an element, so we expect it to have a non-zero ΔH_f^o. From thermochemical reference tables[2,3], the value of ΔH_f^o for CH_4(g) is found to be -74.81 kJ mol^{-1}. Thus, H_r = -74.81 – 0 = -74.81 kJ mol^{-1}. The negative sign indicates that heat must be *removed* from the system for the products to stay at 298 K and not to rise in temperature. In other words, the negative sign indicates an *exothermic* (heat producing) reaction. This

example might suggest that one could take a slab of graphite, discharge some hydrogen gas on it, and convert the graphite into methane. If one were to do this at room temperature, one would find that nothing would happen and no CH_4 could be detected. The reason is because the reaction rate is exceedingly slow for this reaction, in other words, chemical kinetics, which we have not considered yet, prohibits the easy occurrence of this reaction. However, if we were to wait a very long time, we might find that eventually it would be possible to detect some reaction products.

This same problem can be turned around in a useful way. Suppose we have a cylinder of methane gas. Is it likely to spontaneously decompose and revert into C and H_2? To consider this, all that is needed is to reverse the reaction, that is, switch the products and the reactants. Now, the heat of reaction of the reverse reaction becomes +74.81 kJ mol^{-1}. This means that a large amount of heat would have to be added to the system in order to decompose methane, in other words the reverse reaction is *endothermic*. Here, since thermodynamics alone suggests to us that the process will not happen spontaneously and there is no need to consider whether slow reactions would further prohibit the occurrence.

Now consider another simple gas, acetylene, C_2H_2. This time, instead of writing the equation for formation, let us ask whether the decomposition reaction is likely to spontaneously occur:

$$C_2H_2(g) \rightarrow 2C(s) + H_2(g)$$

The heat of formation of $C_2H_2(g)$ is +226.7 kJ mol^{-1}, and two substances on the right side of the equation are both in their reference state, so their heats are $\equiv$ 0. Thus, the heat of reaction is:

$$2(0) + 0 - 226.7 = -226.7 \text{ kJ mol}^{-1}$$

The decomposition reaction of acetylene, having a minus sign for its heat of reaction, is exothermic. Furthermore, the value of –226.7 kJ mol^{-1} is a very high negative number, so the reaction is highly favored by thermodynamics to occur. There is a slight energy barrier to this occurring, however, so acetylene can be handled relatively safely under certain conditions. The role of the heat of formation in evaluating unstable substances is discussed further in Chapter 10 and specific compounds are discussed in Chapter 14.

Next consider a combustion reaction:

$$CH_4(g) + 2O_2(g) \rightarrow CO_2(g) + 2H_2O(l)$$

whereby gaseous methane burns and produces gaseous CO_2 and liquid water. In thermochemistry, the standard reaction which is considered occurs at 298 K: the reactants enter the system at 298 K, the reaction occurs, and then either enough heat is added or removed from the system, so that the products also return to the same 298 K temperature. Real combustion systems, of course, rarely have the products returning to 298 K. For example the exhaust from a car engine is much cooler than the combustion taking place within the cylinder, but it is still above room temperature. Such computations will be considered below.

To find the heat of reaction for the above combustion reaction, it is necessary to look up the heats of formation of the four substances involved. The ΔH_r can then be evaluated as:

$$\Delta H_r = \big(-393.51 + 2(-285.83)\big) - (-74.81 + 0)$$
$$= -890.36 \text{ kJ mol}^{-1}$$

Since we all know that methane, when burned, releases heat, it is not surprising to find a minus sign for the heat of reaction. The *heat of combustion*, ΔH_c is defined as the negative of ΔH_r, in order to conveniently have a positive number for combustible substances. Therefore, the heat of combustion, also called *calorific value*, of methane is +890.36 kJ mol^{-1}. In many cases, the unit of measurement which is convenient is mass, not moles. The molar mass* of methane is 16.04 g mol^{-1}, thus the heat of combustion is more commonly expressed as Δh_c = 55.50 MJ kg^{-1}. When mass-based, instead of mole-based, quantities are used, it is common to adopt the lower-case letters *h*, *q*, and *e* for enthalpy, heat, and internal energy.

There are actually two different heats of combustion which need to be kept straight. In the reaction above for the burning of methane, the water was written as $H_2O(l)$, specifying the liquid state. If the reaction products are actually cooled down to 298 K, then water will condense and be in liquid form. In most combustion systems, however, water remains as vapor and does not condense. The arithmetic needed to correct for the fact that condensation did not occur is then just a burden. Thus, the heat of combustion with water going to $H_2O(l)$ is defined as the *gross (or upper) heat of combustion*. The same reaction, but with water going to $H_2O(g)$, is defined as the *net (or lower) heat of combustion*. Consequently, one must always specify which heat of combustion is being referred to. To keep this straight, the nomenclature ΔH_c^u and ΔH_c^l is often used. The heat of formation of $H_2O(g)$ is –241.82 kJ mol^{-1}. Thus, the heat of reaction when $H_2O(g)$ is the product becomes:

$$\Delta H_r = \big(-393.51 + 2(-241.82)\big) - (-74.81 + 0)$$
$$= -802.34 \text{ kJ mol}^{-1}$$

and ΔH_c^l = +802.34 kJ mol^{-1}, or Δh_c^l = 50.01 MJ kg^{-1}. For any substance, if Δh_c^u is the only published value that is available, the net heat of combustion can be calculated as:

$$\Delta h_c^l = \Delta h_c^u - 0.2183[\%H] \quad \text{MJ kg}^{-1}$$

where [%H] is the percent of hydrogen, by mass, in the fuel, and both heats of combustion are to be expressed in units of (MJ kg^{-1}). Thus, for the methane example, one mole of CH_4 weighs 16.04 g, in which there are 4 atoms of H, the latter having an atomic weight of 1.008 g. Then, to obtain Δh_c^l from Δh_c^u, it is necessary to subtract

* Molar mass used to be known as *molecular weight* to those who studied chemistry not so recently.

0.2183×100×4×1.008/16.04, or 5.49 MJ kg^{-1}, which gives Δh_c^l = 50.01 MJ kg^{-1}, exactly as above.

In most handbook compilations, listings are given for the heats of formation, rather than the heats of combustion. Thus, the user must be able to perform the arithmetic of starting with heats of formation and computing the heat of combustion. For the heat of combustion,

$$\Delta H_c = -\sum n\Delta H_f^o\Big|_{\text{products}} + \sum n\Delta H_f^o\Big|_{\text{reactants}}$$

Now writing a fairly general expression for combustion of a fuel in oxygen:

$$\begin{aligned} &C_cH_hO_oN_nS_sX_xB_bSi_i \\ &\quad + \frac{1}{2}\left[2c + \frac{h}{2} - o - \frac{x}{2} + 3s + 3b + 2i\right]O_2 \\ &\rightarrow cCO_2 + \frac{1}{2}(h - x - 2s - 3b)H_2O + \frac{n}{2}N_2 \\ &\quad + xHX + sH_2SO_4 + bH_3BO_3 + iSiO_2 \end{aligned} \qquad (1)$$

The above expression is unchanged for combustion in air, except that an identical number of nitrogen molecules become added to both sides. The letter *X* is used to indicate any of the halogen atoms (F, Cl, Br, etc.) that may be present. Noting that there will always be only 1 fuel mole on the left side of the equation, and that $\Delta H_f^o\Big|_{O_2} \equiv 0$,

$$\begin{aligned} \Delta H_c = &-c\Delta H_f^o\Big|_{CO_2} - \frac{1}{2}(h - x - 2s - 3b)\Delta H_f^o\Big|_{H_2O} \\ &- x\Delta H_f^o\Big|_{HX} - s\Delta H_f^o\Big|_{H_2SO_4} - b\Delta H_f^o\Big|_{H_3BO_3} \\ &- i\Delta H_f^o\Big|_{SiO_2} + \Delta H_f^o\Big|_{fuel} \end{aligned}$$

In handbook tabulations it will be found that, in general, values of ΔH_f^o are given separately for the crystalline-solid, amorphous-solid, liquid, and gas phases, generally abbreviated as (c), (a), (l), and (g). By convention, the products are generally taken to be CO_2 (g), HX (l), $H_2SO_4 \cdot 115H_2O$ (l), H_3BO_3 (c), and SiO_2 (a), although there is not universal agreement. For water, if the lower heat of combustion ΔH_c^l is computed, then the H_2O (g) state is used, while for ΔH_c^u the H_2O (l) state applies. The state of the reactants is *not* standardized. It is possible for fuel to be in solid, liquid, or gas phases, so the value of ΔH_f^o to be used for the fuel must correspond to the actual state of the substance. If we want to compute the standard (net) heat of combustion, then it is defined to be at a temperature of 298 K. For this purpose, the (g) state should be picked for substances with a boiling point ≥ 25ºC, and the (l) state for liquids having T_b < 25ºC. For substances which are solids at 25ºC, the (c) or (a) state should be used. Inserting the appropriate values for the heats of formation of standard products,

$$\begin{aligned} \Delta H_c^u = &393.51c + 142.92(h - x - 2s - 3b) - x\Delta H_f^o\Big|_{HX} \\ &+ 887.81s + 1094.33b + 903.49i + \Delta H_f^o\Big|_{fuel} \end{aligned}$$

$$\begin{aligned} \Delta H_c^l = &393.51c + 120.91(h - x - 2s - 3b) - x\Delta H_f^o\Big|_{HX} \\ &+ 887.81s + 1094.33b + 903.49i + \Delta H_f^o\Big|_{fuel} \end{aligned}$$

where for $\Delta H_f^o\Big|_{HX}$ the values used are –318.97 kJ mol^{-1} for HF, –166.62 kJ mol^{-1} for HCl, and –121.16 kJ mol^{-1} for HBr, and all of these values refer to these acids in dilute aqueous solutions.

Example Compute the net heat of combustion of methyl chloride, CH_3Cl. Its T_b = –24ºC, so we will take the state to be (g). The heat of formation of CH_3Cl (g) = –80.83 kJ mol^{-1}. Then,

$$\begin{aligned} \Delta H_c^l &= 393.51\times 1 + 120.91(3-1) - 1\times(-166.62) - 80.83 \\ &= 721.12 \text{ kJ mol}^{-1} \end{aligned}$$

or, since the molar mass is 50.49, Δh_c^l = 721.12/50.49 = 14.28 kJ g^{-1}, or 14.28 MJ kg^{-1}. Because of the low heat of combustion, we would not expect methyl chloride to burn easily.

If we wanted to compute the gross heats of combustion, it would be necessary to consider some more details of the products of reaction. Because definitions need to be standardized, products of reaction are standardized. This does *not* means that these particular products will occur in actual combustion, but rather that chemists have agreed to use certain reaction products for developing tables and handbook data. CO_2 and N_2 remain gaseous products even for the gross heat of combustion.

CONSTANT-VOLUME HEAT OF COMBUSTION

The standard definition of heat of combustion entails a process occurring at constant pressure, this being the reason why the heat of reaction is expressed as an enthalpy. It is possible for combustion processes to occur at constant volume. In fact, the standard oxygen bomb calorimeter for measuring heats of combustion is a constant volume device. The constant-volume heat of combustion, i.e., the energy of combustion, ΔE_c, is experimentally obtained, then from it ΔH_c can be calculated as:

$$\Delta E_c = \Delta H_c - RT\Delta n$$

where R = universal gas constant (= 8.314 J mol^{-1} K^{-1}), T = 298 K, and Δn = (gaseous moles of products – gaseous moles of reactants). Note that any reactants or products which are in condensed phase are ignored in the above arithmetic. Fuels are often in condensed phase, but for explosive or pyrotechnic substances, combustion products (e.g., metal oxides) can also be in condensed phase.

EFFECTIVE HEAT OF COMBUSTION; HEATS OF EXPLOSION AND DETONATION

In actual combustion, not all products are simply the standard products discussed above. For instance, in every fire a fraction of carbon becomes CO—all of the carbon does not go just into CO_2. Similarly, other minor species may be produced. The heat of combustion for actual, as opposed to standard, conditions are termed *effective heat of combustion*. This is not a unique value for a substance, since different fire conditions will produce different reaction products. In a large fraction of practical fire situations, the effective heat of combustion is 90% or more of the net heat of combustion. Thus, in many cases it is not necessary to consider actual reaction products and their effects on the heat release.

One situation where (minus) the heat of reaction is greatly different from the heat of combustion is for solid explosives. If the substance were reacted with a sufficient amount of gaseous oxygen, then bomb calorimeter determinations would produce the standard heat of combustion. However, in a real explosion of a solid explosive, the time scales are such that there is not an opportunity for the explosive substance to react with atmospheric oxygen. Thus, the *energy of explosion*, ΔE_{exp}, is measured by using the same bomb calorimeter as for the determination of the heat of combustion, but filling the bomb with nitrogen instead of oxygen. The igniter wire ignites the substance and heat evolved is measured calorimetrically. For this measurement, the pressure of nitrogen in the bomb at the start of the test is set at a recommended value of either[4] 2.53 MPa or[5] 3.1 MPa. The energy of explosion is also referred to as the *heat of explosion*. The *energy of detonation*, ΔE_{det} (more commonly called the *heat of detonation*) is the negative of the heat of reaction, but using a special definition for the reaction products. The reaction products are taken to be at ambient pressure and temperature, but having the composition that the products would have if their temperature and pressure values were those which prevail at the Chapman-Jouguet (C-J) point[4]. The latter—a value calculated from hydrodynamics of detonations—is chosen because it approximates the temperature/pressure conditions found in a detonation. At the C-J point, the temperature may reach 5000 K and the pressure 35 GPa. Thus, substantial calculations need to be made to obtain this value. The difference between the heat of explosion and the heat of detonation is small, unless the oxygen balance (see Chapter 10) is quite negative. Fedoroff[4] reports that the distinction is often ignored by experimentalists, that disagreements exist concerning the exact definition of the heat of detonation, and that, in any case, experimental results show a wide scatter. Values of the heat of explosion and heat of detonation, while numerically rather similar, will be much lower than the heat of combustion, if the substance has a *negative oxygen balance*. The latter concept is discussed in detail in Chapter 10, but briefly it means that a substance having a negative oxygen balance can be further oxidized, if it can react with the oxygen in air, once its initial self-reaction is completed. Consequently, for many explosives, the heat of explosion is only ¼ to ½ of the heat of combustion. Some typical values are given in Chapter 14 under *Explosives*.

Table 1 Gas explosions—explosion energies for stoichiometric fuel/air mixtures

Fuel	Net ht. of comb. (MJ kg^{-1})	Ht. of comb. per unit vol. of fuel* (MJ m^{-3})	Stoich. air/fuel ratio (m^3/m^3)	Explosion energy per volume of fuel/air mixture* (MJ m^{-3})
ammonia	18.6	13.0	3.6	2.8
butane	45.7	108.6	31.0	3.4
cyclohexane	43.4	149.4	42.9	3.4
ethylene	47.2	54.1	15.3	3.5
hydrogen	120.0	9.9	3.4	2.9
methane	50.0	32.8	10.5	3.1
propane	46.3	83.5	23.9	3.4
vinyl chloride	18.4	47.0	13.1	3.3

* for volume of gas at 298 K

In addition, in recent years it has been suggested that the energy of explosion be limited further still to the energy that can be realized as thermodynamic work (e.g., pressures of blast waves moving walls). Not 100% of the energy of the reaction can be converted into work, and the rest can only become heat. Since the heat released in explosions is not destructive in the same manner that mechanical work is, the concept of *available energy of explosion* allows the maximum destructive potential of explosions to be quantified and compared[6].

For *gas explosions*, the energy released, per volume of stoichiometric fuel/air mixture, does not depend much on the nature of the fuel. Table 1 shows that most fuels release close to 3.4 MJ for each cubic meter of stoichiometric fuel/air mixture. As a related quantity, the ratio (heat released)/(mass of oxygen consumed) is nearly constant for most organic fuels, and it comprises the *oxygen consumption principle*. The latter has been the basis of current-day measurements of heat released in fires[7].

RELATIONS BETWEEN FUEL AND AIR

As will be seen throughout the Handbook, the air/fuel ratio is a variable of primary importance in determining the conditions of combustion. The proportion between fuel and air can be expressed in various ways. In many cases, volume-percent of a fuel gas is specified, it being tacitly assumed that the remainder is air. For mixtures which contain special diluents, simply identifying the vol% of each component is appropriate. Next, it is necessary to introduce the concepts of *stoichiometric*, *fuel-lean* and *fuel-rich*. A fuel/oxidizer mixture is referred to as being stoichiometric if the amount

of fuel is exactly such that, upon combustion, there is no extra fuel left unburned and no oxygen left unreacted. If more fuel than needed for stoichiometric combustion is present, then the mixture is fuel-rich. Similarly, if less is present, then the mixture is fuel lean.

The general reaction for the stoichiometric combustion of a fuel can be written as:

$$1\,\text{kg fuel} + r\,\text{kg air} \rightarrow (1+r)\ \text{kg products}$$

In other words, for complete combustion, each kg of fuel requires r kg of air. Thus, the air/fuel ratio for complete combustion is r, on a mass basis. In combustion engineering, the air/fuel ratio is often used on a mole (or volume) basis. If γ is the air/fuel mole ratio, then it can be obtained as:

$$\gamma = r\frac{M_f}{M_a}$$

where M_f = molar mass of fuel and M_a = molar mass of air = 28.96 g mol^{-1}. When the ratio of the fuel and air is not the stoichiometric one, then the fuel/air mixture can be represented by the use of the *equivalence ratio*[*], which is a dimensionless number assigned the symbol φ:

$$\varphi = \frac{(fuel/air)}{(fuel/air)_{st}}$$

where *st* denotes stoichiometric conditions. All values of $\varphi > 1$ correspond to fuel-rich conditions; similarly all values of $\varphi < 1$ correspond to fuel-lean conditions. The equivalence ratio can also be expressed as:

$$\varphi = r \times \frac{\text{mass of fuel}}{\text{mass of air}} = \gamma \times \frac{\text{moles of fuel}}{\text{moles of air}}$$

And it can be shown that the value of φ is the same, regardless if the amounts are all evaluated as moles or as masses.

For example, methane burning fully in air is:

$$CH_4 + 2(O_2 + 3.76N_2) \rightarrow CO_2 + 2H_2O + 7.52N_2 \qquad (2)$$

In the above equation, the amount of oxygen is such that there is no oxygen left among the products; neither is there any fuel left, thus the reaction, as written, is stoichiometric. Suppose now that there are two moles of methane going into the reaction, with the amount of air unchanged:

$$2CH_4 + 2(O_2 + 3.77N_2) \rightarrow CO_2 + 2H_2O + 7.52N_2 + CH_4 \qquad (3)$$

We first compute γ using the stoichiometric reaction, Eq. (2). For each mole of fuel burned, the number of moles of air is 2 × (1+3.77) = 9.54. Thus, γ = 9.54/1 = 9.54. Now compute the fuel/air mole ratio for our desired reaction, Eq. (3). This fuel/air mole ratio is = 2/9.54 = 0.210. Thus, φ = 9.54×0.210 = 2.0.

Consider now what would happen if the ratios were computed as masses. The mass of two moles of air is = 2 × (32.00 + 3.77 × 28.01) = 275.2 and the molar mass of CH_4 is 16.04. Thus, the value of r is 275.2/16.04 = 17.16. Considering now our desired reaction, Eq. (2), the mass of two moles of CH_4 is 2 × 16.04 = 32.08 g. Then, the fuel/air mass ratio is 32.08/275.2 = 0.117 (this, of course, is *not* the same as the mole ratio of 0.210). The value of φ = 17.16×0.117 = 2.0, which is the same as when computed by ratioing volume ratios.

In cases where the fuel is a liquid aerosol or a dust cloud, it is common to express the fuel as a fuel mass concentration in air (g m^{-3}). In such cases, it can be shown that the equivalence ratio can also be expressed as:

$$\varphi = \frac{\text{fuel mass concentration}}{(\text{fuel mass concentration})_{st}}$$

For the fairly general fuel discussed above, the value of γ is obtained as:

$$\gamma = 4.77\left[c + \frac{h}{4} - \frac{o}{2} - \frac{x}{4} + \frac{3}{2}s + \frac{3}{2}b + i\right]$$

where the variables are defined as indicated in Eq. (1). In some cases, the ratio γ_o is desired:

$$\gamma_o = \frac{\text{moles of oxygen}}{\text{moles of fuel}}$$

This, of course, is evaluated simply as:

$$\gamma_o = \left[c + \frac{h}{4} - \frac{o}{2} - \frac{x}{4} + \frac{3}{2}s + \frac{3}{2}b + i\right]$$

For methane γ = 4.77×(1 + 4/4) = 9.54. Similarly, the value of r is obtained as:

$$r = 4.77\frac{28.85}{M_f}\left[c + \frac{h}{4} - \frac{o}{2} - \frac{x}{4} + \frac{3}{2}s + \frac{3}{2}b + i\right]$$

Thus, since the molar mass of methane is 16.04, its value of r is obtained as 9.54×28.85/16.04 = 17.16. Occasionally, the stoichiometric oxygen/fuel mass ratio, r_o is needed. This can be evaluated as:

$$r_o = \frac{32.00}{M_f}\left[c + \frac{h}{4} - \frac{o}{2} - \frac{x}{4} + \frac{3}{2}s + \frac{3}{2}b + i\right]$$

For methane, r_o = 32.00×2/16.04 = 4.0.

The stoichiometric concentration of fuel in a fuel/air mixture, C_{st}, is an often-used quantity. It is defined on a vol% basis and thus it is:

$$C_{st} = \frac{100}{1+\gamma}$$

For the general fuel C_{st} can be evaluated as:

$$C_{st} = \frac{100}{1 + 4.77\left(c + \frac{h}{4} - \frac{o}{2} - \frac{x}{4} + \frac{3}{2}s + \frac{3}{2}b + i\right)}$$

It is often necessary to convert between values of φ and the vol% of fuel, C_f, in a non-stoichiometric fuel/air mixture. This can done according to:

[*] The definition given here is the customary one, but the reader must be warned that some researchers use a definition which is exactly the inverse of the one used here.

$$C_f = \frac{100}{1+\frac{\gamma}{\varphi}} = \frac{100}{1+\frac{\left(\frac{100}{C_{st}}-1\right)}{\varphi}}$$

and

$$\varphi = \frac{\frac{100}{C_{st}}-1}{\frac{100}{C_f}-1}$$

For methane, C_{st} = 100/(1+9.54) = 9.49%. Thus, if a methane concentration of 15 vol% is measured in air, the equivalence ratio φ = (100/9.49–1)/(100/15–1) = 1.68. Thus, this concentration represents a mixture which is 68% fuel-rich.

ADIABATIC FLAME TEMPERATURE

The adiabatic flame temperature, T_{ad}, is the temperature which a fuel-air mixture would reach if it could react without losing any heat in the process to the environment. This, of course, is impossible, but it is a very useful concept since it establishes the upper limit for combustion temperatures. In a real system with heat losses, the actual temperature achieved must be less than T_{ad}. Consider a stoichiometric methane/air mixture:

$$CH_4 + 2(O_2 + 3.76N_2) \rightarrow CO_2 + 2H_2O + 7.52N_2$$

As discussed in the previous section, the heat of this reaction is –890.36 kJ mol^{-1}. This amount of heat would need to be removed from the system (by using cooling coils, for example) in order to bring the combustion products back to room temperature. But here, we will assume that the system is perfectly insulated and will rise to a high temperature. To start with the general case, for a constant-pressure system where the reactants and the products are at two different temperatures T_1 and T_2, with neither one being the standard 298 K reference temperature, and no heat is added or removed from the system, conservation of energy gives:

$$Q = \Delta H = \sum_{i \text{ products}} n_i \left[\left(H^o_{T_2} - H^o_{298}\right) + \Delta Hf^o_{298}\right]_i - \sum_{j \text{ reactants}} n_j \left[\left(H^o_{T_1} - H^o_{298}\right) + \Delta Hf^o_{298}\right]_j$$

Same as with internal energy, the absolute value of enthalpy is undefined. Only the difference in enthalpy between that at one temperature and that at a second temperature can be quantified. The reference temperature can, in principle, be anything, but the reference handbooks compile all use 298 K. Thus, the notation $\left(H^o_{T_2} - H^o_{298}\right)_i$ does not mean that two different numbers are to be looked up and then subtracted—this is a *single* quantity which is looked up in the tables. This term, not to be confused with the enthalpy of formation, discussed above, is the increase in enthalpy sustained when a mole of substance i which is at 1 atm pressure goes from a temperature of 298 K to a temperature T_2. Continuing the example of methane burning adiabatically, the heat entering the system ≡ 0. Simplifying the problem now by assuming that the reactants entered at a temperature of 298 K and not at some different value of T_1,

$$0 = \sum_{i \text{ products}} n_i \left[\left(H^o_{T_2} - H^o_{298}\right) + \Delta H^o_{f298}\right]_i - \sum_{j \text{ reactants}} n_j \left[\Delta H^o_{f298}\right]_j$$

To solve this equation, it is convenient to remember from chemistry the definition of the constant-pressure heat capacity C_p:

$$C_p(T) = \left(\frac{\partial H}{\partial T}\right)_P$$

C_p is a function of the temperature, and at any given temperature it represents the slope of the enthalpy curve with respect to temperature. Enthalpy rises notably with temperature, but its slope, C_p, is rather less affected by temperature. If C_p were a constant, independent of T, then we could write

$$\left(H^o_{T_2} - H^o_{298}\right) = C_p\left(T_2 - 298\right)$$

Since we have assumed the system is adiabatic, $Q \equiv 0$, and

$$0 = C_p(CO_2)\cdot(T_{ad} - 298) + \Delta H^o_{f298}(CO_2) + 2C_p(H_2O)\cdot(T_{ad} - 298) + 2\Delta H^o_{f298}(H_2O(g)) + 7.52C_p(N_2)\cdot(T_{ad} - 298) + 7.52\Delta H^o_{f298}(N_2) - \Delta H^o_{f298}(CH_4) - 2\Delta H^o_{f298}(O_2) - 7.52\Delta H^o_{f298}(N_2)$$

where we have explicitly stated that the T_2 which must be solved for is, in fact, T_{ad}. To simplify this fairly lengthy expression, we can realize that

$$\Delta H^u_c(CH_4) = -\Delta H^o_{f298}(CO_2) - 2\Delta H^o_{f298}(H_2O(g)) + \Delta H^o_{f298}(CH_4)$$

while the heats of formation of O_2 and N_2 are ≡ 0. Thus,

$$0 = \left[C_p(CO_2) + 2C_p(H_2O) + 7.52C_p(N_2)\right](T_{ad} - 298) - \Delta H^u_c(CH_4)$$

If we make the approximation that C_p = constant, then a suitable temperature needs to be selected at which to pick these values. This temperature should roughly be halfway between 298 K and T_{ad}. For the sake of simplicity, we will pick T = 1300 K. At this temperature, C_p (CO_2) = 57.1 J K^{-1} mol^{-1}; C_p (H_2O) = 44.9 J K^{-1} mol^{-1}; and C_p (N_2) = 34.1 J K^{-1} mol^{-1}. Thus,

$$T_{ad} \approx 298 + \frac{890.36\times10^3}{57.1 + 2\times44.9 + 7.52\times34.1} = 2506 \text{ K}$$

which is somewhat higher than the actual value of 2225 K. In the above equation, it was necessary to multiply the heat of combustion results by 1000, since their original units were in kJ, while the units used for C_p in the denominator are in J.

If adiabatic flame temperatures were manually computed in a way as described, even if an approximation for C_p were not needed, the results would still be higher than the true value. The reason is that the actual combustion products are not simply CO_2 and H_2O. For any organic fuel, some products of incomplete combustion (CO, soot, unburned hydrocarbons) will exist, although these are likely to be negligible if the combustion is fuel-lean, instead of stoichiometric or fuel-rich. In addition, however, the actual combustion products will contain *dissociated* species, such as H, OH, O, and will also tend to contain some molecular hydrogen (H_2) and some NO. Since dissociation is endothermic, this means that enthalpy contribution is reduced from the expected value.

Since most unwanted combustion occurs under constant, or nearly-constant, pressure conditions, the above derivation focused on the *constant-pressure* T_{ad}. There is a second type of adiabatic flame temperature which can be derived, a constant-volume T_{ad}. The difference between the two computed T_{ad} values is not trivial. For methane burning stoichiometrically in air, the constant-pressure T_{ad} is 2225 K, while the constant-volume T_{ad} is 2889 K. The reason the constant-volume process gives a much higher temperature is because all of the energy of the reaction goes solely to heating the combustion products. In a constant-pressure system, a portion of the energy is dissipated as a work term, $p\Delta V$. Henceforth in this book we will only concern ourselves with constant-pressure T_{ad}.

The adiabatic flame temperature of most fuels is in the range of 2000 to 2500 K when burned in normal air. For combustion in pure oxygen, T_{ad} is typically 3000 to 3500 K, but in the extreme case of carbon subnitride (C_4N_2), which is a highly endothermic compound, a value of 5300 K is found. One might think that any value of T_{ad} > room temperature would mean a substance can burn. This is not true; to learn why, we must consider combustion reaction kinetics. Empirically, gases and vapors which have an adiabatic flame temperature below about 1600 K will normally not undergo self-sustained combustion in a 21% oxygen environment. The LFL and UFL values for any gas ought to correspond to the same value of T_{ad}, and one would expect the same value to be shared by gases which have the same chemical oxidation mechanism. Actual LFL and UFL values are somewhat apparatus-dependent, but Hertzberg et al.[8] demonstrated for methane that using experimental values of LFL = 4.9% and UFL = 18.5%, T_{ad} is computed to be 1450 K at both the LFL and the UFL.

Since the availability of computers, adiabatic flame temperatures are computed by using standard computer programs for complex equilibrium calculation. A collection of computed results by Egerton[9], BM[10], Melhem[11] and the author are shown in Table 2. It can be seen that for most gases, T_{LFL} values are in the range 1300 – 1600 K. Acetylene, carbon disulfide, hydrogen, and hydrogen sulfide are exceptions having much lower values. But, apart from acetylene—which has the rare triple carbon bond—the others are inorganics, so should not properly be compared to organic gases. Shebeko et al.[12] recently reported T_{LFL} summary results for various families of organic compounds (but not for individual compounds): most results clustered around 1600 K. The T_{UFL} values are much more scattered and are generally lower than T_{LFL}. Hertzberg et al.[8] provided additional data showing that (a) for hydrocarbons, the limit flame temperature increases with increasing number of carbon atoms; and (b) most organic compounds, including substituted hydrocarbons, show an asymptote of $T_{LFL} \rightarrow 1600$ K, as the number of carbon atoms becomes large. The above values assumed that the oxidant is air. For fuel mixtures in oxygen, the values are typically 200 – 300 K lower. A very similar notion of a limiting flame temperature is often used in studying the effectiveness of inert diluents in quenching combustion.

Table 2 Limit flame temperatures and stoichiometric adiabatic flame temperatures in air

Gas	T_{LFL} (K)				T_{UFL} (K)	T_{ad} at stoich. (K)
	Melhem	Egerton	BM	Author	Melhem	
acetaldehyde	1552				977	2300
acetone	1541				1229	2210
acetylene	1268	1280		1250		2541
ammonia	1632	1773			1825	
n-butane		1718	1613			2280
1-butene	1479				1254	
carbon disulfide		720				2250
carbon monoxide	1394	1386			1268	
dimethyl ether	1565				980	
ethane	1534	1564	1483		1399	2259
ethanol	1492				1041	
ethyl acetate	1571				1047	2125
ethylene	1370	1485		1347	1216	2369
n-heptane		1842	1643			2275
hexane		1841	1653	1609		2273
1-hexene	1583				1091

hydrogen sulfide	1045				1383	
iso-octane			1703			2210
methane	1481	1527	1483	1483	1774	2225
methyldichlorosilane	1543				847	
methyltricholorsilane	1602					
n-octane		1848	1683			2275
n-pentane		1758				2275
propane		1656	1553			2267
propylene	1431	1756			1444	2320
trichlorosilane	1260				915	

In a related study, Ogawa and coworkers[13] reported that limiting values of the flame temperature (experimentally measured, not a computed value for adiabatic conditions). are independent of fuel type, but dependent of (a) mixture fraction, and (b) flame stretch. High flame stretch rates (> 10 s^{-1}) led to a measured flame temperature of around 1470 K for mixtures near the LFL; this value dropped to around 1320 K for a stretch rate of 2.5 s^{-1}. For mixtures near the UFL, values were generally about 200 K higher for a given stretch rate. The topic of flame stretch will not be covered in this book and interested readers should consult text-books suggested in *Further Readings*, below.

Real flame temperatures in accidental fires are normally much smaller than the adiabatic flame temperature. Flashed-over room fires commonly show 900 – 1000ºC. Jet fires and pool fires typically show 1000 – 1300ºC. Perhaps surprisingly, dust cloud explosions[14] also typically show 1000 – 1300ºC, despite the presence of solid particles. In general, temperatures close to the adiabatic flame temperature are not achieved except in specialized burners where heat losses have been carefully minimized. The practical examples cited above are all turbulent diffusion flames and the values cited represent those measured by normal sensing instruments. Since turbulent combustion comprises packets of air and fuel mixing and reacting, at any one place there will be a range of temperatures that vary rapidly and average out to the measured value. These turbulent combustion peaks are higher, but they are difficult to measure and have rarely been studied.

In the case of solid and liquid explosives, the detonation temperatures[15-17] are typically 3000 – 4500 K. These values are higher than for ordinary combustibles burning in air and roughly similar to ordinary combustibles burning in oxygen. The higher temperatures can be understood as being due to the efficient reaction, in that it is not necessary to heat an inert diluent such as the nitrogen in air.

Reaction kinetics

For a chemical reaction to occur, molecules must collide. But at ordinary temperatures, it is possible to create a gaseous mixture containing large amounts of both fuel and oxidizer molecules, yet no reaction will be observed, despite the fact that numerous collisions are occurring. In the 19th century, the Swedish chemist Svante Arrhenius first suggested that this was because these collisions did not have sufficient energy. He considered that there was an energy 'hump' which must be overcome by the reactants, even if the reaction itself is exothermic (Figure 1).

The reactants must be raised to an energy E_a above the ambient in order for the reaction to take place. This *activation energy* may be supplied by raising the temperature of the system, which will raise the kinetic energy of all of the molecules. The energy hump exists because—generally—bonds must be broken before new ones can be formed.

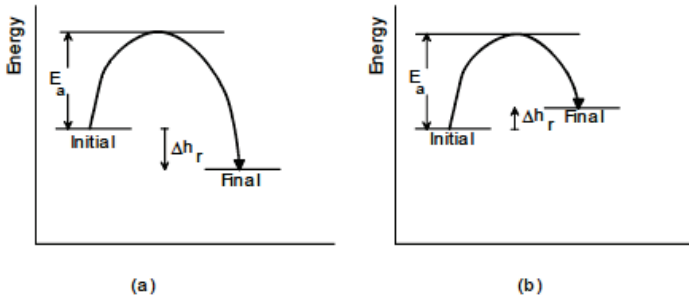

Figure 1 The activation energy needed to complete a reaction. (a) Exothermic reaction. (b) Endothermic reaction.

There are some particles, however, which can enter into reactions directly, without first needing to have external energy supplied to break bonds. These are free atoms or molecules which either have excess electrons or are missing electrons, in other words, species that possess free chemical bonding sites. Such particles are called *free radicals*. Since they are extremely highly reactive, this means they are also very short-lived. As a result, free radicals must normally be created by starting a reaction by raising the thermal energy of the system. The first bond breaks, and one or more free radicals are created. Energy to get over the 'hump' can also be supplied by other means; for example, there are light-sensitive reactions, where light energy is sufficient to cause the reaction to occur.

We may represent a simple reaction as two reactants, A and B, going into products C and D.

$$A + B \rightarrow C + D$$

Arrhenius[18] also discovered that the rate at which the reaction occurs can be represented as:

$$-\frac{dc_A}{dt} = -\frac{dc_B}{dt} = \frac{dc_C}{dt} = \frac{dc_D}{dt} = c_A^n c_B^m A e^{-E/RT}$$

where the concentrations of the various species are c (kg m^{-3}), A is the pre-exponential factor, R = the universal gas constant (8.314 J mol^{-1} K^{-1}), the activation energy E_a (kJ mol^{-1}) has been simply denoted as E, and T = temperature (K). Here, the c and A variables should not be confused with the schematic representation of the molecules in the reaction as A, B, C, and D. The exponents n and m are experimentally determined constants. Most commonly, both n and m will have values ≈ 1. If the amounts of the two reactants are present in the exactly-needed ratios (i.e., the reactant mixture is stoichiometric), then for the above reaction, c_A will always remain identical to c_B as both reactants are progressively consumed. In such a simple case, we can write:

$$-\frac{dc_A}{dt} = c_A^n A e^{-E/RT}$$

where now $n \approx 2$. Such a reaction is termed a 2nd order reaction. This is often a reasonable representation for a mixture of gases. In a different example (considered in detail in Chapter 9) of a pile of porous solids in air, it is often assumed that the oxygen in the air in infinite and inexhaustible. Then the concentration of "B" cannot go down, and it is found that the above equation also applies, but with $n = 1$. This type of reaction is termed a 1st order reaction.

The units of the pre-exponential factor A will depend on the order of the reaction and are: $(\text{kg/m}^3)^{1-n}\ \text{s}^{-1}$. Thus, for a first order reaction, the units are s^{-1}, while for a second order reaction they are $\text{m}^3\ \text{kg}^{-1}\ \text{s}^{-1}$.

It is often stated in elementary presentations that the rate of a chemical reaction is increased by 2× to 3× for each 10ºC rise in temperature. This, however, is only a very crude expression and, in addition, it implies that temperatures only close to room temperature are considered. Figure 3 shows that a 2× increase in reaction rate, going from 25ºC to 35ºC implies that E = 54 kJ mol^{-1} while a 3× increase implies E = 84 kJ mol^{-1}. But if E = 54 kJ mol^{-1} and the temperature is raised from 300ºC to 310ºC, the reaction increases by a factor of 1.2×, not 2.0×. To obtain a 2× increase starting from 300ºC requires that E be 199 kJ mol^{-1}.

A number of researchers[19-21] noted that the two main kinetic parameters—the activation energy E and the pre-exponential factor A—are not independent. Instead, a relation can be found of the form:

$$\ln(QA) = f(E)$$

where E = activation energy (kJ mol^{-1}), A = pre-exponential factor (s^{-1}), and Q = heat of reaction (kJ kg^{-1}). The following relation (Figure 2) has been found to hold for coal[21]:

$$\ln(QA) = 0.95 + 0.314\,E$$

Studies, however, have been performed only on a few families of rather similar substances, so it is not clear to what extent general relationships could be evolved.

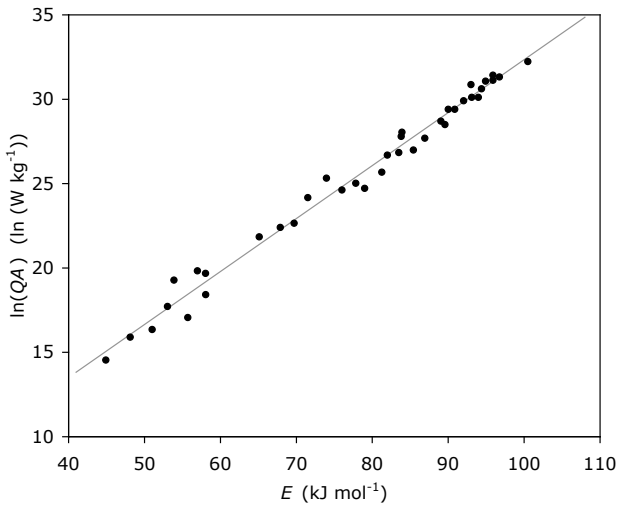

Figure 2 Relation between E and $\ln(QA)$ for coal

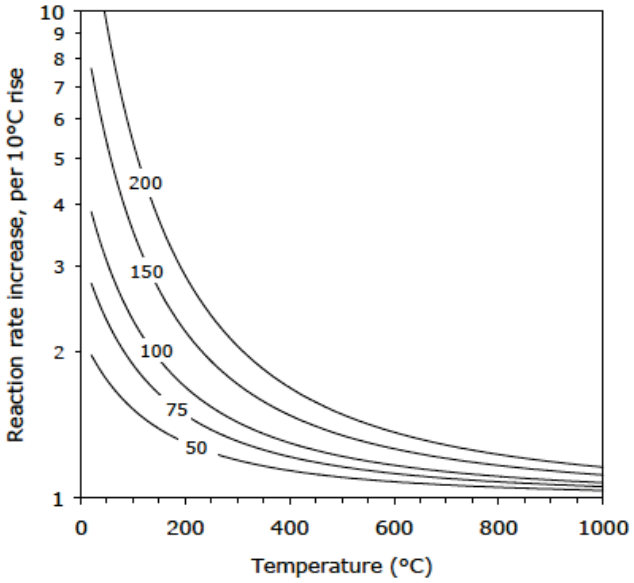

Figure 3 Effect of activation energy E on the reaction rate increase that occurs for each 10ºC rise in temperature (curves given for E = 50, 75, 100, 150, and 200 kJ mol^{-1})

BRANCHING CHAIN REACTIONS

There is no common organic substance which would actually burn by means of a single, simple reaction as depicted above. We can consider why this is so. The formal reaction of methane burning in oxygen is:

$$CH_4 + 2O_2 \rightarrow CO_2 + 2H_2O$$

This would require that three molecules meet and collide: one methane molecule and two O_2 molecules. Statistically, for three molecules to collide is a rare event. What is not rare is for two molecules to collide and thereby to form products which include one of more highly reactive, unstable species, called *free radicals*. We will consider the low temperature oxidation of methane to CO and water as an example. This reaction,

$$2CH_4 + 3O_2 \rightarrow 2CO + 4H_2O$$

clearly cannot occur directly, by waiting for the rare event of 5 molecules to collide! Instead, *initiation* can occur by the reaction[22]

$$CH_4 + O_2 \rightarrow \dot{C}H_3 + H\dot{O}_2$$

where the dots denote a reactive species. In this particular reaction, two free radicals were created in the initiation, but in general, initiation of a chain reaction will occur if at least one radical is created. The next steps can involve chain propagation. For methane, these can include:

$$\dot{C}H_3 + O_2 \rightarrow CH_2O + \dot{O}H$$

$$\dot{O}H + CH_4 \rightarrow H_2O + \dot{C}H_3$$

$$\dot{O}H + CH_2O \rightarrow H_2O + H\dot{C}O$$

The above three reactions are termed *chain propagation* because the same number of free radicals are produced in each as are consumed. With just these two types of reactions, no significant amount of substance could react. Acceleration is introduced by a *chain branching* reaction:

$$CH_2O + O_2 \rightarrow H\dot{O}_2 + H\dot{C}O$$

In a chain branching reaction, intermediates react and produce more free radicals than are consumed; in the above case, two radicals are produced and none are consumed. Further chain propagating steps include:

$$H\dot{C}O + O_2 \rightarrow CO + H\dot{O}_2$$

$$H\dot{O}_2 + CH_4 \rightarrow H_2O_2 + \dot{C}H_3$$

$$H\dot{O}_2 + CH_2O \rightarrow H_2O_2 + H\dot{C}O$$

The above set of all the equations can be seen to produce the desired products, CO and H_2O. It would also leave some unreacted free radicals, thus, it is found that the following *chain termination* reactions also need to occur:

$$\dot{O}H \rightarrow \text{wall}$$

$$\dot{C}H_3 \rightarrow \text{wall}$$

$$H\dot{O}_2 \rightarrow \text{wall}$$

The latter occur simply by collisions of active species with the walls or other molecules not showing reactivity.

The above scheme is one of the simplest realistic oxidation reactions. Most reaction schemes are more complex and can entail hundreds of separate reactions.

Chain reactions differ from simple reactions (sometimes termed *thermal reactions*) in one crucial way: if the reaction is kept isothermal, the reaction rate does not always monotonically decrease. In a simple reaction conducted at a clamped temperature, since the abundance of the reactants decreases with time, so must the reaction rate. In this manner, chain reactions resemble autocatalytic reactions, which we consider next.

AUTOCATALYTIC REACTIONS

Many explosions or fires occurring in chemical plants which produce liquid substances occur when the process undergoes an unwanted autocatalytic reaction. If a *constant-temperature* environment is considered, and the reaction is of the zeroth order, then reactants are never depleted and the reaction rate never changes with time. For 1st, 2nd, etc., order of reaction, the reaction rate continuously drops with time, since it is proportional to some (positive) power of the reactant concentration, and the concentration monotonically drops with time. There is another class of behaviors, however, that can occur—in these reactions, the reaction rate first increases, then reaches a maximum, and finally begins to decrease. These are called *autocatalytic reactions*. To understand this, first consider the normal effect of a catalyst. A *catalyst* is a substance which is not consumed during reaction, but which enhances the rate of a chemical reaction. Thus, an autocatalytic reaction can be viewed as if the reaction product which is being created is a catalyst for the reaction itself. If it were not (and remembering that the temperature is held constant in this simplest illustrative case), then there would be no mechanism for the reaction rate to increase over time.

The autocatalytic reaction of substance *A* going into *B* proceeds as:

$$A + B \xrightarrow{k} 2B$$

Note that it is necessary to postulate that there is at least a tiny amount of *B*, greater than 0, at the start, or the reaction would never start. It is convenient to define a 'conversion fraction' x as the fraction of substance *A* which has been converted into *B*. With this definition, the reaction rate can be expressed as:

$$\frac{dx}{dt} = k\left(x+\beta\right)\left(1-x\right)$$

with the original, tiny fraction of *A* already converted into *B* at the start being β, which is called the autocatalysis parameter. The above is a differential equation in x, and a solution for x, the fraction of substance reacted is:

$$x = \frac{\beta\left(e^{(1+\beta)kt} - 1\right)}{1 + \beta\, e^{(1+\beta)kt}}$$

and the rate at any given time is:

$$\frac{dx}{dt} = \frac{\beta\left(1+\beta\right)^2 k e^{(1+\beta)kt}}{\left(1 + \beta\, e^{(1+\beta)kt}\right)^2}$$

which for $\beta \ll 1$ can be approximated as:

$$\frac{dx}{dt} \approx \frac{\beta\, k e^{kt}}{\left(1 + e^{kt}\right)^2}$$

Since β is assumed to be tiny, at $t = 0^+$ the reaction rate is a small value, $\beta k/4$. For $t \rightarrow \infty$, not surprisingly $dx/dt \rightarrow 0$. But shortly after time zero, a sharp peak is reached. Differentiating the reaction rate equation with respect to x shows that when $\frac{d^2x}{dt^2} = 0$,

$$\beta\, e^{\lambda t}\left(\beta + 1\right) = \left(\beta + 1\right)$$

where we have set $\lambda = \left(1+\beta\right)k$. But this equation can only be true if

$$e^{\lambda t} = \frac{1}{\beta}$$

Thus, at the peak:

$$x = \frac{1-\beta}{2}$$

$$\frac{dx}{dt} = \frac{\left(1+\beta\right)^2 k}{4}$$

But if the starting amount of substance converted was small ($\beta \ll 1$), then the peak occurs at $x \approx$ ½ and peak reaction

rate is $\frac{dx}{dt} \approx \frac{k}{4}$. The time at which the reaction reaches its peak rate is: $t_{pk} \approx -\frac{\ln(\beta)}{k}$.

Many reactions involving autocatalysis are not 'pure' autocatalytic reactions, but also have a non-autocatalytic component. For these, it is not necessary to assume an arbitrary 'seed' fraction of the product, since products are already being produced by the non-autocatalytic portion of the reaction rate. A reaction of this kind can be represented as:

$$-\frac{d(1-x)}{dt} = k_1(1-x)^m + k_2(1-x)^n \cdot x^p$$

since the remaining mass fraction at any time is $(1–x)$. Here, there are two different rate constants k_1 and k_2, and in the general case, the reaction orders m, n, and p may assume various values. The rate constants are assumed to depend on temperature according to the relations $k_1 = A_1 e^{-E/RT}$ and $k_2 = A_2 e^{-E/RT}$.

Flame speed

If one increases the gas flow to a Bunsen burner, it is noticed that the flame, which is roughly conical-shaped, becomes taller. One might suppose that there is a constant speed at which a premixed gas/air volume element tends to burn at. Thus, increasing the mixture flow speed up the tube increases the flame size, so that the burning rate normal to the plane of the flame remains constant. There are a number of nuances about the Bunsen burner flame, and these have been studied. The earliest study, however, that unraveled the flame speed story was a series of experiments by Coward and Hartwell[23] in 1932. They considered the simpler case of a horizontal tube filled with a stagnant fuel/air mixture. The tube is closed at the far end and ignited at the open end. Experimentally, it was found that the flame progresses at a steady speed along the tube. For 10% methane/air mixtures in tubes of 50 – 100 mm diameter, Coward and Hartwell found that the axial motion (with respect to a stationary observer) was ≈ 1.0 m s^{-1}. The flame front, however, was not straight, instead, it was seen to bulge at the top and slump at the bottom. Consequently, the effective area of the flame front was much larger than the cross-section of the tube. By measuring the flame front area and the volume flow rate, however, they were able to determine that $S_L = \frac{\text{volume flow rate}}{\text{area of flame front}}$ was a constant, and that it was a constant irrespective of the propagation direction: horizontally, upward, or downward. Coward and Hartwell called S_L the *fundamental flame speed*. Today, it is commonly referred to as the *laminar flame speed* or *laminar burning velocity*, but numerous other terms are found in the literature. The laminar flame speed is the velocity component that is normal to the flame surface and is measured with respect to the unburned gas; thus, it is commonly also designated S_u, with *u* denoting unburned. Unlike other velocities in the system, e.g., the velocity with respect to the fixed observer, the fundamental flame speed is a characteristic of the chemical reaction and is independent of the geometrical arrangements. The velocity of the flame with respect to the burned gas, S_b, is related to S_L according to:

$$S_b = S_L \frac{\rho_u}{\rho_b}$$

Where ρ = density (kg m^{-3}), *u* denotes unburned, and b burned. Commonly, the density ratio can be ≈ 6; thus if S_L = 0.45 m s^{-1}, S_b = 2.7 m s^{-1}. Thus, the velocity with respect to the burned gases will be much greater than with respect to the unburned*. The velocity that a stationary observer will see depends on the geometrical arrangement. The simplest case is a flat-flame burner. Here, the gas velocity flowing up the tube is exactly = S_L.

The value of S_L depends on the stoichiometry, and is generally maximum close to, but not exactly at, $\varphi = 1$. The tabulated values of S_L normally refer to the composition at which it is the maximum; for methane/air mixtures it has been determined to be 0.45 m s^{-1}. For most hydrocarbon fuels, $S_L \approx 0.3$ to 0.8 m s^{-1}. Hydrogen shows a very large flame speed, with a maximum of about 3 m s^{-1}. Acetylene is also unusual, in having a peak $S_L \approx 1.5$ m s^{-1}. For tubes of widely differing sizes, Coward and Hartwell also found that the axial motion speed increased with increasing diameter, but that S_L remained a constant.

A theoretical explanation of the fundamental flame speed can be developed in the following way. In the flame zone, the temperature will rise from T_o to T_f, where the latter is the flame temperature. If, for the sake of simplicity, it is assumed that no heat is lost to the external environment, then all the combustion products flow away at T_f. Now, the heat release rate of the flame is:

$$QA\dot{m}'''\delta_f$$

where Q = heat of reaction (kJ kg^{-1}), A = flame area (m^2), $\dot{m}''$ = mass consumption rate (kg s^{-1} m^{-2}), and δ_f = flame zone thickness (m). But the HRR is used to raise the gases from T_o to T_f, thus:

$$QA\dot{m}'''\delta_f = \rho_o S_L AC(T_f - T_o)$$

where ρ_o (kg m^{-3}) = density of unburned gas mixture. Solving for the flame zone thickness,

$$\delta_f = \frac{\rho_o S_L C(T_f - T_o)}{Q\dot{m}'''}$$

The heat conducted across the flame zone is

$$\frac{\lambda}{\delta_f} A(T_f - T_o)$$

* The nomenclature in the literature is highly inconsistent and some authors use *laminar flame speed* to refer to S_b and *burning velocity* to refer to S_L; the magnitude of the numbers is usually sufficient to decide which is meant.

where λ (kW m^{-1} K^{-1}) = thermal conductivity of the gas. Now the heat being released is removed from the reaction zone by conduction, thus the equality holds:

$$Q A \dot{m}''' \delta_f = \frac{\lambda}{\delta_f} A \left(T_f - T_o \right)$$

From the above equation, a second expression for δ_f can be obtained:

$$\delta_f = \sqrt{\frac{\lambda \left(T_f - T_o \right)}{Q \dot{m}'''}}$$

The unknown flame thickness δ_f can then be eliminated by equating the two expressions for δ_f to each other:

$$\frac{\rho_o S_L C \left(T_f - T_o \right)}{Q \dot{m}'''} = \sqrt{\frac{\lambda \left(T_f - T_o \right)}{Q \dot{m}'''}}$$

Giving

$$S_L = \frac{Q \dot{m}'''}{\rho_o C \left(T_f - T_o \right)} \sqrt{\frac{\lambda \left(T_f - T_o \right)}{Q \dot{m}'''}}$$

Equating the HRR to the heat required to heat the product gases,

$$Q \rho_o = \rho_o C \left(T_f - T_o \right)$$

$$S_L = \sqrt{\frac{\lambda \ \dot{m}'''^2}{\rho_o^2 C \dot{m}'''}}$$

But the definition of thermal diffusivity, α (m^2 s^{-1}) is:

$$\alpha = \frac{\lambda}{\rho C}$$

Thus

$$S_L = \sqrt{\frac{\alpha \ \dot{m}'''}{\rho_o}}$$

The above computation of the flame speed was developed in 1883 by Mallard and Le Chatelier, and it is a *thermal theory*, since diffusion of gas species is not explicitly treated. Theories which take much more of the actual chemistry into account do exist, and can be found in Glassman's book[22]. An extensive review of experimental studies has been compiled by Andrews and Bradley[24].

Real combustion systems are commonly turbulent rather than laminar. Since turbulence increases the transport of heat and species, it is not surprising that turbulent flame speeds are higher. Turbulent flame speeds, S_T, can sometimes be approximated as:

$$S_T = S_L \sqrt{\mathrm{Re}}$$

where the Reynolds number Re = uD/v is a dimensionless velocity, with u = flow velocity (m s^{-1}), D = characteristic dimension of the system (m), and v = kinematic viscosity (m^2 s^{-1}). Thus, for turbulent systems, S_T is *not* a constant of the fuel/oxidizer mixture, but is also proportional to local turbulent flow velocity.

As considered above, if the fuel/air mixture is in a pipe with two open ends, or if the pipe has one closed end and the mixture is ignited at the open end, then reasonably steady flame propagation will be seen, well below the speed of sound. A steady state is possible since thermal expansion of the combustion products pushes the burnt mixture out the open end. However, if the mixture is ignited at the *closed end*, then a very different situation takes place. The heated combustion cannot escape, except by compressing the unburnt gases. Thus, the combustion wave will accelerate, and the process may lead to a detonation, as shown[25] in Figure 4. The resulting shock wave has been studied extensively in classical combustion literature.

Types of explosions

An ignition may lead to a form of combustion that is considered an explosion. 'Explosions' encompass a very wide range of meanings; some, such as steam explosions or pressure-vessel explosions are not related to combustion phenomena, and we shall not consider them here. In common English usage, 'explosion' connotes a loud sound, but some combustion explosions do not produce a sound. Concerning explosions related to combustion phenomena, it is considered that there are three types[26] (Table 3).

Thermal explosions occur due to bulk self-heating of a substance. The autoignition of a flammable gas mixture is an example, as is the spontaneous combustion of a haystack. Note that there is no sound associated with the latter exam-

Table 3 Types of chemical explosions

Explosion type	Characteristics
Thermal explosion	No defined reaction zone. Self-heating throughout the substance.
Deflagration	Traveling reaction wave. Velocities of 10^{-5} – 300 m s^{-1} (subsonic speeds). Energy transfer ahead of the reaction zone by conduction, convection and radiation Reaction products are usually gases but may be liquids or solids.
Detonation	Traveling reaction wave. Velocities of 1000 – 9000 m s^{-1} (supersonic speeds). Energy transfer by shock compression. Pressure rise of 20 – 80 atm in gases, 25,000 – 350,000 atm in solids. Reaction products are usually gases.

ple. Thus, spontaneous combustion of a haystack would only be considered an explosion by chemists, but not in everyday English usage. To produce a loud sound requires that an abrupt pressure rise propagate through the air, but combustion reactions which are unconfined may not necessarily produce a significant pressure rise.

A deflagration is a combustion wave that is sustained by heat transfer from the combustion zone to unreacted material. A deflagration is not limited to gas phase. Liquid and solid substances can also undergo deflagration. Deflagrations in liquids have been studied by Grewer[27] and Verhoeff[28]. A detonation is a reaction propagated at a velocity greater than the local speed of sound in the unreacted material.

The question may well be asked, What types of combustion are *not* explosions? Apart from the issue of thermal explosions, combustion is not an explosion if the process is not accelerative[29]. Thus, for example, a flame on a Bunsen burner or on a candle is not an explosion because the rate of reaction is fixed by the mechanism that regulates fuel supply and combustion proceeds at a constant (more or less) rate.

If a fuel-oxidizer mixture is contained within a vessel of fixed volume that does not break during the explosion, then the maximum pressure can be computed that can occur within the vessel. In analogy to the adiabatic flame temperature, the maximum vessel pressure will occur if no heat is lost to the outside in the process. If a detonation is not involved, then the pressure can be obtained from the Ideal Gas Law. If '1' denotes the ambient condition and '2' denotes the combusted mixture, then

$$\frac{P_1 V_1}{n_1 T_1} = \frac{P_2 V_2}{n_2 T_2}$$

At ambient conditions, P_1 = 1 atm and T_1 = 298 K. If the vessel does not break, then $V_2 \circlearrowleft V_1$. The n_2/n_1 denotes the moles of product, divided by the moles of reactant*. In the simplest case, a fuel such as CH_4 produces the same amount of product moles as there were reactant moles. Thus, we will take $n_2/n_1 = 1$ here, although the exact value can easily be computed for any substance with a known chemical formula. The peak adiabatic flame temperature occurs for mixtures which are very close to being stoichiometric, and for many organic fuels, $T_{ad} \approx 2200 - 2300$ K. This is our T_2. Thus,

$$P_2 = \frac{1.0 \times 2250}{298} = 7.55 \text{ atm or, say, 8 atm}$$

For substances with $n_2/n_1 > 1$, this value will be slightly higher. In the case of an air atmosphere, however, the preponderance of nitrogen makes it hard for the mole ratio to deviate greatly from unity. If the mixture is within its flammable limits, but far from stoichiometric, then a lower T_{ad} will be found and, consequently, a lower P_2 will be found.

If the initial temperature is colder than 298 K, then higher explosion pressures will be achieved since the adiabatic flame temperature does not change anywhere nearly as much as does the ambient temperature. If the change in T_{ad} is ignored, from an initial temperature of –40ºC, a peak pressure would be expected of:

$$P_2 = \frac{1.0 \times 2250}{233} = 9.65 \text{ atm}$$

or 28% higher than from 298 K; actual experimental results[30] show about a 30% increase.

PRESSURE PILING

There are deflagrations where substantially higher pressures are recorded than 7 or 8 atm, and values of 20 – 30 atm have been experimentally measured. The effect is termed *pressure piling* and arises due to geometrical complexities. In 1906, Beyling[31] first observed that if two interconnected chambers are filled with a flammable gas mixture and ignited in one chamber, the explosion pressure in the second chamber is often much higher than in the chamber where the explosion originated (Figure 5). The Bureau of Mines[32] later conducted more systematic tests with natural gas/air mixtures in a small-scale steel box and found a maximum pressure of 5.4 atm when the box had no subdivisions. Upon dividing the box into two chambers, separated by a plate having a 100 × 100 mm opening, the maximum recorded pressure was 15.6 atm, under the conditions that the larger chamber had a volume 7× times that of the smaller one. They also found that the location of the ignition source within the initially-ignited chamber affected the results.

Conn[33] reviewed various studies of pressure piling and suggests the following explanation. Within a single chamber,

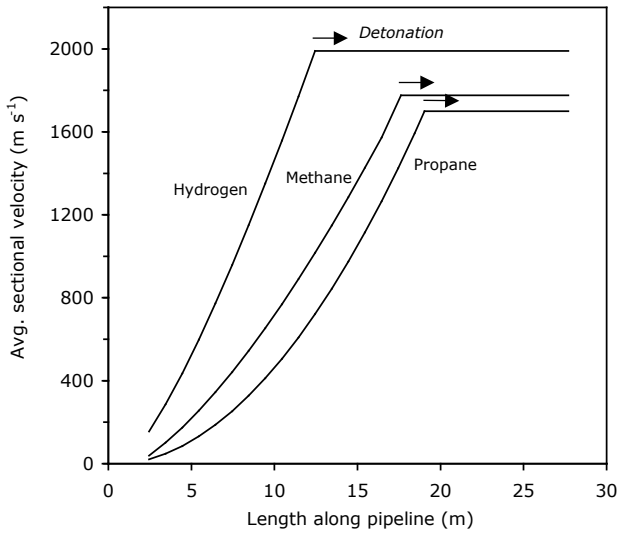

Figure 4 Acceleration of flame along a 200 mm diameter pipeline; ignition by flame jet at closed end.

* Only moles of gaseous substances are considered.

the 7 or 8 atm explosion pressure that is recorded should be viewed as a 7- or 8-fold *rise* in original pressure. Thus, if the starting pressure becomes much higher than 1 atm, the ultimate explosion pressure will also be increased. Pressure piling, then occurs because: (1) the pressure wave in the primary chamber leads to an elevated pressure in the secondary chamber; and (2) the starting temperature in the secondary chamber is elevated since compression happens rapidly and nearly adiabatically. Conn also developed a simple hydrodynamic model of the pressure piling process which predicts that pressures of over 30 atm are possible as the volume of the secondary chamber becomes small compared to the primary chamber. Nonetheless, he points out that even worst-case accident scenario planning will hardly ever entail the specific combination of conditions needed to

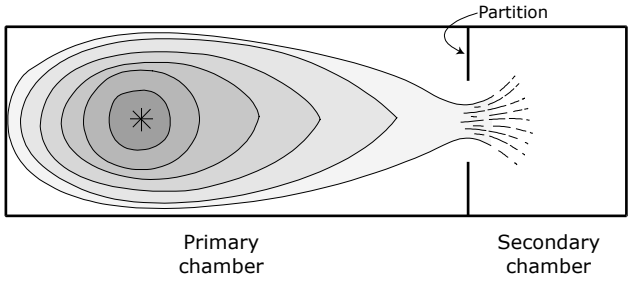

Figure 5 A simple geometry leading to pressure piling

attain such high pressures. Extreme cases of pressure piling may lead to detonation (see below), and this is a problem of some concern in certain industrial facilities.

DEFLAGRATION TO DETONATION TRANSITION

Combustion can start as a deflagration then transition to a detonation. This process of acceleration can occur since the propagation velocity of a shock wave increases with density and a compression wave is being generated in a deflagration ahead of the flame. If such a transition occurs, it is sudden. Transition is promoted by any phenomenon that increases flame speed, the most common being the presence of obstructions. Obstructions create turbulence and a local acceleration of the gas, creating regions of increased velocity.

In pipes, transition to detonation is possible if both the diameter and the pipe length are large enough. For methane and propane, a minimum diameter of 25 – 100 mm is needed, although other gases may be detonated in pipes as small as 12 mm. For detonations, the peak pressure is **not** limited to ca. 8 atm, and may be about 20 atm for gaseous fuels. In some circumstances, however, gas mixtures in larger-diameter pipes can lead to a 'double-discontinuity shock piling,' with pressures in the range of 400 atm being attained[34]. Deflagration-to-detonation transition is considered in more detail in Chapter 4.

Catalytic combustion

Normal combustion occurring in the gas phase is the dominant form of combustion which is of interest for both wanted and unwanted fires. There is a very different category of combustion possible: combustion by means of chemical reactions on an 'active' surface. This is called catalytic combustion. The reactants are a gaseous fuel and a gaseous oxygen, but a third participant—the surface—is needed. The catalyst is normally a noble metal, e.g., platinum. By definition of the term *catalyst*, it is meant that the substance is not consumed. Thus, for example, powdered iron can be ignited in air and it will burn up once ignited. This is not catalytic combustion. But in certain situations iron can act as a catalyst so that it promotes the ignition or combustion of some other substance, without being consumed itself. Such behavior is illustrated at a number of places throughout this Handbook. In any catalytic reaction, one or more reactants are temporarily adsorbed onto the catalyst surface, while reaction products are eventually desorbed from the surface, returning the catalyst to its original chemical form. Apart from the fact that a flame does not accompany catalytic combustion*, two other special traits are found: the reaction temperatures are generally lower than in flaming combustion; and catalytic combustion is not limited to taking place within the flammable limits that are defined for flaming combustion.

In the process of inventing his miner's safety lamp in 1816, Sir Humphry Davy discovered that methane can be burned in a flameless manner on platinum. He did not make use of this discovery, but the German chemist Johann Döbereiner, who had been studying reactions with platinum, learned about it and discovered that when using finely-divided platinum ('platinum black'), ignition is possible, not just sustained combustion. He realized that its ability to produce fire without use of flint or tinder could lead to practical devices. The simultaneous discovery of catalysis and catalytic ignition became a sensation in scientific circles and resulted in more than a dozen publications within 3 months of the invention. This became the basis of Döbereiner's lamp (*Döbereinersches Feuerzeug*, Color plate 3), and during the 19th century it became the first widely used device based on catalytic combustion[35]. The device is ingenious. There is an open-bottom glass vessel held inside a larger glass container. The lamp is part-filled with dilute sulfuric acid. A piece of zinc, suspended on a wire, reacts with the sulfuric acid to produce hydrogen gas. The gas leaves the inner bottle and goes through a stopcock and then through a mass of sponge platinum, where it ignites and burns. When the stopcock is turned off, the H_2 no longer leaves the inner bottle, the pressure consequently rises inside it, and the acid level drops (while rising in the outer container). The reaction then stops once the liquid level drops below the zinc[36].

* In some systems, it is possible to have catalytic combustion on the surface, while flaming combustion also takes place in the gas phase.

Today, catalytic combustion is primarily being exploited in applications where it is desired to reduce pollution-causing nitrogen oxides. The latter are formed only at high temperatures, thus, combustion systems which can run efficiently at lowered temperatures can be made cleaner. An example is the catalytic converter, fitted to modern cars to re-burn some pollutants which are generated in main engine combustion.

Catalytic combustion is also found in various space heater designs. Available since the 1960s, such heaters normally use a porous panel, the front surface of which is impregnated with a platinum catalyst[37]. Fuel gas is supplied to the back of the panel, as is an air stream, for which a fan is used. The catalyst cannot burn the fuel until it has come up to its operating temperature. To preheat the panel, an electrical heating element is included. The operation is safety-interlocked so that fuel gas flow does not start until the needed operating temperature has been reached. The preheating takes 10 – 15 minutes; normal operation involves a 400 – 500ºC temperature of the catalyst.

Some other combustion systems use a combination of catalytic action (heterogeneous combustion) and homogeneous combustion (normal flaming combustion). The analysis of such systems is difficult and can only be done with complex mathematical modeling. For further details, the paper by Park et al.[38] presents a current, state-of-the-art perspective.

Tests for fundamental combustion properties

ASTM provides several test methods which describe the calibration and operation of oxygen bomb calorimeters and the reporting of heat of combustion data. ASTM D 240[39] and the higher precision ASTM D 4809[40] are used for liquids while ASTM D 2015[41] applies to solids. General safety precautions for running oxygen bomb tests are given in ASTM E 144[42].

Highlights and summary of practical guidance

The ignitability of flammable or combustible gases depends on how air (or another oxidizer) is mixed with the fuel gas. If the fuel gas and air are mixed together first, then ignited, *premixed* combustion occurs. If the premixed mixture is supplied in modest amounts at a controlled rate, then the situation basically describes a burner. But if a large volume is filled up with a fuel gas/air mixture and then ignited, a *gas explosion* results. The ignition and combustion of premixed mixtures have been studied extensively. Another possibility is that the fuel gas and the air are not well mixed before being ignited. This situation has been studied less, and is more complicated since there can only be one fully-mixed condition, but an infinity of possibilities of poor or limited mixing. The gases would not ignite at all, of course, if no mixing occurred, but a limited amount of mixing will always occur due to molecular diffusion. Flames that are observed when a fuel gas enters the atmosphere (for example, by evaporating from an open tank of solvent) not having been otherwise mixed with the air are generally known as *diffusion* flames, since mixing can take place through diffusion (molecular-scale motions of gas). The distinction between diffusion and premixed combustion is not absolute, thus, for example, if natural gas escapes from a broken pipe and burns as a jet in the air, this is considered a diffusion flame, even though the strong outflow velocity creates some local mixing and that mixing is much more rapid than would be possible through molecular diffusion alone.

Gas mixtures can be ignited in two basic ways: (1) *autoignition*: by raising the temperature of the whole volume of gas; or (2) *piloted ignition*: by introducing a local source of heat or energy. The minimum temperature which a gas mixture must reach by heating the whole volume is called the autoignition temperature (AIT), sometimes also called spontaneous ignition temperature (SIT). Autoignition suggests that the temperature of the environment is uniform, in both space and time. This is an idealization and practical tests fall short of this ideal. The AIT of a gas mixture is *not* the lowest temperature *of the flame*; rather, it is the lowest temperature to which the mixture must be heated before it 'takes off.' The time between when the mixture was first subject to AIT conditions and the time that a visible flame is seen is termed the *induction period*, or *ignition time*. The word 'piloted' is not limited to a gas pilot, it also includes other localized energy sources, such as a spark, a hot wire, etc. Sometimes the terms 'forced' or 'induced' ignition is used in place of 'piloted ignition' to indicate the broad nature possible for the localized source of energy.

AIT values are extensively tabulated in the literature, but only rarely does the AIT have relevance to actual accidental ignitions of gases. By far the most dominant way in which gases are ignited accidentally is by sparks, flames, or hot surfaces. Hot surfaces have to reach a temperature substantially higher than the AIT of a gas or vapor for ignition to occur. For example, the AIT of methane is 640ºC, but a hot metal bar may have to be raised to over 1000ºC before a methane/air mixture will be ignited. The reason is because the heat losses are different in the two cases. For the AIT determination, a flask is used which is heated throughout, while in hot-surface tests only a small fraction of the surfaces contacted by the gas is at the high temperature, the rest are at the cooler ambient temperature. Because of simplification and conservativeness, regulatory bodies often do not differentiate between AIT and hot-surface ignition and prescribe limits based on AIT when guarding against hot-surface ignition hazards. A rule of thumb is sometimes used that hot surfaces have to be 200ºC higher than the AIT for a hot-surface ignition to occur, but rules of thumb should not be relied upon in critical situations. Even relative rankings of AIT values do not correspond to ease of ignition by hot surfaces. For example, hydrogen (AIT = 520ºC) is easier to ignite by a hot body than is hexane (AIT = 223ºC).

In Chapter 9 it is explained in detail that the concept of a fixed-value ignition temperature is meaningless for the self-heating of solids and that their tendency to thermal runaway must be presented as a temperature/size graph or equation, instead. But the chemical process whereby a gas self-heats to ignition is essentially the same. Thus, the question arises, Why is a fixed-value ignition temperature meaningful for gases? This simple question does not have a simple answer, but the following factors should be considered. (a) As stated above, fuel gas/air mixtures are rarely ignited by bodily

raising their temperature to a high value, thus the situation is only sporadically encountered in practice. (b) As explained in detail in this Chapter, there *does* exist a size dependence for the AIT of gases. (c) Self-heating solids are commonly stored at or near room temperature, where accurate values must be known, i.e., it is not useful to know that the critical temperature is 40ºC±30ºC. But for a gas mixture, a knowledge that a 400ºC AIT has an uncertainty of ±30ºC may be perfectly acceptable.

It is found experimentally that when a fuel gas is mixed with air, flame propagation cannot occur if the fuel gas concentration is too small or too great. The limiting concentration values are known as the *lower flammability limit* (LFL) and the *upper flammability limit* (UFL). They are normally expressed as percent of fuel, by volume, in air, but occasionally are provided in other units, for instance, grams of fuel per m^3 of mixture. In older literature, they are often identified as the LEL (lower explosion limit) and UEL (upper explosion limit). In a rough way, flammability limits can be understood to arise because flames need a minimum temperature to exist. Too much air or too much fuel dilutes the mixture enough that a sufficient temperature rise cannot be achieved. This explanation is extremely simplified and actual prediction of flammability limits from basic science concepts is very difficult. A few gases (e.g., acetylene) have reported values of UFL = 100%. In those cases, the gas does not require oxygen to react, since the fuel molecule itself can explosively decompose. Normal combustion where the fuel combines with oxygen is also possible with acetylene, and this is the reaction that occurs in useful activities such as welding.

Flames cannot propagate through small openings. This is the concept of *quenching distance* and it forms the basis for most designs of flame arresters. These distances are quite small, on the order of 1 – 3 mm for most gases under optimal conditions. In accidental fires, however, gas/air mixtures will rarely be at their optimal ratio, thus, significantly larger distances may suffice to suppress propagation of many mixtures.

Very little energy input is required to ignite any fuel gas/air mixture within its flammability limits, although the energy must be in the 'right' form. A spark having an energy of 1 millijoule will easily ignite many gas mixtures. Yet, the mixture may not ignite if a 100 W bulb is placed in it and electric power is supplied to it for a whole day. In the latter case, the power delivered into the bulb is 100 W = 100 J s^{-1}, while the time is 8.64×10^4 s; thus the energy is 8.64×10^6 J. A wide variety of studies show that, for gases, ignition occurs most easily when energy is delivered fast (microseconds) and into a small volume. This same reasoning must not be applied to solids, where a fast, high intensity application of energy to a small area may vaporize the material, but not leave it burning.

What fraction of a spark discharge goes into heating the gas, versus that which is wasted in the circuit? This question is of significant importance in being able to accurately quantify ignitability, yet the current status of research is unsettled. As indicated both in this Chapter for gases and in Chapter 5 for dust clouds, estimates range from 'nearly all' to '1 to 10%'. Part of the variability comes from well-known circuit parameter effects, but further research is still needed in this area.

Under worst-case conditions, sparks created with electric circuits of very low voltage can ignite flammable gas atmospheres. Limited data show that 4 – 5 V can be sufficient if a high current can be delivered in a resistive circuit during the opening of a contact or the breaking or melting of a wire; voltages as low as 0.5 V, or lower, can suffice in inductive circuits.

Explosions of fuel gas/air mixtures in enclosures tend to be deflagrations if the enclosure has dimensions not too different in the three directions and is not filled with obstructions. Otherwise, for long, narrow enclosures or ones which effectively have baffles within the space, a detonation may be possible.

The Model Regulations promulgated by the United Nations and adopted by various countries (the Dept. of Transportation in the US) define a *flammable gas* as a substance which is in the gas state at a temperature of 20ºC and 101.3 kPa pressure; and has an LFL of 13% or less, or has a flammable range of at least 12 percentage points, irrespective of the value of the LFL. As discussed in Chapter 14, ammonia is a gas which has been involved in numerous explosions and fires but, according to this legal definition, it is not flammable. Thus, one needs to be aware that legal definitions may not be of much use in understanding actual fire hazards.

Exothermic reactions in gases

Exothermic reactions in gases are of three types:

(1) slow oxidation;
(2) cool flames
(3) combustion, or rapid oxidation, or normal flames.

In this section some general features of these reactions are considered. Details of ignitions involving normal flames are then pursued throughout the rest of this Chapter.

SLOW OXIDATION

If a fuel is in contact with an oxidant, then oxidation is expected to occur, even if it is so slow as to give no visible signs. At room temperature, this is the kind of reaction that may be expected between a fuel gas and the oxygen in the air. Even without combustion ('rapid oxidation') occurring, over time a measurable amount of fuel may be consumed during slow oxidation. Figure 1 shows the results of placing a methane/air mixture into an 0.44 L vessel held at 8ºC below the ignition temperature[1]. By the end of the 20 minute

experiment, a sizable fraction of the methane was consumed in slow oxidation. Such results are to be expected only at high temperatures; at room temperature the mixture could have been stored for a very long time without there being a detectable drop in methane concentration.

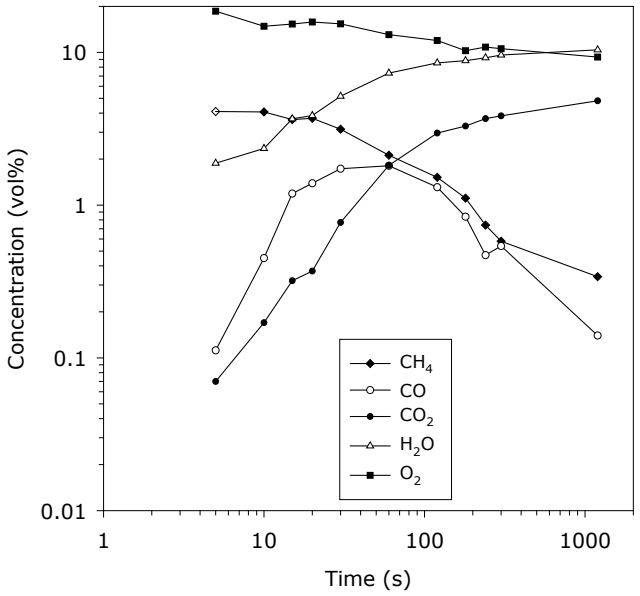

Figure 1 Reactions taking place in a vessel containing a methane/air mixture at 624ºC, which was 8ºC below the ignition temperature of the mixture under the given experimental conditions.

COOL FLAMES

At higher temperatures, some fuel gases start to exhibit cool flames. These flames are pale blue and a darkened room is commonly required in order to observe them. This type of oxidation is possible if the fuel molecule has a primary carbon bond ($–CH_3$) or a secondary carbon bond ($–CH_2–$) available for attack by oxygen and can form hydroperoxides and aldehydes (other than formaldehyde) as reaction products. Such products are partially-oxidized, which accounts for the low heat release in cool flames. The pale blue-white light associated with cool flames is emitted by formaldehyde (CH_2O) in an excited state. Temperature increases of only 10 – 150ºC accompany a cool flame. Cool flames may occur with many common hydrocarbon gases, but most commonly are found at pressures below 1 atm and in highly fuel-rich regimes. Cool flames have been studied extensively in the combustion literature, but since this research has largely been at pressures much below 1 atm, the findings have tended to have only limited application to safety problems. Cool flames have been observed at ambient pressure conditions for acetaldehyde, diethyl ether[2], divinyl ether, glycols[3], MIL-H-83282 hydraulic fluid (but not MIL-H-5606), MIL-L-7808 lubricating oil[4], and a variety of other substances. A safety concern exists, because if enclosed, or if present in large quantities, cool flames can transition to normal flames. Cool flames are also observed for CO burning in air; the pale blue glow is attributed to a combined effect of numerous radicals in the flame[5].

The minimum temperature at which cool flames may be initiated is called the *sub-ignition temperature*. Commonly, the sub-ignition temperature may be 50 – 100ºC lower than the AIT, but bis(2-methoxyethyl)phthalate has an AIT of 393ºC, while the sub-ignition temperature is 204ºC[3]. Cool flames cannot be predicted from thermal ignition theory; if cool flames are found, this implies that branching-chain theory must be used to explain autoignition. Cool flames consume only a small amount of reactants, otherwise the multiple flames seen in many cases would be impossible. Unlike normal-flame ignitions of gases, which are normally very quick, the induction period for cool flames may be on the order of 0.5 h. Cool flames are also associated with *negative temperature coefficient* regions. Most reactions show an increasing reaction rate with a rise in temperature, thus it is unusual when the contrary occurs. It arises because more than a single reaction is involved and the negative temperature coefficient is the net outcome of several competing reactions[6]. Fish[7] and Lignola and Reverchon[8] reviewed chemical kinetics studies on cool flames. It is normally understood that (at 1 atm) gases which show AIT values less than about 300ºC ignite initially with a cool flame, then subsequently transition to a normal flame. Conversely, gases which show AIT values greater than about 400ºC ignite only with a normal-flame. However, there are other views on the subject[9]. Unlike normal flames, the conditions for the ignition of cool flames are highly dependent on the condition of the surface of the test vessel. Some limited data discussed later in this Chapter imply that cool flames are likely to be seen only in vessels having a surface area greater than 80 cm^2; for a sphere this would be equivalent to 67 mL.

Regimes in which cool flames occur are prone to show oscillatory combustion phenomena. Yang and Gray[10] first proposed a theory which can explain the origin and nature of these oscillations. Griffiths and Scott[11] reviewed the oscillatory flames theory from the point of view of the continuous-flow, stirred-tank reactor (CSTR).

MULTIPLE IGNITION TEMPERATURES

In some cases, a substance can have more than one ignition temperature. For low pressures (≈ 0.1 atm), a number of organic compounds show multiple ignition temperatures, that is, a situation where there is a band of temperatures at which ignition does not occur, but ignition occurring at values both higher and lower. On occasion, this behavior is also found at 1 atm. For example, Dykstra and Edgar[12], studying gasoline vapors at 1 atm, found that using a mixture of 4.6% gasoline vapors, 37.7% O_2 and 57.7 N_2, no ignition would occur below 280ºC. Mixtures between 280ºC and 314ºC were ignitable. Mixtures between 314ºC and 444ºC, however, were non-ignitable, but mixtures of all

higher temperatures were. The phenomenon was not seen in 21% oxygen atmospheres, but only in enriched ones. Furthermore, extrapolation of data suggested that the multiple ignition phenomenon also disappears at very high O_2 concentrations, but this was not tested experimentally.

The same phenomenon was found by Frank and Blackham[13] in studying the autoignition of *n*-decane and *n*-dodecane in a normal 21% oxygen atmosphere (Figure 2). Decane showed ignition at 235 – 330ºC and again at over 365ºC, but not for intermediate values. Similarly, dodecane showed ignition at 232 – 325ºC and at over 350ºC. The authors consider this to occur because the lower regime exhibits a cool-flame ignition, while the upper regime is a normal hot flame ignition. For the intermediate region, neither mechanism is sufficient. Other hydrocarbons, e.g., *n*-hexadecane, were ignitable over a continuous range, but for a certain intermediate-temperature range ignitions were possible only for a narrow range of fuel/air ratios. Sortman et al.[14] documented dual ignition temperatures at room pressure and oxygen concentration for cetane, *n*-decane, heptane, decahydronaphthalene, and propylcyclopentane. It must be noted that both Sortman and Frank and Blackham conducted their experiments by dropping liquid droplets into heated crucibles. These types of test methods create a complex combustion environment where some phenomena might be attributable solely to spatial or temporal non-uniformities, as discussed in detail in Chapter 6. Dykstra and Edgar, however, used a concentric-tube method that is not confounded by problems of non-uniform heating and evaporation. An additional example is shown in Figure 20, where multiple ignition regimes can be seen on a P-T diagram, as it would be intersected by a line at 1.0 atm. As explained above, intermediate regimes of non-ignition are due to negative-temperature-coefficient behavior. This phenomenon, however, requires detailed chemical reaction modeling and cannot be represented by a simplified theory.

Autoignition of premixed gases

THEORY

Suppose that a fuel gas and an oxidizer gas (say, air) are quickly introduced and perfectly mixed in a vessel. If the vessel is at room temperature and pressure, in most cases no fire will take place. Only with the most exceptionally reactive gases would a fire result. Suppose now, however, that this vessel is heated. Even with 'ordinary' gases, at a certain temperature *autoignition* may take place. In this Section, we attempt to quantify the conditions under which such ignitions can be expected.

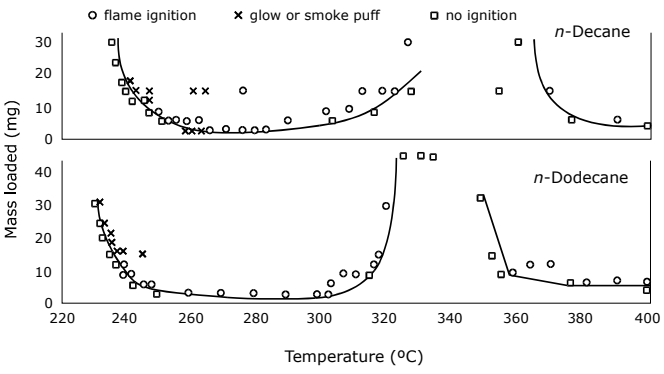

Figure 2 Regimes of ignition and non-ignition for two gases

The simplest concept of autoignition envisions that fuel and oxidizer, which are at a low temperature and non-reacting initially, at some point become immediately raised to a high temperature; most theoretical treatments are based on this assumption. In practice, however, it is difficult to achieve a starting point like that. An experimental rig may comprise a heated, evacuated flask into which gas is suddenly introduced. Figure 3 shows two example time-temperature curves for a centrally-placed thermocouple in the flask[15]. Observe that the y-axis shows not the actual temperature, but the temperature difference between the gas and the original flask wall temperature. The negative excursion is due to cold gas flowing into the hot flask. In analyzing results of this kind according to a theoretical model, the time origin is normally taken from the zero-crossing, not from the actual time when the gas was first admitted to the flask. This appears to be a straightforward treatment, but note that only the readings of the central thermocouple are shown. Thermocouples placed closer to the walls would show a zero crossing at a slightly different time; thus, determining the proper starting time does involve some uncertainty. It can also be seen in Figure 3 that even the non-ignition (slow oxidation) case shows a perceptible temperature rise, but the maximum temperature rise associated with a non-ignition case is modest. Finally, note that both curves eventually go back to zero because reactants become depleted.

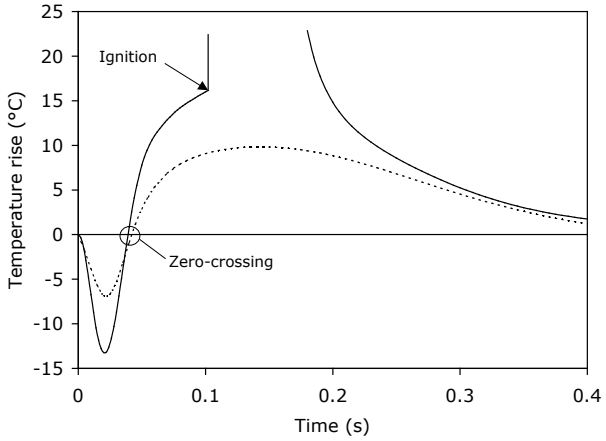

Figure 3 Temperature at the center of an evacuated, heated vessel into which a gas mixture was rapidly introduced. Solid line shows a mixture which ignited, dotted line shows a mixture which did not.
(Copyright The Combustion Institute, used by permission)

If a gas mixture capable of undergoing fast, exothermic reactions is introduced into a vessel, given a high enough starting temperature and a long enough waiting time (generally called *induction period* by chemists and *ignition time* by engineers), the mixture may combust spontaneously, without use of any spark or other ignition device. The Russian scientists Nikolai Semenov and David Frank-Kamenetskii are considered the originators of a theory which can quantify such ignitions. Semenov worked in this area from the late 1920s, and Frank-Kamenetskii since the late 1930s. English-language textbooks by both have been published[16,17,18], but these are quite advanced, and the reader wanting to go beyond our presentation here would best next turn to a modern-day combustion textbook[19,20].

In the simplest analysis, we do not consider the actual details of the chain reactions that carry combustion forth. Instead, the fuel/oxidizer mixture can be considered as having a single exothermic overall reaction, described by Arrhenius kinetics. If such a system were perfectly insulated ('adiabatic'), then it would invariably self heat, go into thermal run-away, and ignite. Thus, in even the most idealized conception, it is necessary to describe in some way the real-world heat losses which the vessel sustains at its boundaries.

If we have, for example, a spherical vessel, then there will be a temperature distribution inside, with the gases being hottest at the center and coolest at the edges. This is because the edges are cooled while the center is far away from this cooled boundary. This difference may be ignored, which was Semenov's initial approach, or it may be expressed according to laws of heat conduction, as done by Frank-Kamenetskii. The thermal conditions at the edges may also be represented in several ways. The simplest is an assumption that the external atmosphere is at one temperature T_o, while the walls of the vessel are at a higher temperature, T_w, and that heat is being exchanged according to simple convective cooling:

$$\dot{q}_c'' = h\,(T_w - T_o)$$

where h is a heat transfer coefficient (kW m^{-2} K^{-1}).

Before undertaking quantitative solutions, it is highly instructive to consider what happens qualitatively. This is best done on a diagram where the heat losses and the heat gains are considered separately, and both are plotted as a function of temperature (Figure 4). Even though time is clearly of great import to the problem, it turns out that one can learn much of the rudiments by considering only steady-state solutions. The solutions, even with numerous simplifications, are mathematically difficult, and our development will show that much can be learnt from considering the steady-state problem.

Figure 4 shows that three different relations are possible between heat losses and heat generation in a volume of gas. The lowest heat loss curve never intersects the heat generation curve. Thus, if the wall temperature and the convective heat loss coefficient are such that the lowest curve holds, then the system will immediately self-ignite. Now consider the situation with the uppermost heat loss curve. Here, there are two points, denoted X and Z, where a solution is possible. Suppose the system is initially at some temperature below that corresponding to point Z. Then, the system will heat or cool until it reaches point X. Point X is a stable solution, since if any random temperature variation moves temperatures to the right, heat losses will rise faster than heat gains, and the system will return to point X, and conversely for cooling excursions. Point Z is also a solution which could be obtained, but any slight increase of temperature will result in heat gains exceeding heat losses. Thus, if it originally started at Z, a small random fluctuation in temperature could take it to a very high temperature, i.e., ignition. Point Y is a unique value, since it corresponds to the highest value of initial environment temperature (T_o) for which a stable solution can be obtained. The gas temperature at point Y can be denoted T_c and is referred to as the *critical temperature*[*]. The rise in gas temperature from T_o to T_c is actually quite small, and is the maximum temperature increase that can occur without thermal runaway. The chemical reactions taking place are more than zero, but slow enough not to give visible signs of combustion.

Defining the heat gain term as Q_G and the heat loss term as Q_L, we may note that the critical point is characterized by two conditions:

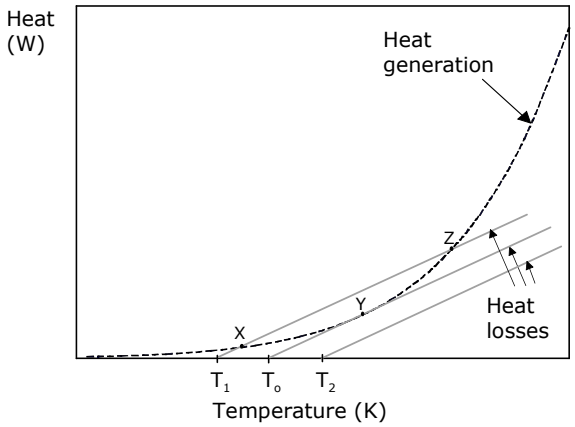

Figure 4 The heat generation and heat loss in a volume of gas; heat losses corresponding to 3 different heat transfer coefficients are shown. The heat loss curve passing through point Y represents the critical condition for 'thermal explosion'

[*] The nomenclature in the literature is not always clear or consistent—sometimes T_o is referred to as the critical temperature, other times it is the temperature at point Y. The physical meaning, however, is different: T_o is the maximum permissible temperature of the environment, while the temperature at point Y is the maximum temperature of the reacting substance that is possible without runaway.

(1) $Q_G = Q_L$

(2) $\dfrac{dQ_G}{dT} = \dfrac{dQ_L}{dT}$

in other words, (1) the values of the two terms are equal; and (2) the slopes are equal. Historically[21], the first condition was discovered by van't Hoff in 1883, while second one by Taffanel and le Floch[22] in 1913, consequently these two conditions sometimes bear their names.

As described in Chapter 3, if the reactant's temperature is T, then the rate at which reactant mass is consumed is:

$$\dot{m}''' = c^n A e^{-E/RT}$$

If the volume is V and the heat of the reaction is Q, then the heat generated* by the reaction is:

$$\dot{q} = QAVc^n e^{-E/RT}$$

The heat loss is

$$\dot{q} = hS(T - T_o),$$

where h = convective heat transfer coefficient and S = surface area. Expressing the equality of values gives:

$$QAVc^n e^{-E/RT} = hS(T - T_o)$$

Now, if we define θ as:

$$\theta = \frac{E}{RT_o^2}(T - T_o)$$

The heat balance equation can be expressed in terms of θ:

$$\frac{E}{RT_o^2}\frac{QAVc^n}{hS}e^{-E/RT} = \theta$$

To arrive at an analytical solution, at this point an approximation is necessary for $e^{-E/RT}$. If $(T - T_o)/T_o << 1$, then we make use of the approximation that for any $x << 1$,

$$\frac{1}{1+x} \approx 1 - x$$

This allows the exponential to be approximated as:

$$e^{-E/RT} = \exp\left(-\frac{E}{R(T_o + [T - T_o])}\right)$$

$$= \exp\left(-\frac{E}{RT_o}\left[\frac{1}{1 + \dfrac{T - T_o}{T_o}}\right]\right) \approx \exp\left(-\frac{E}{RT_o}\left[1 - \frac{T - T_o}{T_o}\right]\right)$$

$$= \exp\left(\frac{E}{RT_o}\frac{(T - T_o)}{T_o} - \frac{E}{RT_o}\right) = \exp(\theta)\cdot e^{-E/RT_o}$$

With this approximation, the heat balance equation can be rewritten as:

$$\frac{E}{RT_o^2}\frac{QAVc^n}{hS}e^{-E/RT_o}\cdot\exp(\theta) = \theta$$

The entire group of quantities preceding the second exponential is a constant and is defined as the Semenov number, ψ:

$$\psi = \frac{E}{RT_o^2}\frac{QAVc^n}{hS}e^{-E/RT_o}$$

Thus, the heat balance equation can be written as:

$$\psi\cdot\exp(\theta) = \theta \qquad (1)$$

To express the equality of slopes, we take the derivative with respect to T of each side of the above equation:

$$\psi\frac{d\theta}{dT}e^{\theta} = \frac{d\theta}{dT}$$

or,

$$\psi e^{\theta} = 1 \qquad (2)$$

The only way that Eq. (1) and Eq. (2) can be true is if $\theta \rightarrow 1$. But substituting that back into the heat balance equation gives:

$$\psi = 1/e$$

We can denote the critical condition by the subscript c, thus

$$\psi_c = 1/e$$

And $\theta_c = 1$

The meaning can be made a bit more clear by writing out the relations in dimensional terms. Thus

$$\frac{E}{RT_o^2}\frac{QAVc^n}{hS}e^{-E/RT_o} = \frac{1}{e}$$

And rewriting it as:

$$\frac{V}{S} = \frac{1}{e}\frac{RT_o^2 h}{EQAc^n}e^{+E/RT_o}$$

This means that for a given ambient temperature T_o, the maximum size of the object is limited to the value of V/S given above. Any larger size will result in thermal runaway and, therefore, ignition.

We must now consider briefly whether the assumption we made, that $(T - T_o)/T_o << 1$, is reasonable. Since we found that the critical condition corresponded to $\theta = 1$, we may express that as

$$\theta = \frac{E}{RT_o^2}(T - T_o)$$

and divide both sides of the inequality by $RT_o^2/(E[T - T_o])$. Thus, the approximation is also equivalent to $RT_o/E << 1$. Now, typical values might be $T_o \approx 600$ K, $E \approx 100{,}000$ J mol^{-1}, and $R = 8.314$ J mol^{-1} K^{-1}. Thus, $RT_o/E \approx 0.05$, which is <<1. For order-of-magnitude estimates, it is also useful to note that ratio E/R will often be in the range of 10,000 – 20,000 K.

* It can be seen that the exponential factor in the equation below does not monotonically keep rising with temperature. Instead, at very high temperatures a plateau is reached, since exp(–E/RT) → 1 as $T \rightarrow \infty$. Thus, in addition to the two intersections of the heat generation curve with the heat loss curve shown in Figure 4, a third intersection occurs at very high temperatures. This is not of concern in our solution, however, since the process already either stabilizes or runs away in the lower-temperature portion shown.

It is also instructive to see in dimensional units the maximum temperature rise that can occur without thermal runaway. Since $\theta_c = 1$, then

$$\frac{RT^2}{E} = T_c - T_o$$

where the gas temperature at criticality is denoted as T_c. This gives a quadratic equation in T_c, whose solution is:

$$T_c = \frac{E}{2R} \pm \sqrt{\left(\frac{E}{2R}\right)^2 - \frac{T_o E}{R}}$$

and it can be shown that physical results correspond only if the minus sign is taken for the second term. This gives

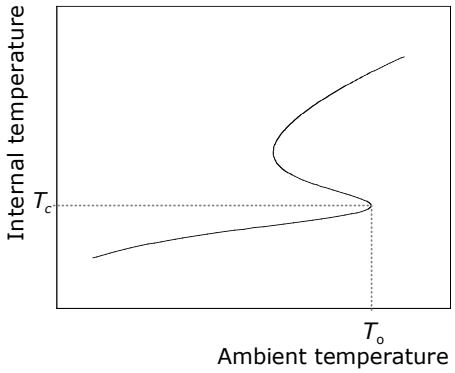

Figure 5 Full solution for T, as function of T_o (schematic)

$$T_c = \frac{E}{2R} - \frac{E}{R}\sqrt{1 - 4R\frac{T_o}{E}}$$

Now, since $RT_o/E << 1$, we can expand the square root expression as a power series in T_o/E, giving

$$T_c \approx \frac{E}{2R} - \frac{E}{2R}\left[1 - \frac{2RT_o}{E} - \frac{2RT_o^2}{E^2} + \ldots\right]$$

or

$$T_c - T_o \approx \frac{RT_o^2}{E}$$

Using the above example values, the difference $(T_c - T_o) \approx$ 30 K. The above treatment was simplified, since only the physically stable part of the solution was developed. In fact, the curve of the steady-state Semenov solution has two additional branches[23], as shown in Figure 5. For certain ambient temperatures below T_o, three solutions for T are possible, but only the lowest value corresponds to a stable, unignited state—the middle branch is unstable, while the top branch would represent an ignited state if the Semenov model were suitable for describing for actual combustion, not just conditions leading up it (which it is not).

A number of authors[24,25] give a further-approximated version of the above development by explicitly assuming that $T_c \approx T_o$. In that case, the equation giving the AIT, i.e., the value of T_o which corresponds to critical conditions, which in our development is:

$$eQAVc^n e^{-E/RT_o} = hS\frac{RT_o^2}{E}$$

becomes, instead:

$$QAVc^n e^{-E/RT_o} \approx hS\frac{RT_o^2}{E}$$

For common hydrocarbon combustion reactions, $n = 2$, and therefore, $c^n \sim \left(\frac{P}{RT}\right)^2$, where P = pressure. Substituting this, and taking logarithms of both sides gives:

$$\ln\frac{P}{T_o^2} = \frac{E}{2RT_o} + \text{const}$$

This relation indicates that raising the system pressure causes ignition to take place at a lower temperature, and vice versa. The relation between the pressure and the temperature can best be represented by plotting $1/T_o$ on the x-axis and $\ln\frac{P}{T_o^2}$ on the y-axis (Figure 6).

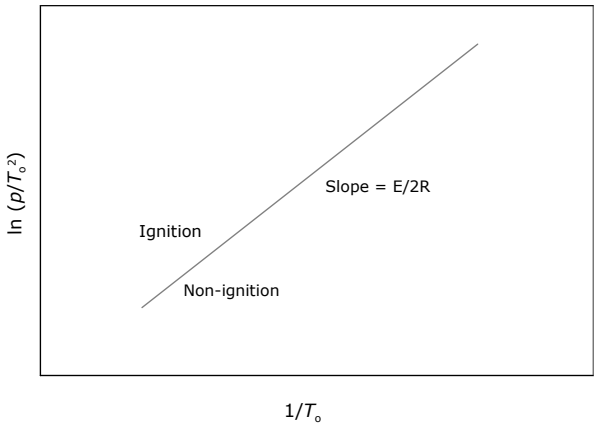

Figure 6 The relation according to Semenov theory between the pressure and the temperature needed for ignition

The above development comprised a *stationary state theory*, that is, we were only seeking to find the conditions necessary for criticality, not the time involved in heating up the system. For actual ignition problems, if the ambient temperature is larger than the T_o corresponding to critical conditions, thermal runaway will occur, that is, the gas will ignite. It then becomes of interest to assess the time required for ignition, t_{ig}. To evaluate this time, the heat released per unit volume during the period from $t = 0$ to $t = t_{ig}$ is:

$$QAc^n e^{-E/RT_o} \cdot t_{ig}$$

Assuming that there are no losses to the outside (that is, the system is adiabatic), this same heat goes to raise the temperature from T_o to T_c:

$$\rho C(T_c - T_o)$$

where ρ = density and C = heat capacity. Thus,

$$\rho C(T_c - T_o) = QAc^n e^{-E/RT_o} \cdot t_{ig}$$

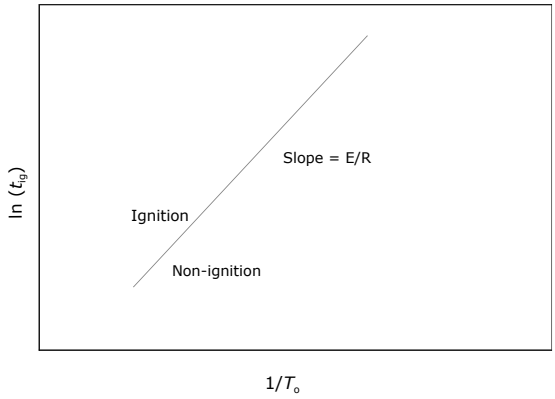

Figure 7 The dependence of the induction period on the gas temperature

But

$$\left(T_c - T_o\right) \approx \frac{RT_o^2}{E}$$

Thus

$$\frac{\rho CRT_o^2}{E} = QAc^n e^{-E/RT_o} \cdot t_{ig}$$

For a second-order reaction, $n = 2$, and $\rho \equiv c$, thus

$$t_{ad} = \frac{CRT_o^2}{cQAE} e^{+E/RT_o}$$

where the subscript *ad* denotes that external heat losses have not been taken into account. Despite the fact that this result was obtained by some highly simplified reasoning, a full solution to the time-dependent problem[26] gives the identical expression for t_{ad}. Now, if we roughly assume in the above equation that the dependence on T_o in the first factor is small compared to the exponential dependence on T_o of the second factor, we can take logarithms of both sides and write:

$$\ln(t_{ad} \cdot c) = \frac{E}{R}\frac{1}{T_o} + \text{const}$$

Since pressure is proportional to concentration, this also implies:

$$\ln(t_{ad} \cdot P) = \frac{E}{R}\frac{1}{T_o} + \text{const}$$

If the above equation holds, then plotting $1/T_o$ on the x-axis and $t_{ad} \cdot P$ on the y-axis should give straight lines if the x-axis is linear and the y-axis is logarithmic (Figure 7); the values of T_o must be in Kelvins for this plot. Spadaccini and TeVelde[27], however, attempted to validate this for cetane and found that the experimental data did not fall into straight lines. Instead, a straight line was obtained if the following equation was plotted:

$$\ln(t_{ad} \cdot P^2) = \frac{E}{R}\frac{1}{T_o} + \text{const}$$

which requires that $t_{ad} \cdot P^2$ be plotted on the y-axis. Figure 8 shows that, with the exception of the leanest mixture (φ = 0.3), the points do fall along a single straight line. Since $1/T_o$ gives very small numbers, Figure 8 was plotted with $1000/T_o$, instead of $1/T_o$, on the x-axis. The slope of the line is 24.54. From this, the value of E can be found, since

$$24.54 = \frac{E}{R}\frac{1}{1000}$$

giving E/R = 24,540 K, and, since 8.314 J mol^{-1} K^{-1}, this gives E = 204 kJ mol^{-1}.

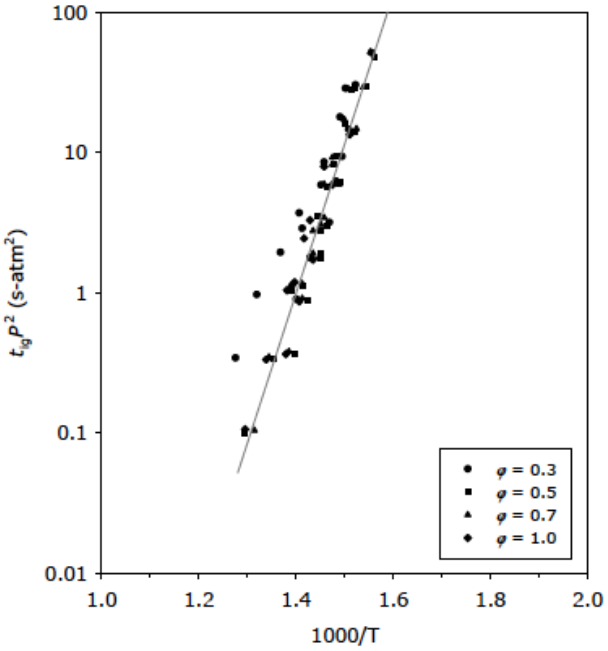

Figure 8 Autoignition data for cetane at several equivalence ratios, plotted as suggested by Spadaccini and TeVelde

For some purposes, it may be useful to make corrections for the non-adiabatic nature of real systems. A suitable correction is[28]:

$$t_{ig} = (n\gamma)^{-1/3} t_{ad}$$

where n = order of reaction ($n \geq 1$), and γ is given by:

$$\gamma = \frac{C}{Q} \cdot \frac{RT_o^2}{E}$$

giving the heat-loss corrected ignition time as:

$$t_{ig} = n^{-1/3} \frac{1}{A}\left[\frac{CRT_o^2}{QE}\right]^{2/3} e^{+E/RT_o}$$

Semenov assumed that there are only two distinct temperatures in the system, the outside environment being at one temperature and the gas inside at another. The assumption that the volume of gas is at a single temperature is a strong simplification. In fact, a gas has a finite thermal conductivity, and this will cause the center to be hotter than the periphery. Frank-Kamenetskii recognized this and created a theory which takes finite gas conductivity into account. His theory, however, discards a p iece of physics which Semenov treated realistically—he assumes the vessel wall is

'clamped' at the environment temperature T_o. The differences are summarize in the table below. A 'blend' of these two theories is possible and this is discussed in Chapter 9.

Table 1 Main differences between Semenov and Frank-Kamenetskii theories

Theory	Temperatures inside the vessel	Temperatures outside the vessel
Semenov	uniform	decrease over a certain boundary-layer thickness from a high value at the wall, to a lower value in ambient air
Frank-Kamenetskii	non-uniform; highest at the center, lower towards the walls	uniform: both the vessel wall and the ambient air are at the same temperature

Frank-Kamenetskii starts by applying the fundamental heat conduction equation to a fixed volume of gas:

$$\rho C \frac{\partial T}{\partial t} = \frac{\partial}{\partial x}\left(\lambda \frac{\partial T}{\partial x}\right) + \frac{\partial}{\partial y}\left(\lambda \frac{\partial T}{\partial y}\right) + \frac{\partial}{\partial z}\left(\lambda \frac{\partial T}{\partial z}\right) + \dot{q}'''$$

where

ρ = gas density (kg m^{-3})
C = heat capacity (kJ kg^{-1} K^{-1})
T = temperature (K)
t = time (s)
λ = thermal conductivity of the gas (kW m^{-1} K^{-1})
$\dot{q}'''$ = heat generation rate (kW m^{-3}).

The heat generation term is a simplified representation of the overall combustion reaction which can take place. Note that here it must be expressed in per-volume units. To make the equation simpler, the 'del operator' can be introduced,

$$\rho C \frac{\partial T}{\partial t} = \nabla \cdot (\lambda \nabla T) + \dot{q}'''$$

We then assume that the thermal conductivity is a constant, allowing it to be taken outside the differential:

$$\rho C \frac{\partial T}{\partial t} = \lambda \nabla^2 T + \dot{q}'''$$

In developing his simplest 'stationary' solution, Frank-Kamenetskii considers only the steady-state solution, by dropping the time-dependent term and only considering the spatial variations. Thus,

$$\lambda \nabla^2 T = -\dot{q}'''.$$

If the heating is symmetrical, for various geometries the 'Laplacian operator' ∇^2 can be evaluated as:

$$\nabla^2 = \frac{d^2}{dx^2} + \frac{j}{x}\frac{d}{dx}$$

where $j = 0$ for a slab, $j = 1$ for radial heat flow in a cylinder, and $j = 2$ for in a sphere.

Now, the heat generation term can be expressed as a product of the heat of reaction, Q (kJ kg^{-1}) and the reaction rate $\dot{m}'''$ (kg s^{-1} m^{-3}). If the reaction rate is assumed to be represented by a first-order Arrhenius expression (which is the simplest assumption, but not generally a realistic one for most gases), then

$$\dot{m}''' = \rho A e^{-E/RT}$$

Here, the pre-exponential factor A has the units of (s^{-1}) since the exponential has to be dimensionless. Thus, the governing equation becomes:

$$\nabla^2 T = -\frac{Q\dot{m}'''}{\lambda} = -\frac{QA}{\lambda}\rho e^{-E/RT}$$

The entire chemistry of the combustion process is then embedded into two constants: A and E. All other variables are either thermochemical constants of the system (conductivity, density), universal constants (R), or distance variables. The boundary conditions for the above differential equation must express the wall temperature, which is taken as a constant,

$$T = T_o \quad \text{for} \quad x = r$$

where x is the radial distance from the center, and r is the radius of the vessel. Furthermore, due to symmetry, $\frac{\partial T}{\partial x} = 0$ at $x = 0$.

Frank-Kamenetskii then made the approximation that the temperature rise at which the system starts to 'run away towards ignition' is small compared with the ambient temperature of the system. To express this, it is instructive to define a temperature rise term T*, where $T^* = T - T_o$. Then, the approximation becomes $T^* << T_o$. The exponential term can then be written as

$$\exp\left(\frac{-E}{RT}\right) = \exp\left(\frac{-E}{R(T_o + T^*)}\right) = \exp\left(\frac{-E}{RT_o}\left[\frac{1}{1 + T^*/T_o}\right]\right)$$

and using the fact that $T^* << T_o$:

$$\exp\left(\frac{-E}{RT}\right) \approx \exp\left(\frac{-E}{RT_o}\left[1 - \frac{T^*}{T_o}\right]\right) = \exp\left(\frac{-E}{RT_o}\right)\exp\left(\frac{ET^*}{RT_o^2}\right)$$

Using this expression, the heat conduction equation becomes:

$$\nabla^2 T^* = -\frac{QA\rho}{\lambda}\exp\left(\frac{-E}{RT_o}\right)\exp\left(\frac{ET^*}{RT_o^2}\right)$$

The equation is then put into nondimensional form by defining two nondimensional variables:

$$\theta \equiv \left(\frac{E}{RT_o^2}\right)T^*$$

and

$$\eta \equiv \frac{x}{r}$$

This gives

$$\nabla_\eta^2 \theta = -\frac{QA\rho}{\lambda}\left(\frac{E}{RT_o^2}\right)r^2 \exp\left(\frac{-E}{RT_o}\right)e^\theta$$

where the subscript η denotes that the Laplacian operator is with respect to η. The boundary conditions become:

$$\theta = 0 \qquad \text{at} \quad \eta = 1$$
$$d\theta/d\eta = 0 \qquad \text{at} \quad \eta = 0.$$

The solution for the temperature distribution can be obtained from the above differential equation and its boundary conditions. For determining ignition, however, the question becomes: Under what conditions is *any* steady-state solution impossible? This condition is, perforce, the ignition point, since the process is encountering thermal runaway.

The analysis is simplified by noting that all the physical constants remaining in the equation show up in a single group, which is defined as δ, sometimes referred to as Frank-Kamenetskii's δ:

$$\delta = \frac{QA\rho}{\lambda}\left(\frac{E}{RT_o^2}\right) r^2 \exp\left(\frac{-E}{RT_o}\right)$$

and the differential equation then is:

$$\nabla_\eta^2 \theta = -\delta\, e^\theta$$

This equation does not have any solution if the value of the constant δ becomes too large. Frank-Kamenetskii showed that the largest value of δ for which a physical solution exists for a sphere is 3.32. Similarly, for an infinite cylinder of radius r, the critical value is 2.0, while for a slab of thickness $2r$ it is 0.88. This solution clearly demonstrates that 'ignition temperature' is not a property of a particular gas mixture; instead, it is related to the size of the vessel in which gas is contained.

In the development above, we assumed a first-order reaction, i.e., that the reaction rate is proportional to ρ. For a second-order reaction, the concentration of reactants to the second power, c^2, would be substituted for ρ.

The above expression for δ can be usefully employed to find the effect of pressure on the autoignition temperature. Noting that the Ideal Gas Law can be expressed as $\rho = MP/RT$, where M = molar mass (kg mol^{-1}), P = pressure (Pa), and T = temperature (K), the expression for δ becomes:

$$\delta = \frac{QA}{\lambda}\frac{MP}{RT_o}\left(\frac{E}{RT_o^2}\right) r^2 \exp\left(\frac{-E}{RT_o}\right)$$

Temperature cannot be explicitly solved from this equation, but a P versus T (or r^2 versus T) relation could be plotted and would show the form of a modified hyperbola. Egeiban et al.[29] explored the ignition behavior at low pressures of di-tertiary-butyl peroxide. The latter was selected as a substance which shows simple ignition kinetics (due to exothermic decomposition). The *P-T* diagram (Figure 9) shows the hyperbola shape which is characteristic for a substance whose oxidation can be modeled by the thermal theory.

When the thermal theory is valid, for spherical vessels of various sizes, plotting $\ln(P\, r^2/T_o^3)$ against $1/T_o$ should give a

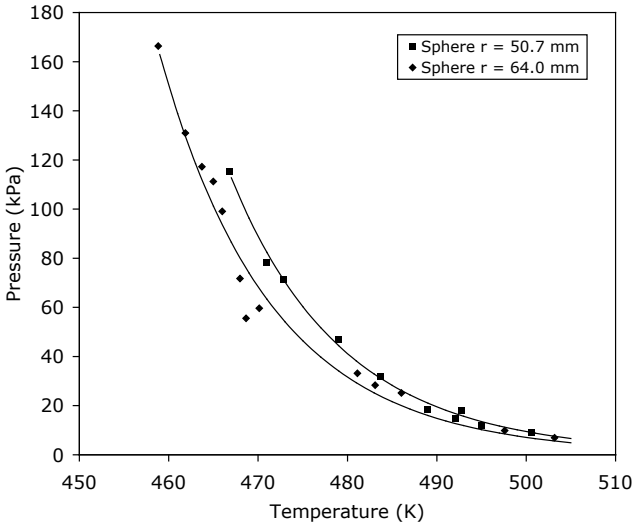

Figure 9 The *P-T* diagram for the ignition of di-*tert*-butyl peroxide

straight line with a slope of $-E/R$. The slope in Figure 10 is –18989, which gives E = 158 kJ mol^{-1}, a value identical to that determined for di-*tert*-butyl peroxide from other means. The authors, however, also determined that the experimental value of δ corresponding to ignition was 6.0 – 6.7, which is quite far from the theoretical 3.32. Thus, the theory, while giving the exact E value and also being able to predict very well the functional dependences of pressure, temperature, and size, does not correctly predict the absolute location of the ignition curve on the $P - T$ plane. For many purposes, however, a simple theory which succeeds to this extent will be more than adequate.

The theoretically-motivated plotting, as shown in Figure 10, is not convenient for illustrating the dependence of T_{ig} on

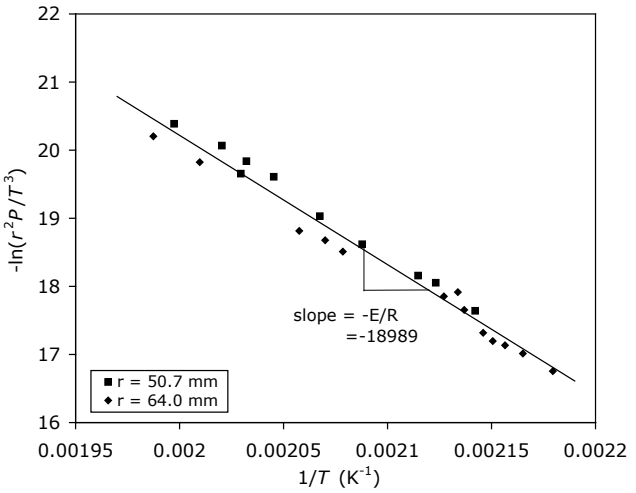

Figure 10 Application of thermal autoignition theory to di-*t*-butyl peroxide (Egeiban et al.)

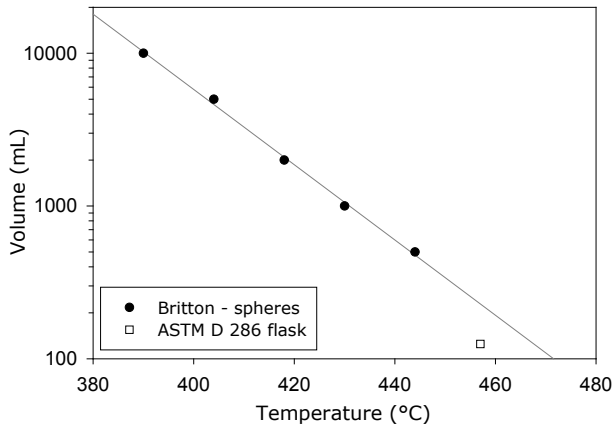

Figure 11 Effect of vessel size on autoignition of ethylene oxide in air

volume, since T_{ig} shows up on both axes. Britton[30] pointed out that, for practical purposes, straight lines will be found if T_{ig} is plotted on a linear x-axis and V on a logarithmic y-axis. This is illustrated in Figure 11 for ethylene oxide in air. Note that since the temperature plot is linear, degrees Celsius can be used just as well as Kelvins. Much early data on autoignition has been reported using the ASTM D 286 flask, and this is also shown for comparison.

Figure 12 shows the ignition regions for a stoichiometric mixture of H_2S in oxygen[31]. At a temperature of 330ºC, for instance, it indicates there are three ignition/non-ignition limits. At very low pressures, no ignition occurs, then at 0.4 kPa ignition can occur up to 1.5 kPa, after which ignition does not occur until 8.2 kPa is surpassed. A diagram of this kind does not arise if purely thermal theory is considered. Instead, the 1st and 2nd limits come about due to the role of chain branching. Note that these pressures are all well below 1 atm (101.3 kPa).

Similarly, most real fuels show ignition time vs. temperature relationships that do not conform to the thermal theory. For example, Figure 13 shows experimental and calculational results[32] for *n*-heptane. Observe that over a certain range of temperatures increasing the temperature makes it harder to ignite the mixture. The calculational results were from a chemical kinetics model which tracked 556 different chemical species.

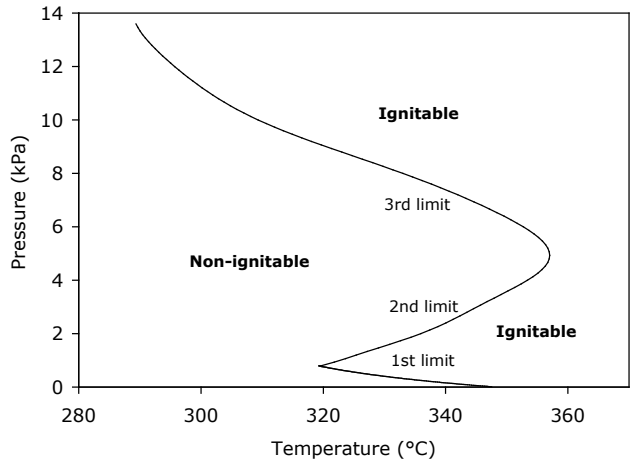

Figure 12 The P-T diagram for the ignition of a stoichiometric mixture of H_2S in oxygen

Both the Semenov and the Frank-Kamenetskii theories were based on the assumption of a simple, single-step chemical reaction. An ignition under such circumstances is termed *thermal explosion* in the combustion literature. As we have seen in Chapter 3, however, combustion reactions normally fail to satisfy this requirement and are, instead, chain reactions. Such ignitions constitute *chain-reaction explosions*, also referred to as *branching-chain explosions*. Setting up and solving equations describing branching-chain reactions is very complex and does not lead to any approximate, closed-form solutions. Instead, solutions must be obtained by elaborate mathematical computer modeling.

IGNITION OF SPECIFIC FUELS

The three simplest fuel molecules of general interest are hydrogen (H_2), carbon monoxide (CO), and methane (CH_4). Since it has only two atoms and both are identical, hydrogen is the simplest fuel that can be studied. CO is important since many organic fuels burn by first oxidizing to CO and then later to CO_2. Methane is, of course, the primary component in natural gas. Theories have been created for the oxidation—including ignition phenomena—of all three. The reaction chemistry of even these simplest molecules is extraordinarily complex. Even though the 'global' reaction mechanism of hydrogen,

$$2H_2 + O_2 \rightarrow 2H_2O$$

represents the simplest possible combustion reaction, in actuality the mechanism is complicated, and Foo and

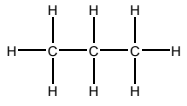
Yang[33] identified the need for 12 reactions to study the H_2 + O_2 system.

The kinetics of CO combustion is unusual, since a pivotal role is played by moisture in the atmosphere: wet CO is easy to ignite, whereas dry CO is highly resistant to ignition. Even minuscule amounts of H_2O (or H_2, or any other hydrogen-containing species) tend to promote certain reactions that are not possible in truly dry systems. But since very little of hydrogen needs to be present for a mixture to be moist, experimental studies of truly dry CO combustion are difficult. These were not being attained until the painstaking studies of Gray et al.[34,35], who elucidated the following types of exothermic responses.

Wet mixtures (> 2000 ppm H_2)

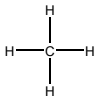
- Ignition. A visible flash occurs suddenly; fuel is completely consumed.
- Slow reaction. No light is emitted. Temperature increases due to self-heating are immeasurably small. pressure and concentration changes are small, even over long time periods.

Intermediate mixtures (200 ppm < H_2 < 2000 ppm)



- *Ignition*.
- *Glow*. This is chemiluminescense. It is observable in a dark room as a blue emission. Reaction is relatively slow; temperature increases are limited; not all fuel is consumed. This response is only found for pressures of less than 0.1 atm.
- *Oscillatory glow*. This is seen as pulses of light. Analogous to cool flames seen with hydrocarbons. Reaction consumption occurs mainly during spikes of light emission.
- *Slow reaction*.

Dry mixtures (H_2 < 50 ppm)



- *Glow*. This is the only reaction that occurs. Ignition is not achieved. The fuel is not 100% consumed. The glow is steady, except for a small range of pressure/temperature conditions (500 < T < 565ºC; 0.011 < P < 0.063 atm) where oscillatory glow is observed[36].

In flow-through systems where sufficient hydrogen is present, if ignition occurs, it is oscillatory in nature[36]. Gray et al. also developed a kinetic model that is able to reproduce most of the experimental features of ignition in a flow-through system[37].

Hydrocarbon molecules of higher molar mass have carbon-carbon and carbon-hydrogen bonds. For example, propane

is . But methane is

and it has no C–C bonds. Normally, the C–C bond is the weakest and the combustion chain reaction can begin with its attack. But in methane, the more difficult-to-break C–H bond must first be broken. Quantitatively, 439 kJ mol^{-1} must be supplied to break a C–H bond in methane, but only 356 kJ mol^{-1} to break the C–C bond in propane, and 305 to 320 kJ mol^{-1} in larger hydrocarbon molecules[38]. Thus, methane oxidation is

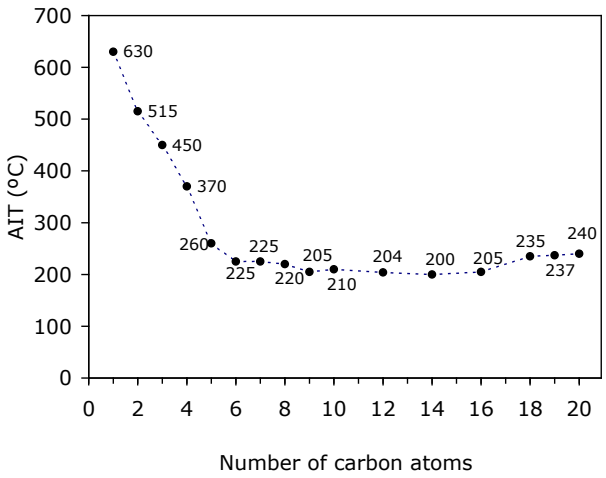


Figure 14 The AIT of *n*-alkane hydrocarbons in air, as a function of the number of carbon atoms

anomalous among hydrocarbons and methane shows an exceptionally high AIT. A recent study[39] has identified some 150 elementary reactions which needed to be computed in order to accurately predict methane oxidation reactions; in another recent study[40], some 177 reactions were used. However, reasonable prediction was obtained using only (!) 55 reactions[41].

If methane's AIT is unusually high, how come that, in the case of spark ignition, the ignition energy required is not higher than for other hydrocarbons? The reason is because the bond strength issues only come into play for starting a chain reaction by providing radicals or other excited species. When a spark is discharged, highly excited species are already introduced in large quantities.

Ignition of other organic fuels. The chemistry of the combustion and, hence, of the ignition, of most organic substances is enormously complex. In the words of chemical mathematician Peter Gray[42]: "In general, hydrocarbon oxidations are chemically the most complex systems studied outside the biological sphere." That the calculational effort needed for modeling is huge can be seen from another example: a recent study on the oxidation of propylene[43] involved solving 377 equations. Fortunately, for many practical applications, details of chemical kinetic steps taking place do not need to be mastered. Readers wishing to delve into these "complex systems" can start with the major monographs that have been published in the field, those by Minkoff and Tipper[44], Bamford and Tipper[45], Hucknall[46], Pilling[47], and Compton and Hancock[48].

EXPERIMENTAL DETERMINATION OF THE AIT

Conceptually, the AIT of a gas mixture is a simple idea. To construct an apparatus which measures it, however, is not simple at all. If substances showed no reaction at a certain temperature, and reacted fully at a slightly higher one,

things would be simpler, but this is not the case. One can imagine, for example, a vessel in which a mixture is placed at room temperature, then heated very slowly. At a certain temperature, flaming ignition will be observed. Things become less simple when it is realized that if the vessel were heated at a different rate, a different temperature of ignition would be recorded. The first experiments on this topic were done by Mallard and Le Chatelier[49] in 1880, who used an evacuated, heated porcelain vessel to which gas mixtures were quickly admitted. The mixture was injected cold, and it, of course, heated non-uniformly. The time required for heating could be eliminated by feeding the fuel and the oxidizer in separate heated tubes to a region where they would mix and potentially ignite. Dixon and Coward designed such an apparatus in 1909, but this was not a perfect answer, either, since an uncontrolled time of mixing was substituted for an uncontrolled time of heating. A detailed review of the various test methods that have been used to measure the AIT is given in the last section of this Chapter.

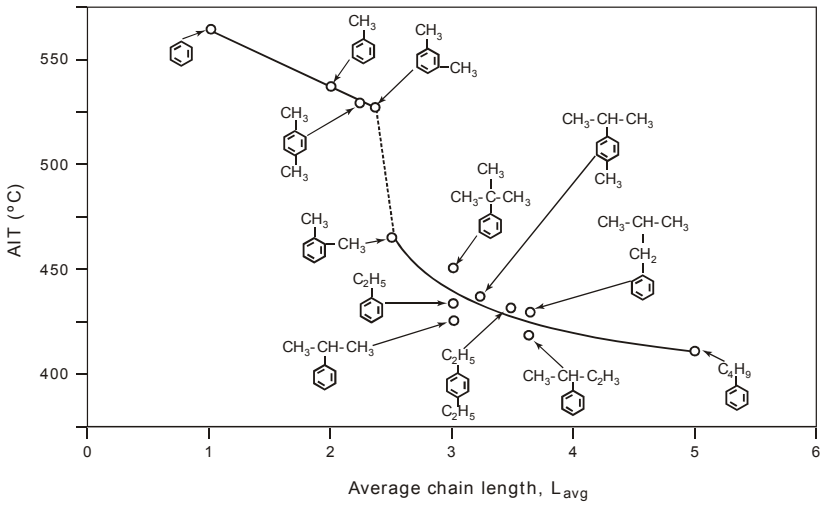

Figure 15 The AIT of aromatic hydrocarbons in air, as a function of average chain length (note the two ignition regimes—high temperature and low temperature)

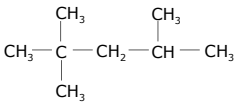
VARIABLES AFFECTING THE AIT

MOLECULAR STRUCTURE



Molecular structure, not surprisingly, influences AIT results and the AIT depends on the bond strength of the weakest bond in the fuel molecule (or the O–O bond in oxygen, in case that is weaker than any fuel bonds). For *n*-alkane* series hydrocarbons, the AIT decreases with increasing number of carbon atoms, going from CH_4 to C_5H_{12}, as shown in Figure 14[50]. For higher alkanes, the AIT becomes nearly constant at 200 – 220ºC. The hydrocarbons starting with pentane (C_5) show a uniformly low AIT values because cool-flame ignitions are possible for them at atmospheric pressure. The much-higher values for C_1 through C_4 molecules reflect the fact that cool-flame ignitions are possible only at sub-atmospheric pressures. For very large molecules C_{16} and higher, the AIT starts to rise because the high molar mass brings about low volatility.

More complex molecules, i.e., branched-chain alkanes can be handled by the more generalized concept of carbon-chain length. Zabetakis[51] describes that the AIT is determined by the average carbon-chain length, L_{avg}, defined as:

$$L_{avg} = \frac{2\sum_{i=1}^{n} g_i N_i}{M(M-1)}$$

where N_i is the number of carbon atoms in any particular chain i, g_i is the total number of chains which have their number of carbon atoms equal to N_i, and M is the number of methyl ($–CH_3$) groups. This is illustrated for a series of aromatic hydrocarbons in Figure 15. None of these compounds show cool-flame ignition at ambient pressure.

Branched molecules typically have higher AIT values than straight-chain molecules. An important example can be cited in connection with *knock* in engines. Knock, which can be damaging to gasoline engines, occurs when the fuel ignites prematurely due to autoignition, instead of igniting from a spark at the correct time in the engine cycle. As is well known, knock propensity is measured as *octane numbers*. This is confusing, however, since the term is a misnomer—the correct term would be 'iso-octane numbers.' The straight-chain molecule, *n*-octane, in fact, has an AIT of 220ºC and an octane number of –18. It is not a suitable motor fuel. Iso-octane, which has the structure

has an AIT of 415ºC and an octane number of 100, by definition. Egolf and Jurs[52] developed a proprietary model for predicting the AIT on the basis of various molecular-structure descriptors. They claim their model shows standard deviations approaching the experimental uncertainty of AIT measurements.

* The series of hydrocarbons methane (CH_4), ethane (C_2H_6), propane (C_3H_8), butane (C_4H_{10}), etc. is alternately referred to as *n*-alkanes or as *n*-paraffins. The prefix '*n*' denotes 'normal,' that is, a molecule with carbons in a straight chain and not branched.

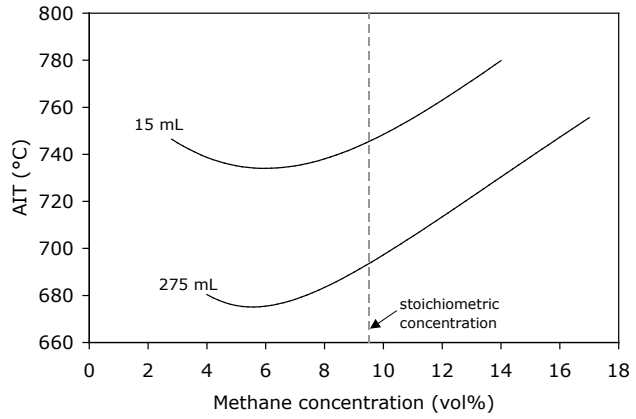


Figure 16 Effect of fuel concentration on AIT for methane, tested in vessels of two different sizes

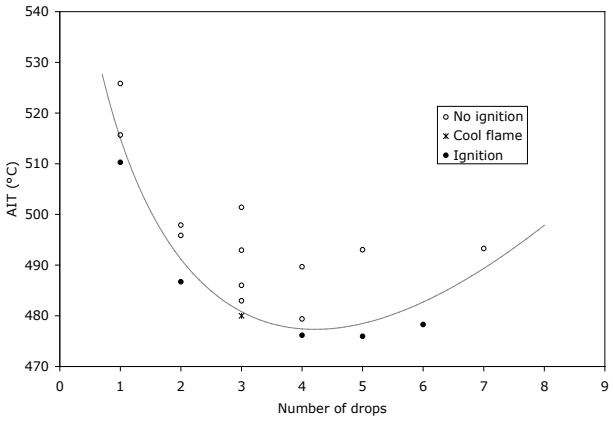

Figure 17 Ignition of 1,1-dineopentylethane in a heated crucible test

FUEL CONCENTRATION

There is an optimum fuel concentration in terms of obtaining the lowest AIT value, as shown in Figure 16 for methane[22]. Note that the optimum is around 5.5 – 6%, which is much lower than the stoichiometric concentration of 9.5%.

The bulk of the AIT data available in the literature were obtained in various heated flask or crucible test apparatus by dropping cold droplets of fuel into a heated volume. Typical results[53] are shown in Figure 17 and these indicate a minimum, which is reported as the tabulated AIT value. However, the results, when obtained in this manner, cannot be related to actual fuel/air ratios. Numerically, a fuel/air ratio could be computed, but it would not have significance because: (1) the fuel concentration is non-uniform in apparatuses of this kind, and (2) the apparatuses are leaky and even the total amount of air cannot be accurately determined.

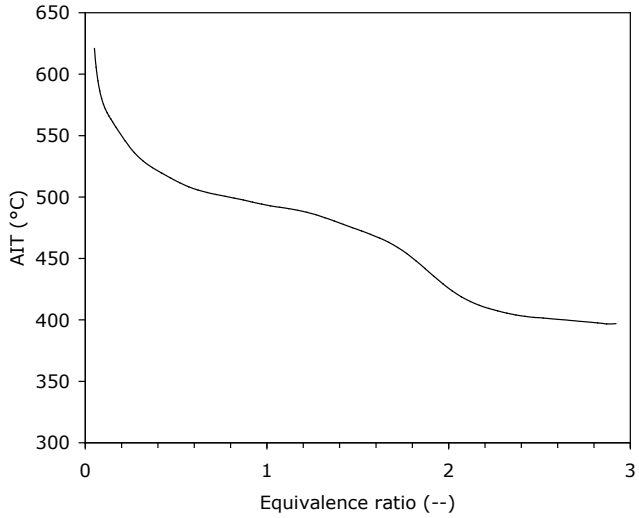

Figure 18 Effect on AIT of the fuel concentration for butane/air mixtures
(Copyright AIChE, used by permission)

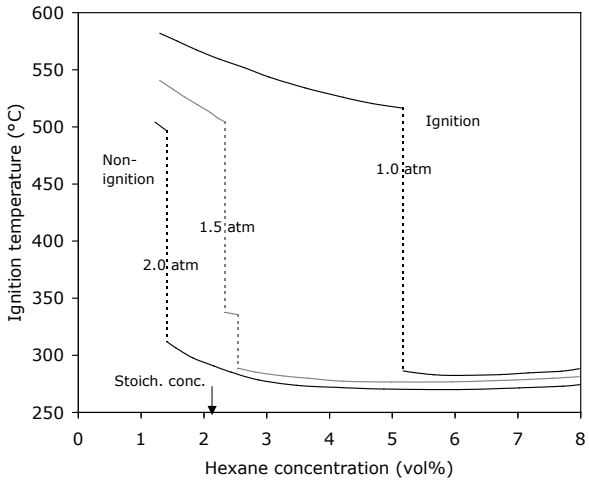

Figure 19 The effect of fuel concentration on the ignition temperature of hexane

A more careful study was done by Griffiths and Gray[54], who determined the AIT as a function of the equivalence ratio for butane/air mixtures in a heated 0.6 L spherical vessel (Figure 18). Their results does not show a minimum at intermediate fuel concentration values, but rather a value which decreases with increasing fuel concentration. The Bureau of Mines AIT value for butane is 370ºC, which is somewhat lower than the lowest value (397ºC) shown by Griffiths and Gray. The authors also studied other gases and showed some exceedingly irregular functions describing the AIT dependence on equivalence ratio.

The above results were obtained, as are most AIT data, at 1 atm pressure. But pressure can have a pronounced effect on

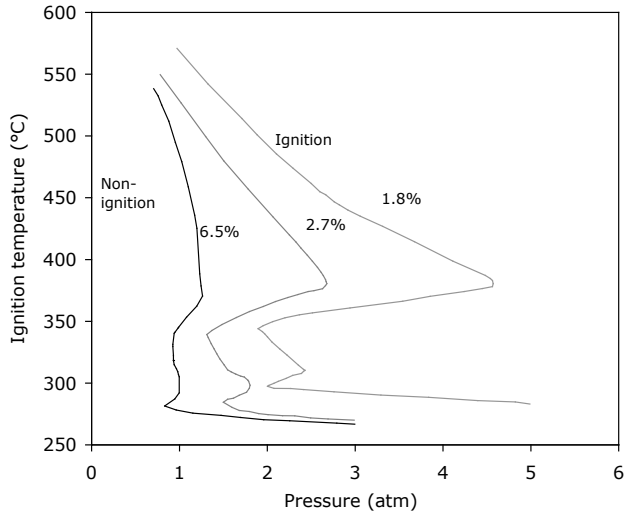

Figure 20 The dependence of ignition regimes on fuel concentration for hexane/air mixtures

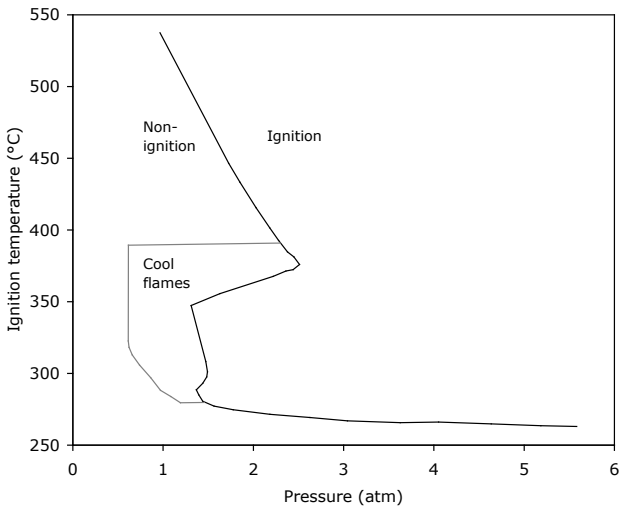

Figure 21 The ignition regimes for a mixture of 3.1% hexane in air

AIT, as shown in Figure 19 for hexane/air mixtures, determined by Townsend et al.[55]. The reaction kinetics for mixtures in the 'upper branch' of the curves is different from that in the 'lower branch.' As with all AIT measurements, there is a significant apparatus-dependence; thus, the minimum value of AIT obtained by Townsend et al. for 1 atm conditions (282 C) is higher than the value adopted by the Bureau of Mines (225 C). The existence of two ignition regimes is common for more complex organic fuel molecules and corresponds to the possibility of cool flames and two-stage ignitions.

PRESSURE

Raising the pressure generally lowers the AIT. The theory discussed above indicates that:

$$\ln\frac{P}{T^2} = \frac{A}{T} + B$$

and over a small enough range this may also be true in experiments. But Figure 22 shows results from Demidov[56], Furno et al.[63], Gödde et al.[57], and Kuchta[50,150] and they indicate that the exact relation will depend on the substance involved. Furthermore, the effect tends to be more pronounced when smaller experimental vessels are used[50,63].

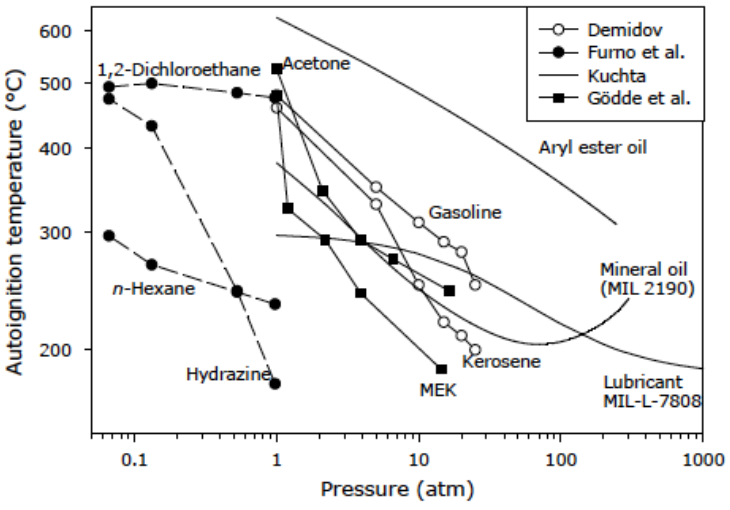

Figure 22 The effect of pressure on the AIT of various vapors

The effect is even more pronounced when there are several combustion modes in which the fuel can burn. Figure 21 illustrates this for a 3.1% hexane mixture in air[55]. The effect of fuel concentration on these ignition/non-ignition boundaries is illustrated in Figure 20. Each of the mixtures also has associated with it a separate cool-flame region, but, for legibility, these are not illustrated in Figure 20. Many practical devices, e.g., air compressors, are operated at high pressures. Thus, the large drop in AIT when going to high pressures must be considered both for lubricants and for any adventitious contaminants.

OXYGEN CONCENTRATION

The effect of oxygen concentration on the AIT is hard to discern from tabulations (e.g., Table 1 in Chapter 15) which combine the results from numerous investigators, but it becomes more evident when data from a single apparatus are assessed, e.g., the results of Ono[58]. Zabetakis[51] considers that there are two distinct possibilities. The compounds that show 'low-temperature' ignitions (< 300ºC) are ones that also show cool flames and a two-stage ignition process.

For these substances, the AIT values in oxygen are nearly identical to those in air. Compounds that show 'high-temperature' ignitions (> 400ºC) undergo direct, normal-flame ignitions. The AIT in oxygen for such substances can be greatly below its air value. This happens because, in oxygen, the ignition regime changes to the two-stage ignition process.

Increasing the oxygen concentration generally decreases the ignition time. Experiments show that the oxygen concentration effect is:

$$t_{ig} = \frac{\text{constant}}{[O_2]^n} e^{E/RT}$$

where $[O_2]$ = oxygen concentration (vol%) and n = constant, but there seems to be little agreement as to what the value of n is, or what influences it. Jackson and Brokaw[86] got 0.25, Freeman and Lefebvre[59] 0.6, Chang et al.[60] 0.74, Miller[61] 1.0, while Mullins[62] obtained 2.0. There is a huge difference in these results, and it would appear that some intervening variable has been neglected. The data of Miller suggest that for AIT values greater than about 1000ºC, the above equation is no longer obeyed at all.

VESSEL SIZE AND OPERATING CONDITIONS

Increasing the vessel size lowers the AIT[63.] Figure 23 shows this relation for a range of common gases and vapors[56,64,65]. The pertinent quantity is the surface/volume ratio, but for vessels of similar shapes, volume or surface alone can be used to plot data. The effects of surface losses were already recognized in 1922 by Mason and Wheeler[66], who suggested plotting AIT values against the surface/volume ratio of the vessel, with the implication being that a 'true' value could be obtained by extrapolating the data down to a ratio of 0.

Kuchta et al.[67] noted that a change in regime is possible with certain substances, leading to large changes in AIT with modest changes in critical dimension of the system. As an example, the AIT of *n*-decane was found to be 224ºC for a radius of 11 mm, 214ºC for 18 mm, but a huge 602ºC for 4 m m. In addition, ranking of fuels was drastically changed when vessel sizes < 11 mm were explored. This is indicative of a change in ignition chemistry, with cool flames and two-stage ignitions not being possible for the smaller vessel sizes. Figure 24 shows AIT values given by White[68] for aviation kerosene, with sizes expressed as the area/volume ratio. Gray analyzed these results and note that a discontinuity of slope for the ignition/no-ignition boundary can indicate that there is a negative-temperature coefficient region in the heat generation vs. temperature relation for the substance, that is, over a certain region, raising the temperature decreases the reaction rate. In that case, there can be two-stage ignitions, with these occurring as sketched out between the gray curves.

Table 2 Effect of using a sealed vessel for conducting AIT tests

Substance	AIT (ºC)		
	Open vessel, DIN 51794 test	Open 0.5 L vessel	Sealed 0.5 L vessel
acetone	535	525	NA
methyl ethyl ketone	475	480	325
2-pentanone	445	470	285
methyl butyl ketone	420	NA	210

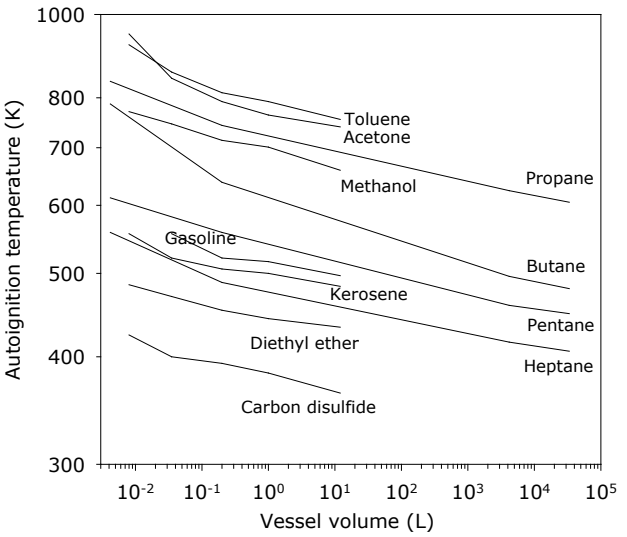

Figure 23 Effect of vessel volume on the AIT of various gases and vapors

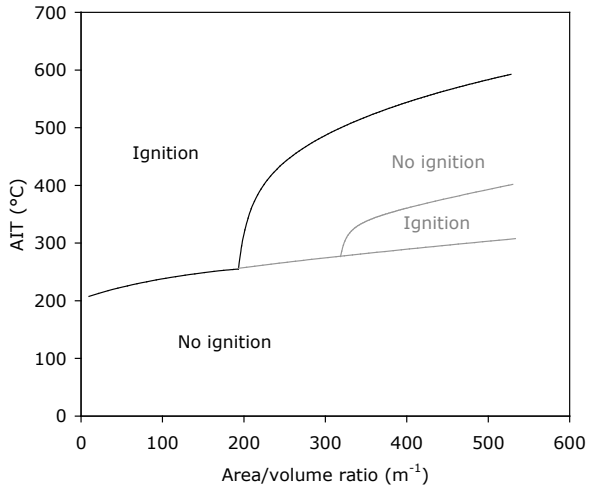

Figure 24 Effect of vessel area/volume ratio on the AIT of aviation kerosene. Experimental results are shown in black; potential second ignition region shown in gray (qualitative only).

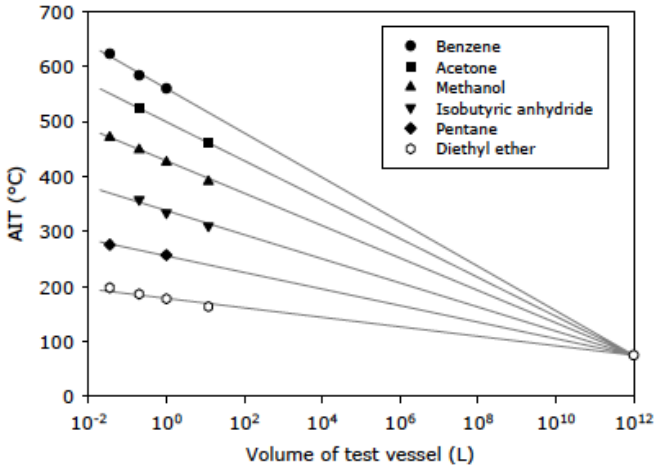

Figure 26 Universal asymptote proposed by Beerbower for scaling AIT results

It is evident that if AIT data are obtained from laboratory equipment of 1 L or so in size, and applied to chemical factory reactors where sizes are several orders of magnitude greater, accidental autoignitions may be observed 'below the AIT.' HSE have warned against this type of misapplication of data[90]. But since it is very difficult to run tests in production-scale vessels, an estimating technique is needed for AIT values applicable to large-size vessels. A. Beerbower (quoted by Coffee[69]) suggested that for common C,H,O compounds (i.e., ones without halogen, sulfur, or other heteroatoms) a universal asymptote exists, so that knowing the AIT for one vessel size, it is possible to estimate the AIT for another size. He proposed that, if extrapolated to a vessel volume of 10^{12} L, all gases and vapors will show AIT = 75ºC. Thus, if the measured AIT = T_1 at volume = V_1 (L), then the AIT (= T_2) for any other volume V_2 is computed as:

$$T_2 = 75 + (T_1 - 75)\left[\frac{12 - \log_{10} V_2}{12 - \log_{10} V_1}\right]$$

Figure 25 illustrates the data obtained by Beerbower demonstrating that the agreement is rather good.

Standard tests are run in vessels which are open or otherwise in pressure equilibrium with ambient atmosphere. But since increased pressure lowers the AIT, if tests are run in sealed vessels, much lower AIT values are found. This was demonstrated by Gödde et al.[57], as shown in Table 2.

WALL MATERIAL

As discussed above, wall surfaces have a chain-termination effect in chain reactions. Not surprisingly, different materials can show different efficiency for chain-termination reactions. For some common materials, the order is[70]:

lowest AIT	clean dry Pyrex, quartz
medium	porcelain; surfaces coated with KCl, $BaCl_2$
highest AIT	silver

Demidov[56] shows data that for some vapors, changing the wall material of the test vessel changes the AIT results by hundreds of degrees. For example, in one set of experiments the AIT of diethyl ether was found to be 188 C in a glass retort, 193 C in a steel block, 533 C in an iron tube, and 549 C in a quartz tube. For many substances, a platinum crucible gave the lowest AIT values, but in the case of ethanol, the platinum crucible value was more than 100 C higher than the value in a steel block. Frank and Blackham[13,71], however, found that the AIT of diethyl ether was 207 1 C, when tested in aluminum alloy, black iron, brass, copper, Inconel, or stainless steel vessels. Based on a large number of compounds studied, they concluded that the material of the walls does not affect substances with AIT < 290 C (i.e., those that show cool flames and multistage ignitions), but can have an effect on substances with high ignition temperatures. The results of Ono[58], however, show that numerous exceptions exist to such a simple rule. In a series of comparison tests using stainless steel vessels with oxidized and bright-metal surfaces, in the worst case, a 48 C difference was found, but in most cases the agreement was within 10-30 C. In an interesting series of explorations, Setchkin[72] used a 1 L glass flask, where the material on the *outside* of the flask (i.e., in between the glass flask and the surrounding heating elements) was varied. Results for a copper layer showed AIT values about 10ºC higher than those for a refractory material. However, a mirrored surface gave values another 5ºC or so lower than for the refractory. These results are hard to interpret and Setchkin merely noted that a mirrored surface was not practical for routine work.

FLOW VELOCITY AND TURBULENCE

The tabulated values of AIT refer to stagnant gas conditions. For ignition to take place at a given temperature, a time period equal to the induction period is needed. If a gas moves very fast through and past a heated tube or vessel,

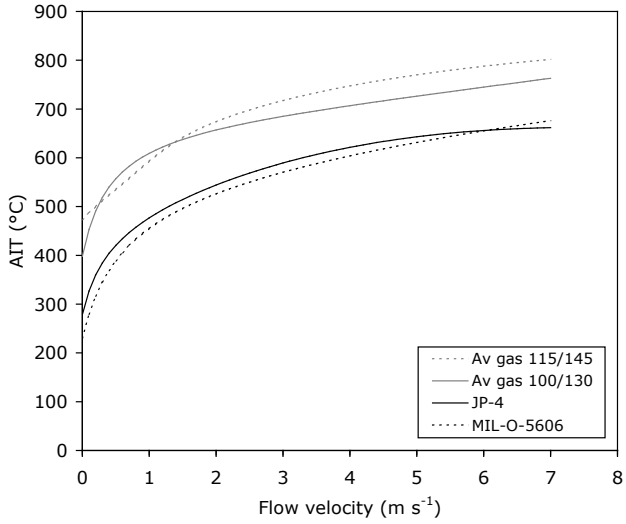

Figure 25 Effect of flow velocity on the AIT of several aviation fluids

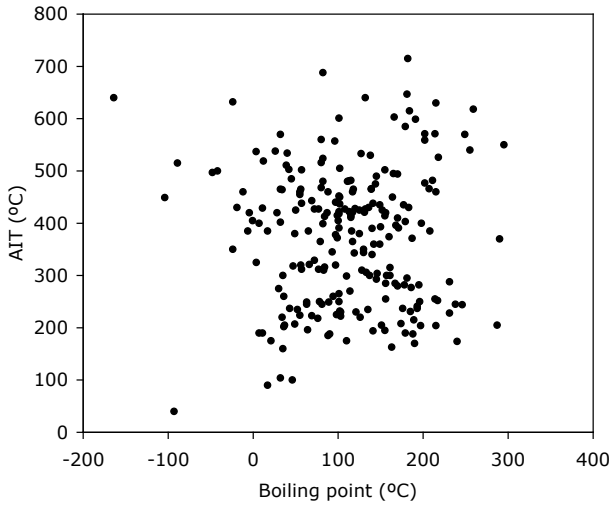

Figure 27 The absence of relation between boiling point and AIT

ignition will not occur if the residence time spent by the gas there is less than the induction period pertinent to the temperature in question. In practice, things get more complicated, since gases rapidly flowing through areas of changing temperature cannot be approximated as all being at a single temperature. Consequently, the residence time vs. induction period relationship may be more helpful for qualitative studies than for actual numerical determination. A limited amount of available data[73] indicates that the AIT rises steeply as flow velocity goes from zero to about 2 m s^{-1}, then rises at a slower rate for higher velocities (Figure 26). The authors suggest that these data can be approximately represented by:

$$\frac{1}{T_u} = \frac{1}{T_o} - a\,u^{1/4}$$

where T_o = AIT (K) at zero velocity, T_u = AIT (K) at a given velocity, u = velocity (m s^{-1}), and a = fuel-dependent constant. Observe that the temperatures have to be expressed in Kelvins in this equation. The effects of turbulence have been found to be inconsistent[74]

OTHER RELATIONS

Wiezevich et al.[75] proposed that there is a relation between the AIT and the boiling point, but Figure 27, which presents data for some 228 pu re compounds, shows that there is none. Indeed, none should be expected, since the AIT is primarily determined by the compound's reactivity (i.e., kinetics) while the boiling point is simply an expression of the volatility of the compound.

AIT OF MIXTURES

The AIT of mixtures has rarely been studied. Figure 28 shows the relation for acetaldehyde/ethylene oxide mixtures[30]. It is clear that the relation is not linear and that it is dominated by the lower-AIT component over most of the range. Similar, non-linear relations have been found for methane/ethane and methane/butane mixtures. The non-linearities arise due to chemical kinetics effects and complex kinetic models are able to reproduce most of the features of these curves[76]. See also *Ethylene oxide* in Chapter 14.

IGNITION TIME

The time needed for a gas mixture to ignite, when exposed to an elevated temperature environment, can range from about 0.01 ms to hundreds of seconds. Decreasing the temperature increases the ignition time[66] (Figure 29), but for any substance, there is a maximum time for ignition. In the case of gases, this time is fairly short, e.g., in one study on methane in a 1.2 L apparatus, it was found that, at any temperature, if ignition did not occur in 30 s, it will never occur[77]. Same as with ignition temperature, the ignition time is not independent on the size of the system, as shown in Figure 35.

As indicated in the Theory section above, if simple Arrhenius kinetics is used and Semenov's theory is adopted, then a relation of form:

$$\ln t_{ig} = \left(\frac{E}{R}\right)\frac{1}{T} + a$$

is expected, where a is an experimental constant. Thus, if $1/T$ is plotted on the x-axis, and $\ln(t_{ig})$ on the y-axis, the results should be straight lines with a slope of E/R and a y-axis intercept of a. Note that T must be in absolute units, that is Kelvins and not degrees Celsius. For convenience, actual plots are generally presented whereby a $\log_{10}$ scale is used for plotting t_{ig} on the y-axis, as illustrated in Figure 30 using the data of Anagnostou et al.[84]. A number of other experimental results collected by the Bureau of Mines[78] are shown in Figure 32. If a single Arrhenius expression for

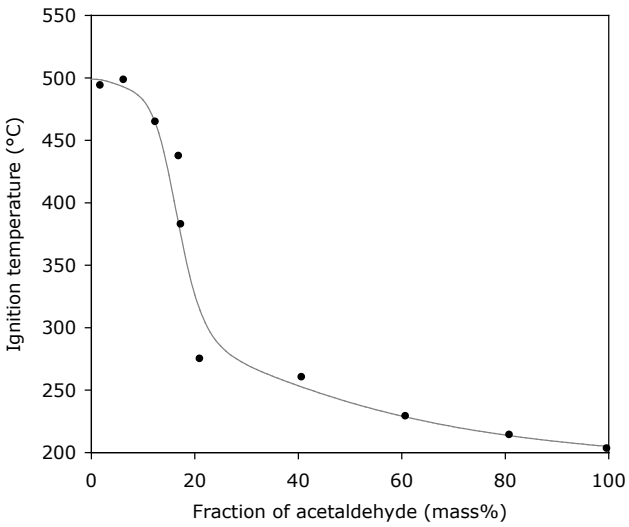

Figure 28 AIT of acetaldehyde/ethylene oxide mixtures in air

global kinetics would be sufficient for any gas, then results for any particular gas would fall along a single, straight line. Instead, most gases show lines with two slopes: a higher temperature and a lower temperature regime. In the high-temperature regime, the effective activation energy E is 50 to 90 kJ mol^{-1}, while in the low-temperature region values are E 140 to 190 kJ mol^{-1}. Not surprisingly, hydrogen, which is the simplest molecule, shows only a single regime. Perhaps surprisingly, given the large number of reactions that take place in real gases, the curves are all composed of two straight lines, rather than being complex shapes. As shown by Sano and Yamashika[79], this straight line relationship emerges even from complex computer modeling of detailed chemical reactions.

Experimental results for much shorter ignition times were reviewed by Goodger[80] and his collation of data for *n*-heptane is shown in Figure 31. In addition to the two regimes identified by the BM work (2 – 100 s), two more regimes can be seen. From the shortest times experimentally examined, around 0.01 ms, to about 0.5 s, a single slope of $E \approx 170$ kJ mol^{-1} can be seen; in the range of 0.5 s to 2 s, a shallow slope of $E \approx 30$ kJ mol^{-1} is found. Chemically, it is more appropriate to attribute the regimes to changes in temperature than changes in time, and thus the results are summarized in Table 4 as temperature regimes. For most other hydrocarbons, the data were not as extensive as for heptane, but Goodger generally found similar trends, with there being four different regimes. For the short ignition times, since the data primarily come from tests where liquid drops were used to produce the vapor, it may be appropriate to take the advice of Zabetakis et al.[81], who suggest that the results can be strongly affected by the evaporation time and not be any direct reflection of actual chemistry.

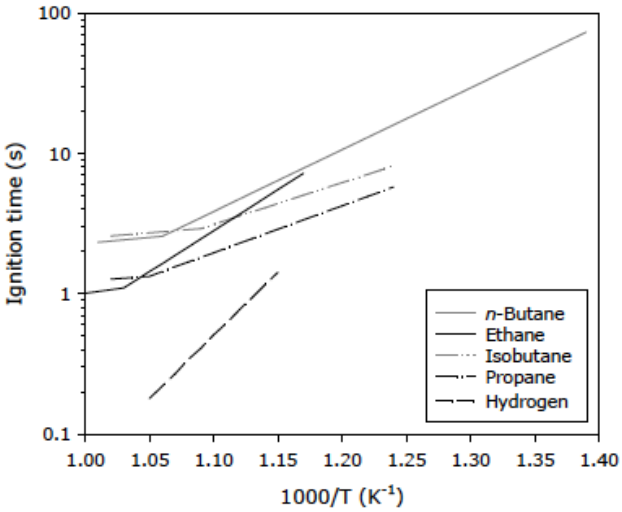

Figure 30 Ignition times for several fuel gases (stoichiometric concentration of the fuel gas in air), as measured by Anagnostou et al.

EFFECT OF FUEL TYPE AND MIXTURE COMPOSITION

For hydrocarbons, the Bureau of Mines developed some general guidance, shown in Table 3. This may be useful when data are available for certain compounds that are similar to the desired one.

The effect of the mixture composition on ignition time was studied in the 1920s by Mason and Wheeler. For methane[66], they found that the shortest times were recorded for the leanest fuel mixtures, and that increasing the fuel concentration increased the time to ignition. No special feature was observed near the stoichiometric value—the induction period just kept increasing with increasing equivalence ratio, φ.

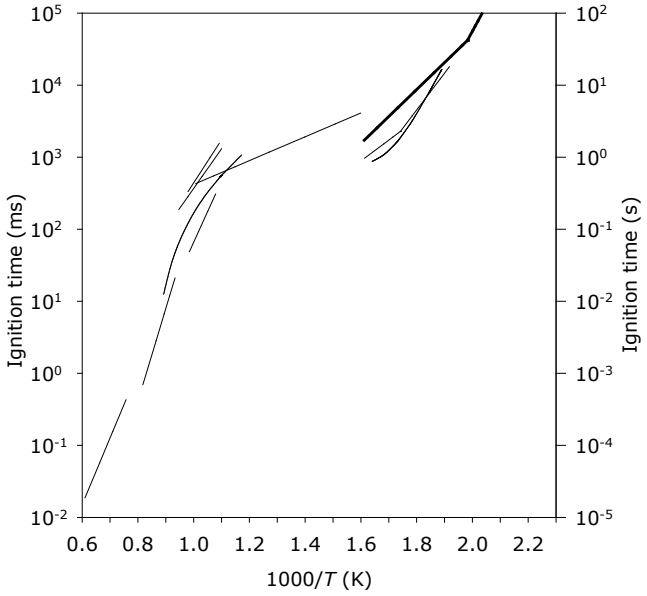

Figure 31 Experimental data for ignition times of *n*-heptane (BM data shown in bold)

Table 3 Effect on ignition time of changing chemical structure of hydrocarbons

Change in chemical structure	Example		Effect on ignition time
	Change from	To	
lengthening chain	*n*-heptane	*n*-octane	decreases
adding side chain	cyclohexane	methyl-cyclohexane	decreases
lengthening side chain	methyl-cyclohexane	ethyl-cyclohexane	decreases
cyclization	1-octene	ethylcyclohexane	increases
saturation	1-octene	*n*-octane	decreases
shifting double bond	1-octene	2-octene	nil

The exact opposite was found for other alkanes: ethane, propane, butane, and pentane[82]. For these gases, the ignition time, at any particular temperature, decreased monotonically with φ. Salooja[83] confirmed the latter finding for a number of other gases. For temperatures in the range of 550 – 750ºC, over concentrations spanning $0.5 < \varphi < 2.0$, the fuels showed a monotonically decreasing ignition time as φ increased. At 800ºC, however, all of the fuels he examined showed very short ignition times which did not detectably vary with φ. Anagnostou et al.[84] used a heated-tube apparatus and found that the results were quite dependent on apparatus minutiae. Nonetheless, they were able to observe that (a) ignition time drops monotonically with fuel concentration, extending even to very rich mixtures; and (b) the ignition time drops monotonically with oxygen concentration, at least over the range 5 – 40% for several hydrocarbon gases that they tested. For kerosene/air mixtures[85], some experimental data show that fuel concentration does not influence the ignition time, if only very lean mixtures are considered. Figure 33 illustrates that a roughly power-law relation is obeyed for ethane/air mixtures even up to extremely rich mixtures. For ethane, the 50% fuel concentration is way above its UFL (12.4%), but combustion is possible since the temperatures involved are very high.

For propane/oxygen/nitrogen mixtures, Jackson and Brokaw[86] found that:

$$t_{ig} \propto X_F^{-1} X_O^{-0.25}$$

where X_F = fuel concentration (mole fraction), and X_O = oxygen concentration. For kerosene/air mixtures, Mullins[87]

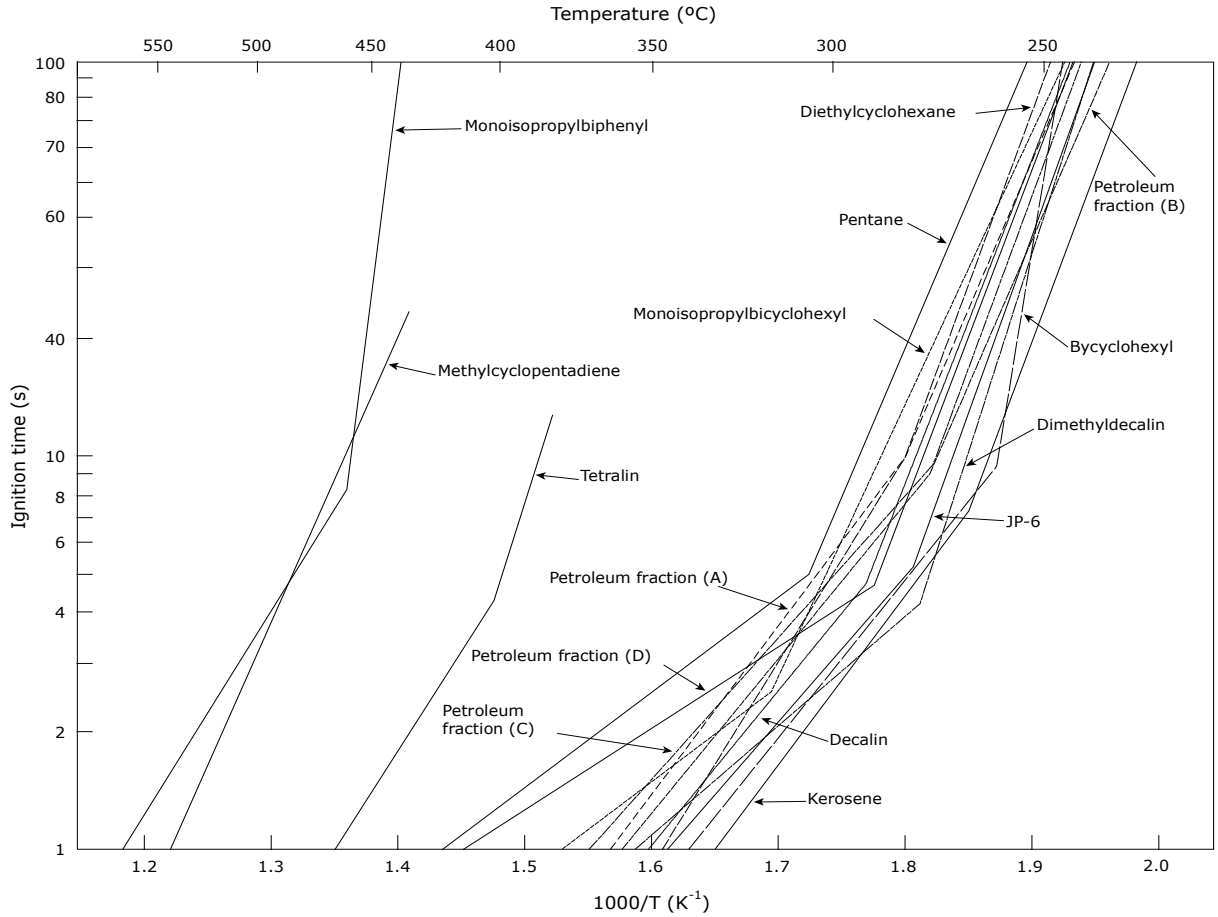

Figure 32 Ignition times for a number of gases measured by the Bureau of Mines

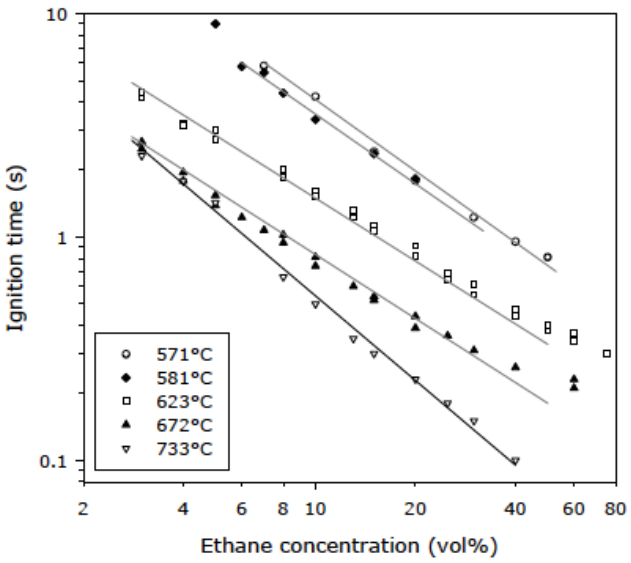

Figure 33 Effect of fuel concentration on the ignition time for ethane

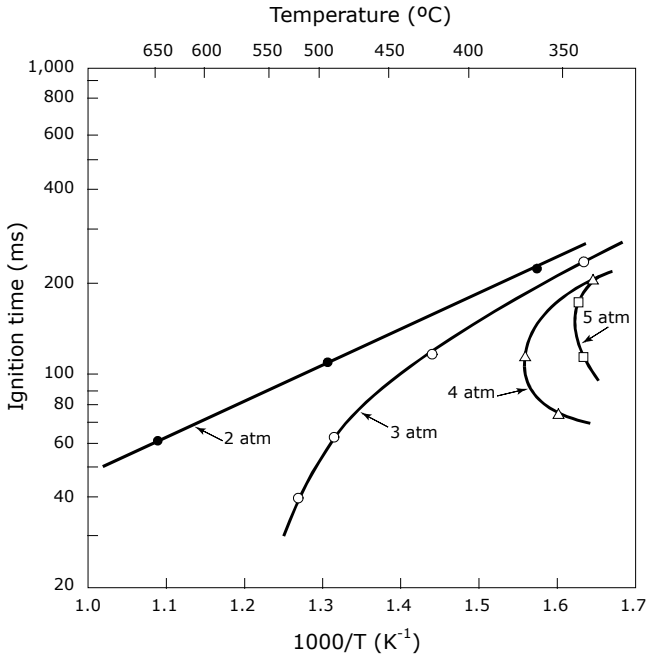

Figure 34 Effect of pressure on the ignition time of pentane

stated the results that

$$t_{ig} \propto (OI)^{-2}$$

where OI = oxygen index (--), but he did not provide experimental details. The most extensive studies, although only on a single fuel, LPG, were done by Miller[61]. Over a very wide range of fuel concentrations, he found no fuel concentration effect and found that the only mixture property that governed ignition times was the oxygen index, OI. His results were given by:

$$t_{ig} = \left(\frac{1}{OI}\right) 4.88 \times 10^{-13} \exp(32{,}400 / T)$$

where T = temperature (K). The conclusion from the above research studies, unfortunately, must be that the experimental results and their derived correlations are in very wide disagreement and that useful recommendations of some generality do not emerge.

EFFECT OF PRESSURE

Increasing the mixture pressure generally shortens the ignition time, as measured by the Bureau of Mines[78] (Figure 34). It has typically been proposed that the pressure-dependence has the form:

$$t_{ig} \propto P^{-n} e^{E/RT}$$

or, alternatively, as:

$$\ln t_{ig} = \left(\frac{E}{R}\right)\frac{1}{T} - n \ln P + a'$$

where the constant a' is different from the a used before. As shown above, Spadaccini and TeVelde concluded that n = 2, but not all experimental results obey this power law. Schihl et al.[88] surveyed the literature and found proposed values to span $0.4 \le n \le 2.5$, although most of the values were between 1.0 and 1.25. Unfortunately, Figure 34 shows that, apart from the pressure dependence, even the temperature dependence no longer follows the expected exponential form at higher pressures.

EFFECT OF FLOW RATE

Jackson et al.[89] studied the ignition of propane/air mixtures using a test apparatus where the fuel and oxygen were separately preheated to the same temperature, then introduced as a flow stream into a mixing chamber. They found that (a) there was an optimum flow rate at which the minimum ignition time was recorded; and (b) this flow rate increased with increasing fuel concentration.

SUB-IGNITION, TWO-STAGE, AND MULTI-STAGE IGNITIONS

Many organic substances, when tested in flask-type AIT tests, show a surprisingly long time to reach flaming ignition—minutes, rather than seconds[90]. This is taken as indirect evidence that much of the induction period is taken up by slow oxidation reactions, and that fast oxidation takes place only at the very end of that period. For some hydrocarbon fuels, over a certain range of pressures and temperatures, ignition occurs as a two-step process. First, a 'sub-ignition,' that is, a cool-flame (weak blue) ignition occurs,

Table 4 Effective activation energy for *n*-heptane ignition

Temperature range (C)	E (kJ mol^{-1})
220 – 300	130
300 – 350	75
350 – 650	30
650 – 1300	170

then some time later this is followed by a hot-flame (orange) ignition. The process is important to designers of internal combustion engines, since it manifests itself as 'knock.' Kane's study[91] provides an example of experimental research on the topic. Photos obtained by Pearlman[92] (Figure 36) illustrate the two-stage ignition process and also show the effect of buoyancy due to normal gravity. In the presence of buoyancy, a heated zone first develops at the top of the test vessel, consequently, reactions are also earliest completed at the top. For unwanted fires, it may be important because a cool ignition could lead to a hot-flame ignition. In systems not involving cool flames, raising the temperature shortens the time needed for reactions to take place. But because of the competing-reactions nature of cool flames, fuel/air systems involving cool flames sometimes show a minimum when ignition time is plotted against temperature. In other cases, a single straight line plot is obtained for both regimes. Figure 35 shows experimental results obtained by D'Onofrio[3]. Since both regimes are correlated by a single line, it can be concluded that, for ethylene glycol, the limiting step of reaction kinetics is identical, irrespective of whether the mixture ignites in a cool flame or in a hot one. Under some pressure/temperature/concentration conditions, multi-state ignitions may occur[11,93]. The whole field of multi-stage and oscillatory ignitions has produced rich possibilities for research in mathematical chemistry, but it has not been readily possible to reduce the findings to tabular or simplified data that might be then applied to safety issues.

IGNITION DUE TO COMPRESSION OR SHOCK

A gas volume can be ignited without the use of a localized external source of energy by raising the pressure of the system. This particular mode is occasionally the cause of unwanted fires or explosions. The primary examples are air compressors (see Chapter 14) and high-pressure oxygen systems (Chapter 13). As far as wanted fires go, in a Diesel engine the fuel/air mixture is ignited by compressing the volume by about 15-fold. The Diesel engine, however, uses

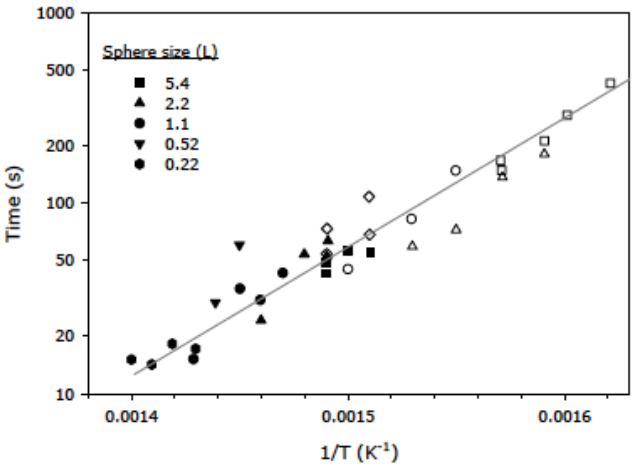

Figure 36 Ignition (solid symbols) and sub-ignition (open symbols) times for ethylene glycol

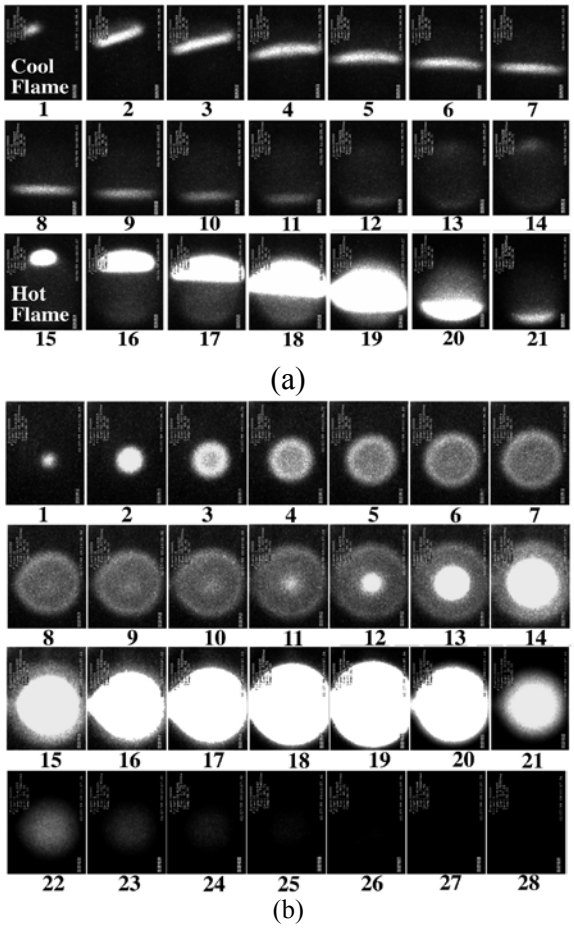

Figure 35 Two-stage ignition in butane/oxygen (50/5) mixture, P = 0.33 atm, T =310°C. (**a) Normal gravity**; time between sequential frames = 1/10 s. (**b) Microgravity**; time between sequential frames = 1/30 s. *(Courtesy Howard Pearlman)*

a mixture which is a liquid aerosol, not a premixed gas mixture. The mathematical basis for predicting compression ignition is treated in Chapter 11.

If compression is rapid, the process can be treated as being adiabatic, since the time available for heat losses to occur is small. Ignition temperatures have been reported from such 'rapid compression machines,' but these have little applicability to non-engine applications, since the ignition temperature is evaluated at some high pressure (typically 10 – 20 atm), and ignition temperature is pressure-dependent (as shown above). In addition, the limits of flammability reported from compression ignition experiments are much wider than for ignition of stagnant mixtures. For example, Shepherd[94] found a flammability range of 2 – 75% for methane/air mixtures undergoing compression ignition. He also found that there is a *maximum* pressure for ignition to occur, and at very high compressions it was not possible to obtain ignition. An additional complication is the need to keep the gas mixture at an elevated temperature for some

time (induction period) before ignition will take place. The fluid dynamics and heat transfer in a rapid-compression environment are highly non-steady, and it becomes hard to interpret the time variable.

Shock waves also form a potential ignition source which acts by compression. However, the same quantitative relations cannot be applied since, unlike piston compression, (a) the compression is not isentropic and (b) multiple wave reflections can be involved, which serve to increase local pressures. Wolański and Wójcicki[95] conducted experiments showing that an abrupt discharge of a fuel gas into the atmosphere can cause a shock ignition if a certain Mach number is exceeded; they also described a numerically-solved model for predicting the necessary ignition conditions. The situation can arise in practice if a pipe containing a fuel gas under high pressure breaks.

Piloted ignition of premixed gases

A mixture of fuel and oxidizer gases does not need to be heated to an elevated temperature for ignition to occur. A mixture of methane and air that is at room temperature and pressure will readily ignite if (a) the mixture proportions are within certain bounds; and (b) a small source of energy (typically, a spark or a pilot flame) is introduced into the mixture. In this Section, we examine the conditions under which piloted ignition will occur. When the ignition energy source is something other than a pilot flame, the term *forced ignition* is sometimes used to emphasize the more general nature of this ignition energy. We shall use *piloted ignition*, however, to include all forms of introduced energy, and not limiting it to pilot flames. Laser ignition is a mode that has some very specific peculiarities and it will be treated by itself.

In this Section, we shall first consider the basic phenomena involved in piloted ignition. Then, we shall examine applied engineering concepts of flammability limits, and the requirements for the ignition energy source. The two main requirements for the latter are the energy amount and a size limit (quenching distance). Concepts behind these energy source requirements are also presented in this Section.

For piloted ignition, it is important to appreciate the distinction between localized combustion and flame propagation. Sources of adequate energy or temperature will cause a *localized* combustion to take place, sometimes referred to as a "flame cap." If the mixture is not within the *flammability limits*, however, combustion will not propagate to other parts of the gas volume. The localized combustion then is basically of no hazard. Flammability limits are addressed later in this Chapter. It will generally be seen that there is no direct connection between the AIT of a particular gas mixture and the temperature which a local-heating agent, such as a hot surface or a hot gas jet, must attain in order to propagate flame throughout the gas mixture.

There have been a variety of dissimilar theories proposed to quantify piloted ignition. In this Chapter, we will discuss only a few selected simpler or newer theories. We refer the reader to Jones[96] for a review of some other theories.

IGNITION WITH THE PRESENCE OF EXCITED SPECIES

The simplest mode of 'forced' ignition involves just a heated surface. In that case only heat energy is added to the system. An electric spark or arc, apart from high temperatures, also contributes excited species and those can help get the combustion chain reaction started. Quite obviously, an existing zone of combustion, i.e., a pilot flame, will also contribute excited species. Ignition of gases by ignition sources involving excited species are thus considered as a group in this section. Ignition by mechanical breaking of current-carrying wires clearly involves ignition by an electric spark. When wires break due to melting out (fusing), the ignition mechanism also involves excited species, as produced by the electric spark the occurs when the wire ends separate. However, to consolidate the presentation of all of the material concerning hot wires, fused-wire ignitions are discussed together with hot-surface ignition in the section dealing with ignition in the absence of excited species.

SPARK IGNITION PHENOMEMA

The theory and fundamental physics of electric spark and arc discharges are presented in Chapter 11. The theory of gas ignition from a spark is given in the next section. Following that, experimental results, apparatus-dependent factors, and data for common gases will be considered. The most important variable relevant to the spark ignition of gases is the *minimum ignition energy* (MIE). A related variable of great importance is the quenching distance. It is found experimentally that flames cannot propagate through very small spaces, and the minimum distance between solid surfaces (which act as heat sinks) is called the *quenching distance*. Quenching distance is of great importance in various flames, not just those ignited by sparks, but it has traditionally been studied—both theoretically and experimentally—in conjunction with spark ignition work. A quantity related to the quenching distance is the *maximum experimental safe gap* (MESG). For reasons to be made clear later, MESG concepts are discussed under piloted ignition in the absence of excited species.

In general, ignition from a spark or an arc between two metallic electrodes can be caused in two ways: (1) by applying a sufficiently large voltage across electrodes held a fixed distance apart, or else, (2) by opening or closing and electric contact. As will be seen in detail below, for fundamental research studies only the first method is suitable. The second possibility, however, can represent actual industrial ignition scenarios, if for instance, a wire breaks and a flammable gas mixture is ignited. Thus, significant research has also been done in geometries where contacts are

rapidly opened and closed in order to test for ignitability. These studies are taken up in a later section.

Even if the fuel/oxidizer ratio is within the flammability limits, ignition will not occur if the gas mixture is confined in a very narrow tube or other enclosure. The walls of such a tube serve to break the chain reaction necessary for combustion to continue. The active radicals which propagate the chain reaction are able, instead, to react with the walls. Such radicals cannot then continue on to reactions which would increase the 'radical pool.'

The first experimental work on quenching distances was published in 1782 in Vienna by Jan Ingen-Housz[97]. This received little notice until the phenomenon was rediscovered in 1815 by Sir Humphry Davy[98]. Davy determined that flames of a methane/air mixture would not travel along a metal tube with a diameter less than 3.6 mm. He also considered that metal tubes were more effective to suppress flame propagation than glass, since the conductivity of metal was much higher. The idea of a minimum diameter was correct, but the notion of ranking the effectiveness according to conductivity was soon disproved. The subject was approached systematically by Holm in 1932 who conducted extensive experiments using a variety of gas mixtures[99]. A minimum diameter of about 3.4 mm was needed for the worst-case CH_4/air mixture, 9.9% methane in air. For 6.5% or 13% mixtures, a diameter of 8 mm was sufficient to prevent propagation, with a parabolic-shaped curve for intermediate mixtures. For coal gas*, the smallest needed diameter was 1.8 mm, for a 21% mixture. For hydrogen, 0.8 mm diameter was found, under the worst-case of 35% mixture. The needed diameters were roughly the same for both tubes and orifices, but Holm learned that an orifice which was adequately sized to prevent initial flame passage must not be heated for a protracted period. If it is , then flame-arresting action no longer holds, and flame is able to break through.

The minimum opening size through which a flame can pass differs, depending on whether the opening is circular, or slot-like (e.g., between parallel plates). Unfortunately, the term 'quenching distance' is often used for both conditions, so the context must make clear which geometry is being considered. The term 'quenching diameter' is applied only to circular openings.

THEORIES FOR SPARK IGNITION, MIE, AND QUENCHING DISTANCE

In this section we consider theories that attempt to predict the conditions necessary for a spark to ignite a gas mixture and the related topic of the minimum size of a flow channel below which a mixture, even if ignited, will not propagate flame. We will generally see that simple theories for spark ignition give results which are only semi-quantitative. Conversely, sophisticated theories have been developed in recent years which appear to be able to predict experimental results to a reasonable accuracy, but these involve a large computational effort and fall into the realm of fundamental research, rather than fire safety applications. The simplest theories are those which endeavor just to relate the MIE to the quenching distance, with one of these two quantities being required to be experimentally determined. Theories for predicting quenching distance without the aid of experimental MIE data have thus far failed to become useful or, as Jarosiński[100] described the situation: "Numerous existing theories connected but loosely with the facts create considerable bewilderment."

The nature of the spark discharge itself is considered in Chapter 11. Here, the question to be addressed is the following. A spark has been discharged into a combustible mixture: Under what conditions will the spark result in an ignition? To answer this question, the microscopic behavior of the *flame kernel* must be considered. A spark raises a small volume of gas to a very high temperature so that any fuel within the volume can be burned. This kernel flame will proceed to grow if the heat that is released in the process of fuel combustion exceeds the heat losses from this volume. The heat release is proportional to the volume of the kernel, but the heat losses are proportional to its surface area. For a sphere, the volume is $^4/_3\pi r^3$ while the surface area is $4\pi r^2$. Thus, the heat release/heat loss ratio is proportional to volume/surface, which in turn is proportional to r. Given this fact, it is not surprising that there exists a minimum size of kernel flame that is necessary for ignition. It is also evident that ignition is simply to be viewed in this case as a growth of the initial flame volume. Conversely, if no ignition occurs, then the volume of flame will not grow. Only a fraction of the energy delivered by the spark is actually available for heating and sustaining the temperature of the flame kernel. The remainder is dissipated as shock wave energy and as heat conduction and radiation. It is empirically found that if the amount of energy delivered by the spark is insufficient, then the flame kernel rapidly decays and extinguishes after consuming only a small amount of fuel. If, on the other hand, the amount of energy is greater than a certain value, a steadily propagating flame occurs, which consumes all of the fuel available. A successful spark ignition theory, then, should be able to predict this minimum energy.

The simplest theory is Litchfield's[181]. He suggested that the MIE and the quenching diameter can be related by means of a simple conceptual model. The flame kernel is viewed as an expanding gas bubble, and the mechanical work needed to expand the bubble to the quenching diameter d_T is taken as being equal to the MIE. In ambient atmosphere tests, the bubble will be at nearly atmospheric pressure, thus $W = PV$, where $P = 1$ atm and $V = \frac{1}{6}\pi d_T^3$. Therefore,

* Coal gas is a mixture of about 50% H_2, 18% each CH_4 and CO, and rest CO_2, O_2, N_2, and miscellaneous hydrocarbons.

$$MIE = 0.053 d_T^3$$

where MIE (mJ) is given solely as a function of d_T (mm). Litchfield noted that experimental data showed this relation to be true, to within about a factor of 2.

Litchfield's theory considers no chemical or thermal properties of the gas mixture. A number of authors suggested taking the basic thermochemical properties into account by considering the energy that must be put into a sphere of diameter d_T in order to raise its temperature to the adiabatic flame temperature T_f:

$$MIE = mC\left(T_f - T_o\right) = \frac{\pi}{6}\rho C\left(T_f - T_o\right) d_T^3$$

In this formulation, the MIE also varies as d_T^3, but with different numeric constants. If a stoichiometric fuel/air mixture in air is considered, then $\rho \approx 1.18$ kg m^{-3}, $C \approx 1.0$ kJ kg^{-1} K^{-1}, and $(T_{ad} - T_o) \approx 1900$ K. Inserting these constants gives:

$$MIE = 1.17 d_T^3$$

This formulation turns out to be of limited use, since the predicted MIE values are about 20× higher than experimentally measured ones.

Pursuing a slightly more sophisticated thermal theory, Lewis and von Elbe[70] proposed the relation:

$$MIE = K\frac{\pi}{4} d_T^3 \rho C T_o \left(1 - \frac{T_o}{T_f}\right)$$

where K (--) is a 'flame stretch factor.' The flame stretch factor is not easily obtained, but if one sets $K = 1$, and inserts the same ambient-air properties as above, then their equation becomes:

$$MIE = 0.24 d_T^3$$

This is more reasonable than the previous result, but is still not as satisfactory as Litchfield's result.

Various simplified conceptual models have also been proposed to predict the needed value of d_T. Lewis and von Elbe[70] consider that the spark rapidly raises the kernel to a very high temperature, many times greater than the adiabatic flame temperature of any fuel/oxidizer mixture. This kernel then grows in size, but decreases in temperature. If flame propagation (i.e., ignition) is to occur away from this kernel, then by the time that the temperature of the kernel has dropped to T_f, the diameter of the kernel needs to have grown to such a size that the temperature gradient between the burned gas in the core and the unburned gas at the edge has approximately the same slope as the temperature gradient in a steady-state laminar flame through this particular fuel/oxidizer mixture. This theory is a *thermal model*, which considers the heat and mass balance within a spherical or cylindrical body. We will assume that the kernel is spherical, which is a fairly reasonable assumption for a spark created by capacitive discharge between two closely-spaced electrodes. Following Turns[101] we express the heat balance of the flame kernel as

$$\dot{Q}''' V = \dot{Q}_{cond}$$

where $\dot{Q}'''$ = heat generated (W m^{-3}), V = volume (m^3), and $\dot{Q}_{cond}$ = conduction heat loss to the cold gas at the edge of the sphere (W). The volume of a sphere is $\frac{1}{6}\pi d^3$, while its surface area is πd^2. The heat generation term can simply be expressed as fuel mass production × heat of combustion. Since fuel is being lost, the latter is a negative quantity $-\dot{m}_F'''$, while the heat of combustion is simply Δh_c. The gas volume inside the kernel is viewed as all being at one temperature; therefore, this is equivalent to a sphere which has infinite thermal conductivity. Outside the sphere, the temperature goes down from T_f at the edge to T_o as $r \to \infty$. To evaluate the conduction losses at the sphere edge, then, the standard expression[102] for a sphere is:

$$\dot{Q}_{cond} = 2\pi d\lambda\left(T_f - T_o\right)$$

Substituting this into the heat balance equation gives the critical kernel diameter d_T as:

$$d_T^2 = \frac{12\lambda\left(T_f - T_o\right)}{-\dot{m}'''\Delta h_c}$$

To obtain a useful expression for the mass loss occurring per unit of flame kernel volume requires a development of laminar flame theory. This is not trivial, since coupled equations are to be solved for chemical reaction, heat transfer, and diffusion. Instead, we shall simply quote the results from Turns:

$$\dot{m}_F''' = \frac{-\rho S_L^2}{2\alpha\left(r_o + 1\right)}$$

where α = thermal diffusivity (m^2 s^{-1}), S_L = laminar flame speed (m s^{-1}), and r_o denotes the stoichiometry of the combustion reaction according to the definition:

$$1\,\text{kg fuel} + r_o\ \text{kg oxidizer} \rightarrow \left(r_o + 1\right)\text{kg products}$$

In laminar flame theory, a chemical kinetics calculation can be made in order to estimate the laminar flame speed S_L. For our purposes, it will be sufficient to treat S_L as an experimentally determined quantity (see Chapter 3). Thus, d_T can be evaluated as:

$$d_T^2 = \frac{12\lambda\left(T_f - T_o\right)2\alpha\left(r_o + 1\right)}{\rho S_L^2 \Delta h_c}$$

But the heat of combustion Δh_c of 1 kg of fuel goes into raising the temperature of $(r_o + 1)$ kg of products from T_o to T_f. Thus

$$\Delta h_c = \left(r_o + 1\right) C\left(T_f - To\right)$$

This gives an expression for the critical flame kernel diameter as:

$$d_T = \sqrt{24}\frac{\alpha}{S_L} = 4.9\frac{\alpha}{S_L}$$

As Turns points out, the multiplying constant of 4.9 should not be viewed as anything more than qualitative, due to

some extreme simplifications which were made in solving the problem. Not only was the whole system assumed to be isothermal, but even for temperature-dependent variables such as α it is not at all clear what reference temperature needs to be selected. Having said that, however, the dependence of d_T on α/S_L is a useful result, and one which recurs in some much more ambitious theories.

Another approach was taken by Ballal and Lefebvre[103], who undertook to predict both the MIE and the d_T for: (a) quiescent, slightly turbulent, and very turbulent flow conditions; (b) gases, monodisperse aerosols and polydisperse aerosols; and (c) various stoichiometry conditions. Their theory was primarily based on dimensional reasoning and was not a detailed solution of conservation equations. Nonetheless, they found agreement with experimental data. The equations, although closed-form, were lengthy and cumbersome, so we give here solely their results for gases under quiescent conditions. For these,

$$d_T = \frac{10\alpha}{S_L}$$

This is the same as our previous result, but with a different multiplying constant.

A slightly different thermal theory was proposed by Friedman[104] who suggested the relation:

$$\frac{d_T S_L}{\alpha} = k\left(\frac{T_f - T_{ig}}{T_{ig} - T_o}\right)^{1/2} = Pe$$

where d_T = quenching diameter (m), S_L = laminar flame speed (m s^{-1}), α = thermal diffusivity (m^2 s^{-1}), k = a constant, and the subscripts denote f = flame, ig = ignition, and o = ambient. The non-dimensional grouping of constants Pe is identified as the *Peclet number*. The temperature at which quenching occurs is not known *a priori*. But, if it can be approximated that T_{ig} is roughly proportional to T_f, then the whole right hand side of the equation becomes approximately constant, and for most fuels Pe ≈ 46. Expressed[105] on the basis of the parallel-late quenching distance d_{II} instead of d_T, Pe ≈ 40. Subsequently, Mayer[106] showed that Pe increases slightly with increasing T_{ad}, and increases significantly with increasing activation energy of the combustion reaction. However, since lumping all of flame chemistry into a single activation energy is a gross empiricism and its value cannot be foretold from more fundamental considerations, it did not appear that such relations were going to be helpful. Furthermore, even if this were successful, it would be much easier to actually measure d_T than to accurately determine both S_L and α. A large number of later, more sophisticated theories have been reviewed by Potter[107]. None of them offer any greater help in interpreting, collapsing, or extending empirical results than the simple relationships given above.

Experimentally[100], it has been found that:

$$\frac{d_{II}}{\delta_L} = 2.0 \text{ to } 2.2$$

where δ_L = laminar flame thickness. That is unsurprising, although the relation is not all that useful, since δ_L is not a quantity that is simple to measure, nor is it widely tabulated.

The relation between the parallel-plate quenching distance d_{II} and the quenching diameter in a tube, d_T, has been found to be[107]:

$$d_{II} = 0.65\, d_T$$

Note that there is no difference between the parallel plate geometry and the geometry where flanged electrodes are used (described later in this Chapter).

For turbulent, flowing gas mixtures, Ballal and Lefebvre[161] proposed the relations:

$$d_{II} = \frac{10\alpha}{S_L - 0.16u'} \qquad \text{if } u' < 2S_L$$

$$d_{II} = \frac{10\alpha}{S_T - 0.63u'} \qquad \text{if } u' > 2S_L$$

where S_T = turbulent flame speed (m s^{-1}), and u' = turbulence intensity (m s^{-1}).

More accurate results might be expected if additional phenomena involved in the flame initiation are included. The phenomena are very complex, since the spark discharge causes a tiny, localized shock wave to be propagated and the energy going into this shock wave is a crucial factor determining ignition or non-ignition. Thus, it was not until 1980 that a model was developed which includes some of these advanced features[108]. According to Adelman, the critical kernel diameter is the same as the critical quenching diameter d_T which is experimentally found to be $b\alpha/S_L$, where b = 10 to 16. For ignition to occur, when kernel reaches the critical diameter, the kernel must be expanding at a speed at least equal to the laminar flame speed. From his theory, a relation for MIE was developed:

$$MIE = \frac{\pi}{4}\left(\frac{\gamma}{\gamma - 1}\right) d_g P d_T^2$$

where d_g = spark gap (m), P = pressure (Pa), d_T = critical kernel diameter (m), and = 1.4 for air. To compare with the simpler theories, if $d_T = d_g$ = 2 mm and P = 1 atm, then Adelman's theory predicts MIE = 2.3 10^{-3} J = 2.3 mJ. Experimental values of MIE for gases having d_T ≈ 2 mm are typically found to be 0.3 – 0.5 mJ, so the prediction is not very accurate. By contrast, Litchfield's simplistic theory predicts MIE = 0.4 mJ, so unfortunately the more sophisticated theory does not give better results. Adelman also predicted that the time period for the energy pulse must be greater than about 1 μs for ignition to occur.

A new theory was offered by Frendi and Sibulkin in 1990[109], which required knowing the diameter over which

the spark energy will be deposited. At the smallest diameters, it led to a predicted MIE for methane about 70× lower than the measured value. Sloane and Ronney[110] concluded that the huge discrepancy was because Frendi and Sibulkin simplified the chemistry by using only a 1-step global Arrhenius reaction rate. Their own model, using detailed chemical kinetics, indicated an MIE, valid over a b road range of small deposition diameters, which quite closely matched the experimental value; as might be expected, their model is highly complex and requires detailed computer simulations to be run for each case. Sloane and Ronney's detailed calculations also showed that the energy required for ignition rises if the spark energy is deposited over too-broad a region. For a minimum value of ignition energy to be reached for methane/air mixtures, the region over which the energy is deposited had to be no greater than ca. 0.6 mm diameter. Even though a reasonable result is computed by the Sloane/Ronney theory, it requires as input the diameter over which the spark energy is deposited. Clearly, the theory is incomplete, because this diameter is not under the control of the experimenter. Other purely-computational theories have also been presented[111].

The usefulness of a particular theory depends on the time scale of the spark discharge. For very rapid spark discharges (1 μs), high pressures (> 200 atm) are created in the spark region, and complex hydrodynamic phenomena, including shock waves, become important[112]. For the more typical slower discharges (50 – 100 μs), these phenomena play a smaller role and thermal theories can have a reasonable utility, at least qualitatively.

It has been proposed[56] that there is a relationship between the induction period measured under autoignition conditions, and the minimum spark energy needed for ignition for spark-induced ignition. If the time required for the spark to cool down to the AIT is shorter than the induction period, then ignition will not occur.

All of the theories give the basic result that $MIE \propto d_{II}^3$. A large amount of Bureau of Mines data that Lewis and von Elbe collected are shown in Figure 37 along with the correlation:

$$MIE = 0.07\, d_{II}^2$$

where MIE = min. ignition energy (mJ) and d_{II} = quenching distance (mm). It can be seen that the experimental data follow a proportionality to the power 2, and not to the power 3. The reason why the data do n ot fall along a line of slope 3 is because of the flanged electrodes that were used in the Bureau of Mines studies. Ballal and Lefebvre[161] conducted experiments where the electrodes were 2 mm rods, and found that a power-of-3 relation *was* obtained.

Pitt et al.[113] argued that the poor agreement of even the complex theories was because of an incorrect assumption as to the basic fluid dynamics. As shown in Chapter 11, the spark kernel has a *toroidal* shape over most of the critical

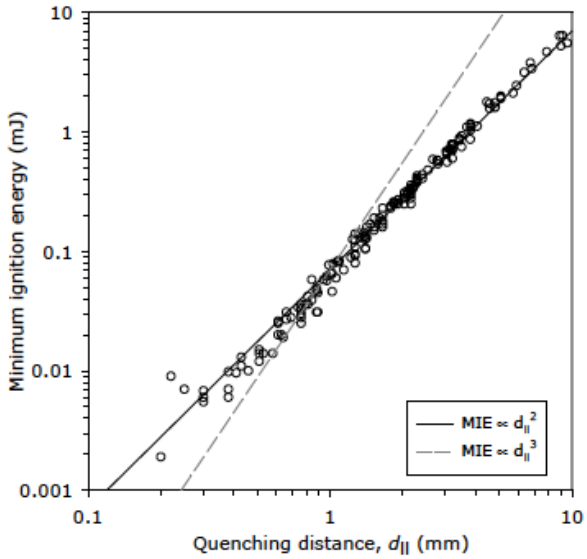

Figure 37 The relation between d and MIE, based on data with flanged electrodes (data for hydrogen, methane, ethane, and propane are included, but there is no effect of fuel type on the relation)

time period, but modeling of this shape is very complicated, partly because the structures become turbulent after an initial laminar growth period. Pitt et al. themselves made substantial progress in fluid-dynamical modeling of the problem, but did not evolve a theory to the point of providing a predictive equation. Most other modelers simplify matters by presuming the shape to be *spherical*. Anderson and Lim[114] concluded that sphericity is a very reasonable assumption despite the toroidal appearance. They measured separately the volume and the surface area for a large number of spark kernels and found the relation is $V \propto A^{1.51}$. This is very close to the relation for a sphere, which is $V \propto A^{1.5}$.

The minimum energy MIE decreases with increasing pressure or increasing initial temperature. Fenn[115] proposed that the relation is:

$$MIE \propto \frac{(T_f - T_o)T_o}{X_o^{3/2} P^2} \exp(3E / 2RT_f)$$

where T_o = initial mixture temperature (K), T_f = adiabatic flame temperature (K), X_o = mole fraction of oxygen in mixture, P = ambient pressure (Pa), and E = activation energy (kJ mol^{-1}). Since the activation energy will differ for each gas and is not necessarily easily obtainable, Fenn further proposed it can be estimated as:

$$E = 67\, T_{LFL}$$

and T_{LFL} = flame temperature at the LFL (K). If the LFL is known from experiment, then the flame temperature at the LFL can be calculated from theory. Fenn provided extensive validation data showing that the agreement with his equation, while not highly precise, is accurate enough for many practical purposes.

IGNITION FROM BREAKING WIRES OR MOVING CONTACTS

UK coal mines in the early years of the 20th century used to have bell signaling circuits powered by 24 VDC. Originally it was thought that arcing from such power supplies would be non-incendive, but accidents soon proved this wrong[116]. These circuits contained inductive elements, such as iron-core bell coils, relays, and other devices. Thus, for many years the Safety in Mines Research Establishment (SMRE) conducted studies on ignition of gases from low-voltage, inductive circuits. Contact arcs or sparks are not limited by Paschen's Law (see Chapter 11), thus discharges can occur at low voltages.

In laboratory breaking-wire experiments, a wire is notched, then pulled apart by two opposing rollers. Once the wire breaks, the two ends comprise electrodes of finite size and their mass can act as a quenching mechanism. Thus, Lord et al.[117] showed that broken-wire ignitions take place at lower currents if the wires are broken very fast or if the wire gauge is very fine. They used the same 24 VDC power supply and an inductance coil of 95 mH, similar to what was used for standard testing by SMRE. For an 8.3% methane/air mixture, the SMRE 'Break-flash No.3' apparatus* which uses a pair of electrodes moving at slow speed to create the arc, gave a minimum current of 185 mA. In Lord's tests, thin copper wires notched and then broken by rapidly pulling apart required currents of 100 – 115 mA. Thick copper wires broken apart needed 160 mA. Very thin tungsten wires (0.025 mm) needed a current of 82 mA. The differences were attributed to quenching. When a flame kernel is forming, the metal parts act to quench it. This quenching will be minimized if the metal parts are either removed very fast from the kernel, or else if they are very small to begin with. The theoretical value of energy that can be stored in an inductor, and therefore delivered from it into a contact spark is $\frac{1}{2} LI^2$, where L = inductance (H) and I = current (A). Based on this theoretical value, in early SMRE experiments[118], about 1.0 to 2.5 mJ was needed to ignite methane/air mixtures. But building on the ideas of Lord and using an optimum circuit inductance and 0.025 mm wire, Berz[119] found a minimum ignition energy of 0.3 mJ which is very close to the 0.2 mJ value commonly cited for capacitive discharge. In actual testing of the potential for breaking parts to ignite gas mixtures, ultimate limits such as the one shown by Berz will not be reached. Thus, practical testing devices (see Chapter 12) simulate realistic heat sink effects, not minimal ones.

Circuits with capacitive elements are also likely to be found in modern electronics. Zborovszky[120] studied in detail the current needed to cause a break-spark discharge in a capacitive circuit. There can, in the general case, be three resistances in such a circuit, one is series each with the power supply, the capacitor, and the break-spark contacts. She considered the simplest case where a resistor exists in series only with the power supply (Figure 38). There are four basic regimes of ignition from such a circuit. To the left of point A, the circuit acts as a purely-resistive circuit. Between point A and point B, the charge on the capacitor contributes some energy, but the major part of the energy comes directly from the power supply. Between point B and point C, the bulk of the energy comes from the charge on the capacitor, while beyond point C, ignition energy is drawn only from the charge stored on the capacitor, and the energy flowing from the power supply is negligible. Observations also indicated that to the left of point B, ignition occurs at a break-spark, while to the right of point at a make-spark.

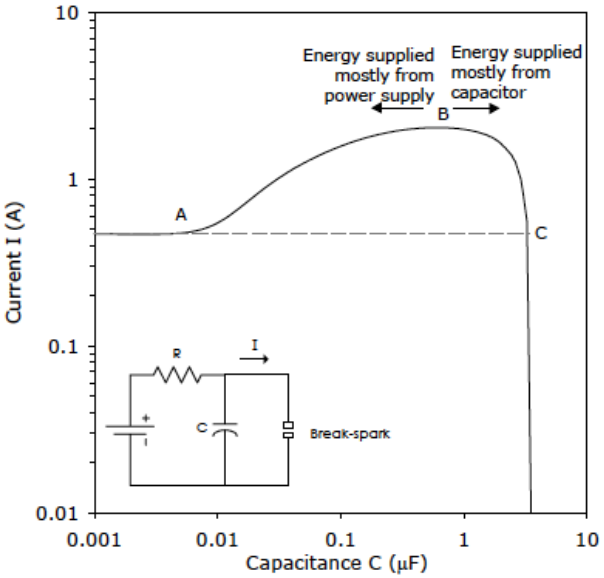

Figure 38 Current needed for ignition of an 8.3% CH_4/air atmosphere using the IEC/PTB break-flash apparatus (IEC 60079-11) fed from a 30 V power supply. At lower supply voltages, the curve would move up and to the right.

In a circuit where resistance plays a minimal role, the loss of energy into the electrodes of a break-spark arrangement can be demonstrated in a plot of capacitance versus voltage required for ignition. If there were no losses, then the voltage required would be:

$$V = \sqrt{\frac{2 \times MIE}{C}}$$

in other words, the results should fall on a line of slope = – ½, when plotted on a log-log scale. The data collected by Magison[149] on methane/air mixtures are shown in Figure 39; the slope is ≈ – ½ for higher voltages, but deviates significantly at lower voltages and a plateau is reached at around 10 – 20 V. This is consistent with a minimum voltage of 10 – 15 V needed to sustain an arc discharge (see Chapter 11).

Some similar data were obtained by Thomas[129], even though he used a capacitive discharge circuit having a non-

* A break-flash or break-spark apparatus involves a cam-operated set of contacts which keep being opened and closed as the cam rotates. This type of test equipment is further discussed in Chapter 12.

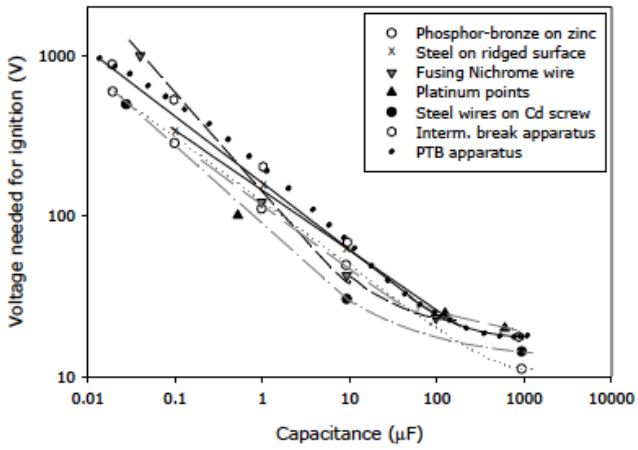

Figure 39 Ignition of methane/air mixtures from break-spark capacitive discharge

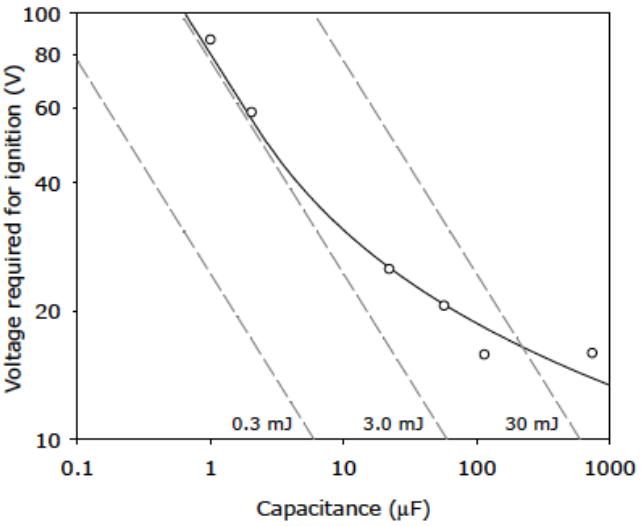

Figure 40 Ignition of 8.5% methane/air mixtures by low-voltage capacitive-discharge sparks (shown in gray are constant-energy contours)

standard arrangement where two pointed electrodes were brought slowly together. Figure 40 shows that, due to quenching effects at small electrode spacings, substantially more energy is needed than the 0.3 mJ that would be required in a circuit where a capacitor charged to a high voltage is discharged across stationary electrodes. The data points are for a circuit where there was essentially zero resistance in series with the capacitor. Thomas also noted that for capacitances greater than about 100 µF and a non-zero resistance (not shown), the ignition curves are nearly horizontal, indicating that a minimum voltage—rather than minimum energy—criterion is governing.

The most common arrangement for break-spark testing is an inductive circuit, with the reported result being the minimum igniting current (MIC). The MIC is dependent both on the circuit voltage and on its inductance[121], as shown in Figure 41. The circuit inductance of 0.095 mH is commonly selected for use in standardized testing, since it corresponds, in most cases, to the end of the plateau portion of the curve. The numerical values refer only to the SMRE Intermittent Break-flash apparatus; Zborovszky[237] has shown that somewhat different results are obtained in the IEC/PTB break-flash apparatus. Methane concentration of 8.3% is used, since this was found to be the most easily ignitable concentration. For a circuit containing a resistance R and an inductance L in series with a power supply of voltage V_o, the energy delivered into the discharge is[122]:

$$E_d = V_m\left[(V_o - V_m)\frac{t_d}{R} + \left(\frac{V_o}{R} - I_m\right)\frac{L}{R}\right]$$

where V_m and I_m are the minimum voltage and current pertinent to the contact materials in question (see Chapter 11) and t_d = discharge duration:

$$t_d = \frac{L}{R}\ln\left(\frac{V_m}{V_m - V_o + I_m R}\right)$$

The value of E_d is greater than the stored energy in an inductor, $\frac{1}{2}LI_o^2$, since part of the energy comes directly from the power supply and not from the inductor; here $I_o = V_o/R$. Note that the equation for t_d indicates that the discharge stops once the current decreases to I_m. The derivation of the above equations presumes that the voltage across the gap is V_m; this is not true if the separation speed is very high, and no simple equations exist in that case.

Figure 42 shows data collected by Magison[149] on the effect of experimental conditions and of inductance for high-inductance circuits. A slope very close to –½ is seen in the high-inductance regime. Also shown are Gehm's data[123] on the minimum current necessary to create a spark that is visible in a dark room.

In a circuit where resistance is the only impedance element present, there is a definite—although not simple—relation between circuit voltage and the MIC and Figure 43 shows results obtained in the SMRE Intermittent Break-flash Apparatus. The results should be viewed as indicative and not absolute, since different values are found using different test rigs[124,129]. UK authorities have used relations of this kind to approve dry cells for use in intrinsically-safe mine equipment that are intended for use in non-inductive circuits. The effect of adding inductance to a resistive circuit is to lower the two leftmost branches of the curve shown in Figure 43; the rightmost branch is unaffected by inductance. Sufficient data points are not available in Figure 41 to derive smooth curves, but it can be seen that they would fall as indicated if plotted on Figure 43. Note also that the minimum voltage of 4 V found needed to ignite a flammable mixture with the SMRE Intermittent Break-Flash apparatus is close to the limit of 5 V that Vogt found needed in fused-wire experiments, as discussed below. These are extreme

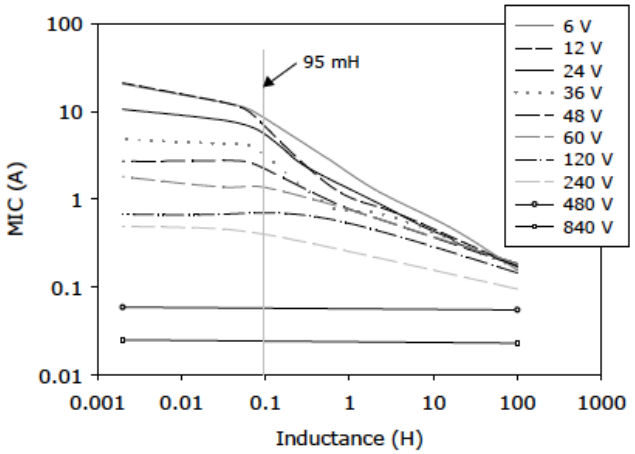

Figure 41 Effect of voltage and inductance on MIC for methane/air mixtures using the SMRE Intermittent Break-flash Apparatus

cases and typically a lower limit of 8 – 15 V is reported in purely resistive circuits. In inductive circuits, however, ignitions have been reported at the 0.5 V level[125], and lower-yet values are not precluded.

The speed at which a contact is opened or pulled apart influences the results. Apart from the quenching effect already discussed above, the voltage/current/time/gap-distance relationship for the spark channel and the associated circuit must be considered. For inductive circuits, at high levels of inductance, a fast break is the most incendive, while for low inductance values a slow break or repeated (intermittent) breaks are most incendive[149].

The role of the discharge time in break-spark experiments with inductive circuits is not fully clear. In one series of tests[126], it was found that conditions were most incendive if spark duration was around 3 ms; discharges that only lasted

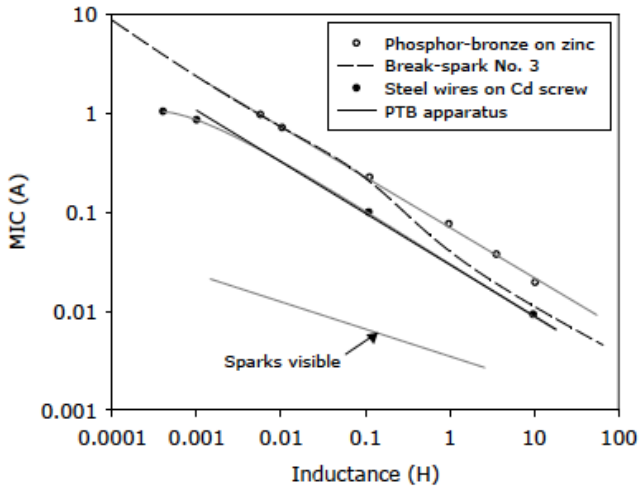

Figure 42 Effect of circuit inductance on the ignition of 8.3% methane/air mixtures in high-inductance circuits

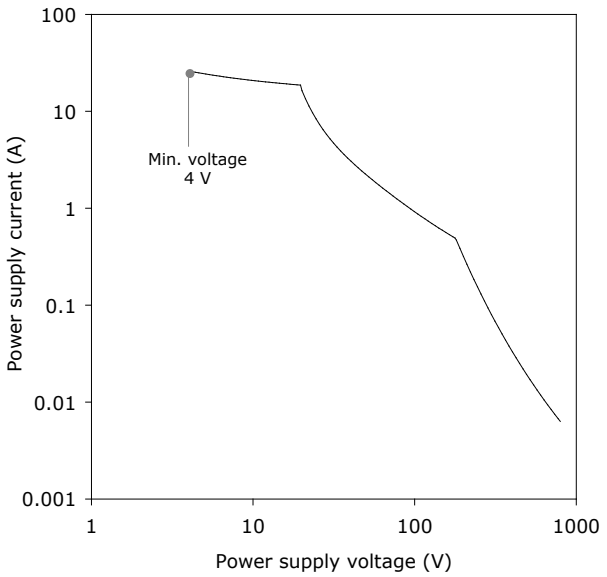

Figure 43 Ignition of 8.3% methane/air mixtures with a resistive circuit: relation between voltage and MIC (SMRE Intermittent Break-flash test apparatus)

microseconds were typically non-incendive (Figure 44). But in another study, varying the spark duration over the range 10 – 30 µs showed no systematic effects on the minimum energy required for ignition[127]. Most of the studies with capacitive discharges have been under conditions of a high voltage causing a breakdown between stationary electrodes, not the creation of an arc or spark by opening a contact in a low-voltage circuit. The issue of spark duration for those conditions is considered later in this Chapter.

The metal used for the electrodes affects the results. The relation is not simple, since different rankings are obtained when testing under conditions of (a) rapid separation, low voltage, and high inductance; or (b) slow separation, high voltage, low inductance. In the former case, it is necessary that the metal be both hard and of a high boiling point for

Table 5 Effect of contact metal on incendivity for slow-separation, high-voltage, low-inductance break-sparks

Metal	Melting point (°C)	Resistivity (nΩ-m)	Incendivity of sparks
tin	232	115	most incendive
cadmium	321	68	
zinc	420	59	
beryllium	1287	35.6	
chromium	1907	125	
aluminum	660	26.5	
nickel	1455	69.3	
iron	1538	96.1	
copper	1085	16.8	
silver	962	15.8	least incendive

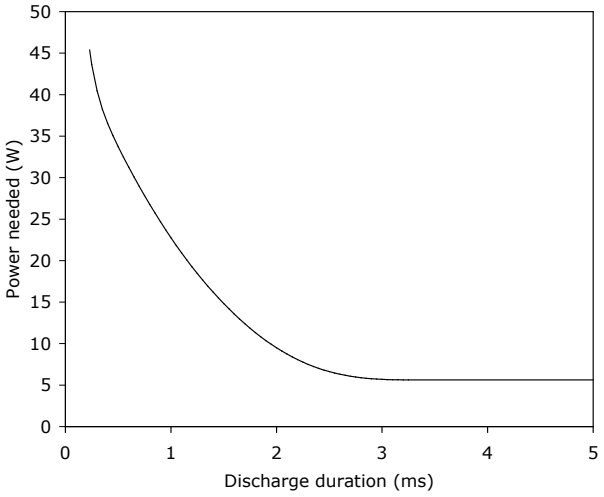

Figure 44 Circuit power necessary for ignition of an 8.3% methane/air mixture using the IEC/PTB break-flash apparatus (27 VDC power supply, resistive circuit, spark at a tungsten wire separating from a cadmium plate)

the most incendive results to be obtained. Tungsten is the most incendive under those conditions. In the latter case, the opposite prevails—soft, low melting-point metals are found the most incendive. These include cadmium, zinc, and magnesium. According to German studies[128], the rank ordering of contact metals under those conditions is as shown in Table 5. Thomas[129] summarized some of the early research on this topic, but simple guidance was not possible under all conditions.

Fuel concentration strongly affects the MIE value in the case of high-voltage capacitive discharge sparks. But for break-sparks, experiments showed that it affects the results only to a small extent, provided the mixture is well within the flammability limits[237].

From the above discussion, it can be seen that, apart from details of test electrodes, the main parameters determining whether or not a given flammable gas atmosphere can be ignited are:

- the voltage available from the power supply
- the current available from the power supply
- the nature of the circuit elements.

To determine if an actual electric device can ignite the given atmosphere, testing is normally required, since the effective values of circuit capacitance or inductance may not be easy to calculate. Procedures for used for this type of testing are described in Chapter 12.

PILOT FLAME IGNITION

The introduction of a pilot flame into a fuel/oxidizer mixture well within its flammable limits will not necessarily result in ignition of the mixture. As early as 1906, Beyling[130] pointed out that a flame may be ejected from

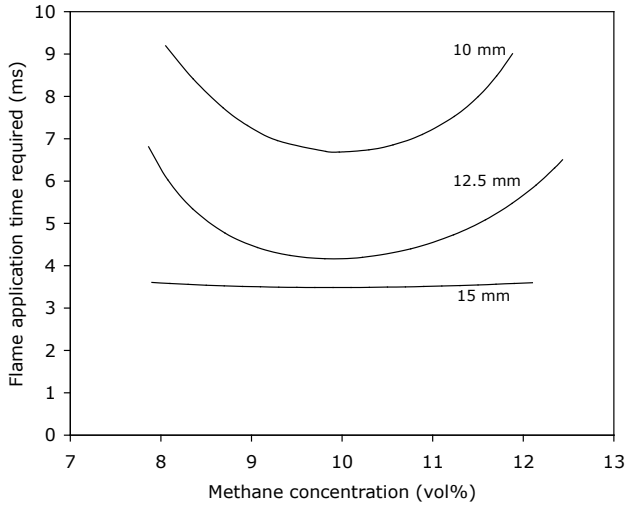

Figure 45 Ignition of methane/air mixtures by a pilot flames of various lengths

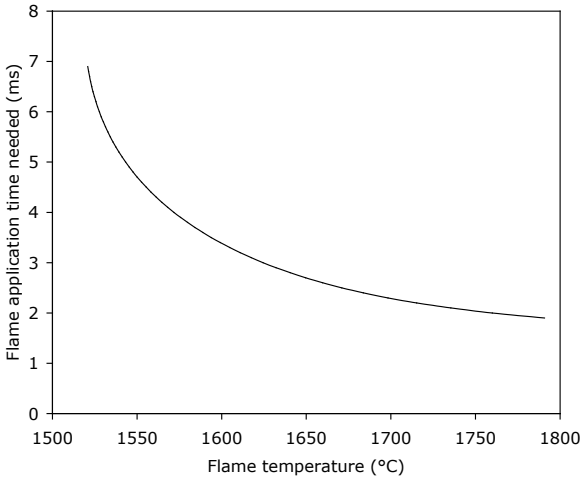

Figure 46 Flame application time needed to ignite methane/air mixtures of optimum ignitability with a small flame

small openings of a vessel wherein an explosion was taking place, yet fail to ignite a flammable mixture located outside the vessel. The concept is also well-known in the testing of 'permissible explosives,' which may emit a flame yet fail to ignite a flammable atmosphere. In general, studies have shown that for ignition to occur, the flame has to:

- have a sufficient temperature
- be of sufficient size (i.e., high enough HRR)
- be applied for a sufficient time

In 1926 Walls et al.[131] measured the time that it takes for a small, downward-pointing pilot flame to ignite methane/air mixtures. The results (Figure 45), not surprisingly, show that the minimum time required is near the stoichiometric concentration (9.5%), although slightly above it. Perhaps less expected is the substantial effect of the igniting flame

size on the time required. In additional tests using a different apparatus, where flame shape and dimensions were not specified, the authors varied the flame temperature and measured the application time needed for ignition (Figure 46).

Wolfhard and Burgess[132] later demonstrated that the temperature of a pilot flame capable of igniting the mixture is unrelated to the AIT of the mixture. In studying methane/nitric oxide (NO) mixtures, they determined an AIT value of 1110ºC, but the temperature of pilot flames had to reach 2100 – 2300ºC (varying slightly with the fuel type used for the pilot) for pilot-flame ignition to occur. Somewhat higher pilot flame temperatures were required at very low pilot-flame flow rates. Observations indicated that ignition of the mixture occurs not near the main reaction zone of the pilot flame, but above the visible tip of the pilot flame. It was also found that fuel-lean pilot flames ignited mixtures more readily than pilot flames operating at stoichiometry. Wang et al.[133] proposed a s teady-state theory relating the length and velocity of the pilot flame to the burning velocity of the gas mixture, but its experimental validity is not clear.

A number of anomalies have been discovered with pilot flame ignition of fuel/air mixtures. Sawerysyn[134] et al. found that, under some circumstances, introducing a pilot flame into a stagnant methane/air mixture somewhat above its LFL did not result in flame propagation. They attributed this to the dilution effect of the pilot flame's combustion products. For ignition to occur, a location has to exist where the fuel/air mixture ratio is favorable and the temperature is sufficient. The experiments of Sawerysyn indicated that there can be an absence of a location of this kind. Not surprisingly, then, their work also showed that, under some circumstances, a smaller pilot flame was more effective in causing rapid, complete combustion of the gas/air mixture than was a larger flame. Conversely, Karim et al.[135] studied the ignition of flowing fuel/air mixtures with pilot flames and found that these were flammable in some cases at lower fuel concentrations than published in standard tabulations. This was attributed to the heating effect of the pilot flame on the flowing gas mixture.

Gases which contain halogen atoms can be difficult to ignite with a flame, since halogens interfere with chain propagation needed for combustion. According to Jones[136], such substances are more easily ignited by a spark but his study did not establish quantitative trends.

IGNITION BY BURNING PARTICLES

It is not difficult to ignite gas mixtures with burning particles, which may be friction sparks, flying brands, etc. Sparks caused by metal tools impacting upon solid objects are a well-known cause for coal mine explosions. In warfare, burning particles are exploited in incendiary weapons. Homan and Sirignano[137] examined the propensity of burning aluminum particles to ignite methane and propane mixtures. For methane/air mixtures near $\varphi = 1$, the minimum particle diameter was found to be 20 μm. For $\varphi = 0.6$, about 80 μm particles were needed, while for $\varphi = 1.4$ about 40 μm. For propane, the minimum size was found to occur not at $\varphi = 1$, but rather at φ of 1.3 to 1.8; a diameter of 20 μm being needed in that range. For $\varphi = 1$, a diameter of 40 m was needed, for $\varphi = 0.6$ around 100 μm, and for $\varphi = 2.1$ around 40 μm. The energy delivered by the burning metal particle is the product of the particle's mass times Δh_f, the heat of formation of the metal oxide (minus sign disregarded). Thus, a 20 μm diameter aluminum particles delivers

$$E = \frac{1}{6}\pi d^3 \rho \cdot \Delta h_f = \frac{1}{6}\pi \left(20\times10^{-6}\right)^3 2700\times31\times10^6$$
$$= 0.35 \text{ mJ}$$

where the heat of formation of Al_2O_3 is -31×10^6 J kg^{-1}. A comparison of the aluminum particle results with those for spark ignition showed that, to within the expected accuracy of the determination, there was no difference in the MIE obtained by the two methods. By comparison, an aluminum particle which was at the same 2300 K temperature as a burning one, but without combustion taking place, would have to be of 140 μm size under conditions where a 20 μm burning particle sufficed for ignition. Additional information on this topic is given in Chapter 11.

VARIABLES AFFECTING IGNITION OF GASES WHEN PILOTED WITH THE PRESENCE OF EXCITED SPECIES

In this section we consider the effects that various variables have on the piloted ignition of gases that involves the presence of excited species. The information is generally restricted to ignition from a high-voltage capacitive discharge circuit. There is almost no information of this type for ignition from pilot flames, burning particles, or other forms of ignition that entails the presence of excited species. As discussed above, the behavior of fuel-air mixtures when ignited from low-voltage sparks generated by making or breaking electric contacts can be quite different from that when ignited by a high-voltage spark passed between stationary electrodes. However, again there is not much systematic information on the effects of chemical or physical variables.

CHEMICAL NATURE OF THE FUEL

The theories considered above indicate that the quenching distance depends on the laminar flame speed (S_L) of the gas and that, in turn, MIE depends on the quenching distance. Thus, MIE should be a function of S_L. This was explored to a very limited extent by researchers in the 1950s. Metzler[138] proposed a correlation that $S_L \propto \text{MIE}^{-0.8}$. Potter and Berlad[139] suggested that the laminar flame speed and the quenching distance are related as:

$$S_L d_{ll} = 1.2\times10^{-4} T_o T_f$$

where S_L = laminar flame speed (m s^{-1}), d_{ll} = quenching distance (m), T_o = ambient temperature (K), and T_f = flame temperature (K). Further research appears not to have been

pursued in this vein. The reason is a practical one—it is much easier to obtain a reliable value for MIE or d_{II} than it is to measure S_L to a reasonable accuracy.

Within a given chemical family, for fuel-rich mixtures, the quenching distance decreases with increasing molar mass of the fuel[107]. A dependence has not been documented for lean mixtures.

OXYGEN CONCENTRATION

Increasing oxygen concentration lowers the MIE as does increasing the total pressure of the mixture. This is illustrated in Figure 47 and Table 6. Chin[140] proposed that MIE is proportional to oxygen concentration to the –4 power. This appears to be a rather high exponent, and Ural et al.[141] noted that the data of Lewis and Von Elbe[70] are better represented by $MIE \propto (OI)^{-2.5}$, where OI = oxygen index, $O_2/(O_2+N_2)$, with the propane data following the power law:

$$MIE_{propane} = 0.0034 P^{-2.1} (OI)^{-2.5}$$

where at any OI value, the propane concentration used was the one giving the lowest ignition energy. Whether this has applicability to other gases can be tested, to a limited extent, by plotting Litchfield's data from Table 6 according to a –2.5 power law. Figure 48 shows that the results for acetylene are well predicted; however, for the remaining three gases the expected slope is not followed.

The effect of oxygen concentration on the quenching distance of methane is illustrated in Figure 49[142]. For tests run in O_2 instead of air, quenching distances about a factor of 5 smaller are found experimentally[50]. As an example, ethylene shows 1.25 mm in air, but 0.19 mm in O_2. The number of substances where quenching distances in O_2 have been reported is small, however. Most of these reported values are in the 0.15 to 0.30 mm range. Table 6 shows additional data.

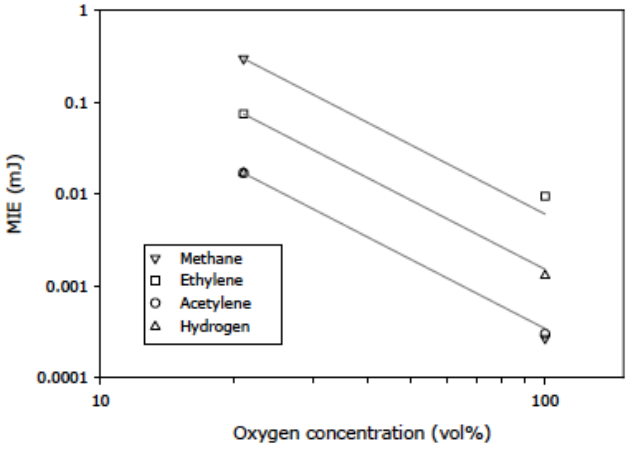

Figure 48 Correlation of MIE according to a -2.5 power law dependence on oxygen concentration

DILUENTS

If the fuel is mixed into an atmosphere which comprises oxygen and a diluent gas other than nitrogen, then MIE values and quenching distances can be expected to change. Lewis and von Elbe[70] present a illustrative data for a few gases. Not enough experimental data are available to draw quantitative conclusions, but basically the dominant effect is the heat capacity of the diluent gas—gases with higher heat capacity values show higher MIE values and greater quenching distances. Anomalous results, as often in combustion, are found when very small molecules, such as He, are involved.

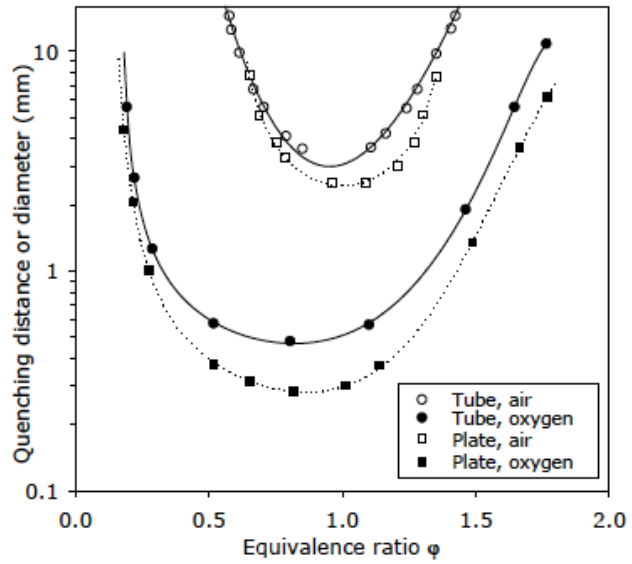

Figure 49 The effect of equivalence ratio and oxidizer type on methane quenching distance (between flat plates) and quenching diameter (in tube)

Table 6 Effect of oxygen concentration on MIE[181] and on quenching distance[107]

Fuel	MIE (mJ)		Quenching distance *d* (mm)	
	Air	O_2	Air	O_2
acetylene	0.017	0.0003	0.52 – 0.65	0.08 – 0.10
ethylene	0.075	0.00095	1.25	0.19
hydrogen	0.017	0.0013	0.5 – 0.64	0.2 – 0.34
methane	0.3	0.00027	2.2 – 2.5	0.3
propane	NA	NA	1.75 – 2.28	0.21 – 0.27

FUEL CONCENTRATION

The effect of the fuel/air ratio on the MIE, as measured at the Bureau of Mines[143] for various alkane-series hydrocarbons is shown in Figure 50. If the fuel and the oxidizer had identical diffusivities, the minimum energy would fall at the stoichiometric mixture condition ($\varphi = 1$). Molecules lighter than air (hydrogen, methane) have higher diffusivities and the MIE for those occurs at $\varphi < 1$. This is because it is more difficult for oxygen molecules to diffuse into the reaction zone than for fuel molecules, consequently, a super-proportional amount of oxygen molecules is needed. Conversely, most other fuel molecules are heavier than air, and for them the MIE occurs at $\varphi > 1$.

Ural et al.[141] noted that the value of φ at which the minimum ignition energy occurs depends on the molar mass in a predictable way. For alkane-series hydrocarbons, a correlation can be found (Figure 51) which is:

$$\varphi\big|_{\text{MIE miminum}} = 0.29 + 0.155\sqrt{W}$$

where W = molar mass (g mol^{-1}) and it is assumed that the atmosphere contains 21% oxygen.

In the experiments represented in Figure 50, varying amounts of fuel gas were introduced into an atmosphere which was at 21 vol% oxygen, prior to the introduction of the fuel. If the oxygen/nitrogen proportions are different, then the MIE will be strongly affected. Figure 52 shows this for methane[70]. The concentration of oxygen is expressed as the oxygen index, OI = $O_2/(O_2 + N_2)$. For alkane-series hydrocarbons (e.g., ethane, propane, etc.), *except* methane, Chin[140] noted that the value of for which the minimum MIE is obtained decreases with OI at the same rate. This enables the following equation that includes the effect of both molar mass and oxygen index to be derived:

$$\varphi\big|_{\text{MIE miminum}} = 0.41 + 0.155\sqrt{W} - 0.57(OI)$$

Thus, for example, for propane W = 44.1 and at room conditions (OI = 0.2095) the value φ to obtain the lowest MIE is = 0.41 + 0.155×6.64 – 0.57 (0.2095) = 1.32, while in pure oxygen (OI = 1.0) it falls to 0.87. A limited amount of validation data indicates that the equation is valid at ambient and sub-atmospheric pressures and for both still and flowing mixtures.

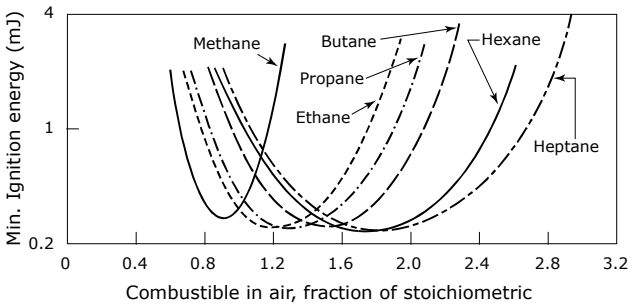

Figure 50 The effect of fuel/air mixture on the MIE for alkane-series hydrocarbons

The means used to cause ignition has some effect on the most-easily-ignitable gas concentration. Singer et al.[144] collected data on this issue for methane/air mixture, shown in Table 7. Stoichiometric concentration of methane in air is 9.5%. This limited study emphasizes that extrapolation of capacitive-spark results to other applications may not necessarily be valid.

The MIE values for hydrocarbons in air are seen to be generally in the range 0.2 – 0.4 mJ. It is important to appreciate that these energies are extremely small quantities. The potential energy equivalent of 0.2 mJ consists of raising a 2 g weight by about 1 cm. For ignition of hydrocarbons in O_2, the values drop further by about a factor of 10. In considering the above information, it must be remembered kept in mind the role of the MIE, versus the ignition energy needed at other fuel/air ratios. For safety purposes, it is imperative that the lowest value be used, since the most-unfavorable mixture can occur. But in explaining events and non-events in real life, it must be remembered that mixtures will very rarely be close to the worst-case proportion. Thus, it may be that an ignition source was available which was above the MIE for a particular fuel in air, but ignition did not occur. Apart from probabilistic aspects of ignition, this may simp-

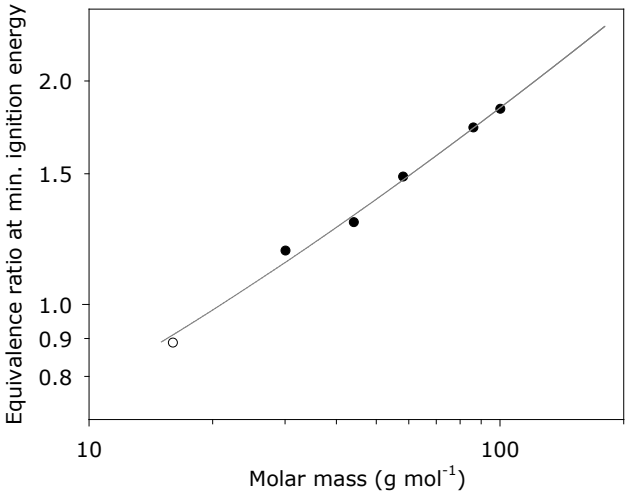

Figure 51 Effect of molar mass on the equivalence ratio at which the minimum ignition energy is found

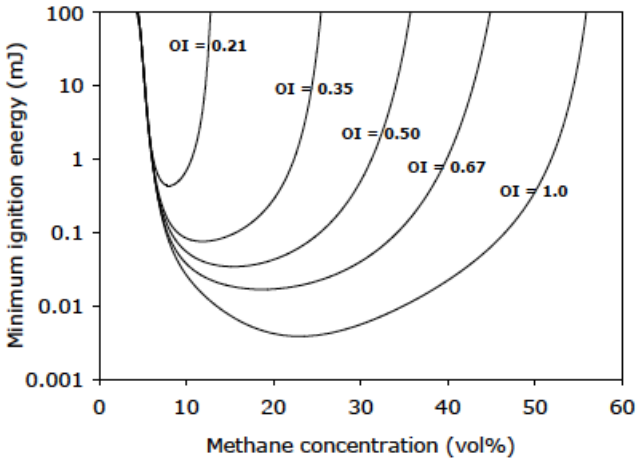

Figure 52 The effect of oxygen index and fuel concentration on the MIE of methane

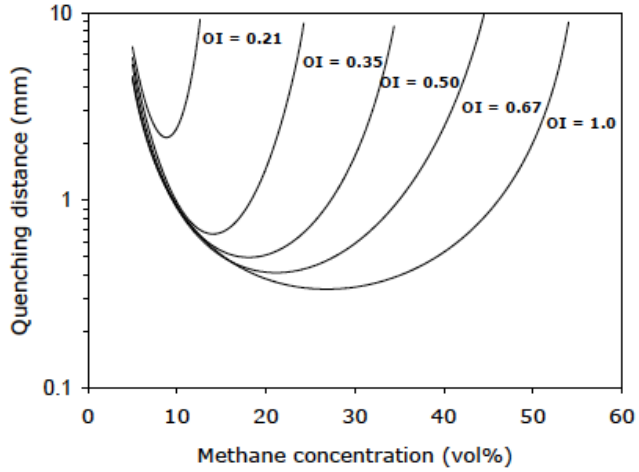

Figure 53 The quenching distance for methane, as a function of oxygen index and fuel concentration[70]

ly be because the mixture had an equivalence ratio far from 1.0. At the lower and upper flammability limits, maybe 100× more energy can be needed for ignition to occur than is needed for the worst-case mixture. It must also be remembered that 'flammability limits' can become an indistinct concept if very large ignition sources are contemplated; this is discussed in more detail later in this Chapter.

The quenching distance is normally reported at the fuel concentration where the smallest distance is found. As shown for methane in Figure 53, the minimum value is close to the stoichiometric. Similar curves are available for a few other gases[145,154]. For many hydrocarbons, the lowest quenching distance is found at φ = 1.1 to 1.3. As a mixture approaches the flammability limits, the value of the quenching distance increases greatly. A recent study[146] confirmed that for methane in air, at the lean limit $d_{\|} \approx 9$ mm. This distance is the same irrespective of whether the propagation is upward or downward, however the lean limit for upward

Table 7 Effect of means of ignition on the most-easily-ignitable concentration for methane

Means of ignition	Methane conc. (vol%)
electrically heated surfaces, large	4.0 – 5.0
heated bomb	5.0
hot gas stream, laminar	5.0
heated plane surfaces, small	5.0 – 6.0
hot quartz tube surface	6.0

wires, electrically heated	6.7
hot jets, pulsed	6.5 – 7.5
sparks from impact of rocks against steel	7.0
hot metal surface, electrically heated	7.0
cannon shots of permissible explosives	8.1
spark, inductive	8.3
spark, capacitive	9.5
flames	9.9

propagation is lower than for downward propagation (5.3% versus 6.0% in one study[100], but varies slightly with experimental conditions). A study of the fuel concentration effect for propane was reported by Jarosiński et al.[147]

TEMPERATURE

Increasing temperature lowers the MIE, as illustrated by the data of Fenn[115] and King and Calcote[148] in Figure 54, with additional data of King and Calcote showing the equivalence ratio effect in Figure 55. In rough terms[50], a 100ºC increase in temperature decreases the MIE by a factor of 2. The straight-line relationship indicates that $\ln(MIE) \propto 1/T$. Furthermore, since the slopes for the various gases are essentially identical, a universal relation can be used for estimating the MIE at one temperature, if it is known at another:

$$E_2 = E_1 \exp[0.008(T_1 - T_2)]$$

where E_2 is the MIE (mJ) at T_2 (K) and E_1 is the MIE (mJ) at T_1 (K). This temperature effect will only be found if the test is run so that the spark electrodes are far enough apart to be out of the quenching distance; otherwise little temperature effect is seen[149]. This point is especially pertinent to breaking wire and break-spark test arrangements, where the gap perforce starts at zero and thermal losses can be high. The temperature effect on MIE becomes more complicated when the fuel/air mixture is not a predefined mixture, but rather is the fuel vapor in equilibrium with the liquid fuel. This situation is considered in Chapter 6.

The quenching distance decreases with increasing temperature according to:

$$d \propto \frac{1}{T^n}$$

where $n \approx 0.5$ to 0.85[104]; a more precise relation has not been evolved. If more specific data are not available, Potter[107] recommends using n = 0.5. The temperature dependence has practical implications, since it means that in heated

environments strategies for flame arresting may not work, if they were tailored for cooled conditions.

PRESSURE

Increasing pressure lowers the MIE[150]. The relationship is generally considered to go as $MIE \propto P^{-n}$, where n is in the range 1.72 to 2.1[151]. Example data for ethane[151] and methane[155] are shown in Figure 56.

The quenching diameter decreases with increasing pressure as:

$$d_T \propto \frac{1}{P^n}$$

where $n \approx 0.8$ to 1.0. Potter[107] shows that there is a complex relation between n and the effective reaction order of the combustion reaction, n', but that the relation can be approximated as $n \approx 0.55\ n'$. Note that in this type of relation the value of n' is not constrained to be a whole fraction, but assumes various values in the range of about 1.3 to 2.2. Where specific details are lacking, Barnett and Hibbard[152] suggest using $n = 0.9$, Friedman and Johnston[153] $n = 0.91$, and Glassman[19] $n = 1$. Even with all else held constant, the air/fuel ratio of the mixture affects the n value to a limited extent[154]. The pressure effect on quenching diameter is important in situations where a gas mixture is in a closed space and flame will or will not propagate out small openings.

A high pressure *gradient* along the length of a tube through which a flame may pass can significantly lower the value of the quenching distance. High pressure gradients will occur if along the vent path from a nearly-sealed vessel undergoing an explosion, to the outside. This is closely related to the MESG problem, but with the difference that the issue here is the physical propagation of a flame through the passage, not necessarily the ignition of an atmosphere on the far side of the vessel. Potter[107] reports some very old data which indicate that an explosion pressure of 8 atm will lower the quenching distance by about a factor of 2 for most fuels. For hydrogen, the reduction was 3×, while for acetylene a higher-yet value was reported. However, the sole available study is sufficiently old that questions may be raised about the general validity of its results.

GRAVITY

Ronney[155] examined the effect of zero-g conditions on the spark ignition of methane/air mixtures. Under test conditions where the LFL was 4.68% at 1-g, the LFL rose slightly to 5.08% at 0-g.

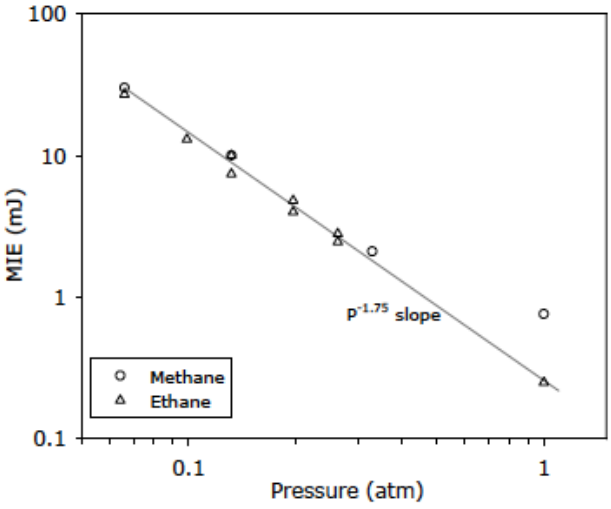

Figure 56 Pressure effect on MIE

TEST GEOMETRY

When the quenching distance is measured in tubes, the direction of propagation has an effect, but quantitative relations are not available[107].

MIXTURE VELOCITY AND TURBULENCE

Theoretical predictions are that flow velocity has an influence on the MIE, but only if it is appreciably higher than the burning velocity of the mixture[156]. The available experimental data indicate that if a mixture has a non-zero velocity, the quenching distance will become larger than the standard value measured in stagnant conditions. But if the mixture has a sufficient outflow velocity, flashback may be avoided as the mixture will be moving faster forward than flame can propagate backwards in it. In an early study, Swett[169] examined the effect for several gases and concluded that, for $u >> 0$, there is linear dependence on velocity in the form:

$$MIE(u) = a + c\,u$$

where u = velocity (m s^{-1}) and a and c are fuel-specific constants. Russian data on propane/air mixtures[157], obtained over the range 1.3 – 17 m s^{-1}, showed that MIE increases monotonically with velocity according:

$$MIE(u) = MIE(0) + c_1 u^{3/2}$$

where MIE (0) refers to a stationary mixture and c_1 is a duel-specific constant. Kono and Hatori[179] studied the effect of velocity for propane/air mixtures using very small-diameter electrodes (< 0.8 mm). For an electrode gap of 3 mm, velocity had no effect until it exceeded ca. 8 m s^{-1}; for larger velocities, the MIE increased steeply, so that at 20 m s^{-1} it was about 10× that for stagnant conditions. For spark gaps smaller than the quenching distance, however, the relationship was complicated. A minimum MIE was found at a velocity of 3 – 5 m s^{-1} and, again, a steep increase at high velocities. But for smaller velocities there was also a sharp increase and also a local minimum at around 1 m s^{-1}. The authors consider that the local hump is caused by details of heat loss to the electrodes.

The effect of turbulence has been investigated in several studies. Swett[158] found that high turbulent velocities raise the MIE. For low-pressure propane-air mixtures, the MIE rose by about 2× as turbulent intensity went from nil to 2.3 m s^{-1}. Akindele et al.[159] investigated smaller turbulent velocities both experimentally and by theoretical modeling and found the turbulence effect to be minimal. Furthermore, they concluded that the initial development of the flame kernel cannot be affected by turbulence when its size is less than the scale of turbulence. For times greater than ca. 0.1 ms, they found that kernel radius growth rates were very slightly increased by turbulence. De Soete[160] presented extensive data on propane/air mixtures, showing that turbulent intensity raises the MIE; he also evolved a calculation formula for predicting the effect. Ballal and Lefebvre[161] concluded that bulk velocity, by itself, has no effect on MIE, but that the turbulent intensity does.

Table 8 Effect of capacitance and electrode diameter on MIE (mJ)

Gas	Capacitance (pF)	Electrodes			
		15 mm	1.6 mm	0.5 mm	points
28% hydrogen/air	6.1	0.022	0.016	0.019	
	30	0.094	0.079		0.034
	50		0.160		
	146	0.390	0.260	0.210	0.073
8.5% methane/air	6.1	0.21			
	13		0.40		
	30	0.94	0.87		
	50		1.06		
	146	4.67	2.21	2.09	0.75

The general conclusion is that both flow velocity and turbulent intensity normally lead to increases in MIE, but that sufficient data are not available on which to base a robust calculational formula. Ballal and Lefebvre[162] showed that in propane/air mixtures, the quenching distance shows a modest increase both with increasing velocity and with increasing turbulent intensity.

WALL MATERIALS

In tests to determine the quenching diameter, the tube material has been found not to materially affect the results. Since heating is not sustained, the wall temperature does not rise significantly above its original ambient value, and, thus, the actual thermal conductivity does not play a role.

CIRCUIT TOPOLOGY

The entire topology of the electric circuit used to create spark ignition must be carefully considered, including values of resistance and capacitance or inductance. In capacitive discharge testing, the capacitance and the charging voltage can be independently controlled. The energy stored in a capacitor, from fundamental physics can be expressed as:

$$E = \frac{1}{2} C V^2$$

But all of this energy is not available for igniting the gas mixture. Some of the energy is lost in the circuit resistance, and, furthermore, a practical circuit cannot discharge a capacitor to zero voltage during the time frame when the energy can contribute to the flame kernel. While circuit topology influences the effectiveness of the energy delivery, other factors must be considered too. The most effective gap size is slightly greater than the quenching distance. If a typical quenching distance may be 2 mm, then the voltage needed to cause a spark discharge across say 2.3 mm is (3×10^6 V m^{-1}) (2.3×10^{-3} m) ≈ 7 kV. If the MIE is 0.25×10^{-3} J, the needed capacitance can be solved from the above equation:

Table 9 Effect of capacitance and electrode diameter on voltage needed for ignition (V)

Gas	Capacitance (pF)	Electrodes			
		15 mm	1.6 mm	0.5 mm	points
28% hydrogen/air	6.1	2700	2300	2500	
	30	2500	2300		1500
	50		2500		
	146	2300	1900	1700	1000
8.5% methane/air	6.1	8300			
	13		7850		
	30	7900	7600		
	50		6500		
	146	8000	5500	5350	3200

$$C = \frac{2 \times MIE}{V^2} = \frac{2 \times 0.25 \times 10^{-3}}{\left(7 \times 10^3\right)^2} = 10 \times 10^{-12} \text{ F} = 10 \text{ pF}$$

Thus, it can be seen that a primary constraint is the breakdown voltage of the gap. If the capacitance is increased beyond the optimum value needed, the voltage cannot be decreased to compensate, because the voltage would drop below the breakdown voltage needed to cause a spark at all. This has been found experimentally—the voltage stays constant, but as the capacitance increases so likewise does the ignition energy needed [163,164,176]. If it is realized that breakdown requires a constant voltage, rather than a constant energy, then the results[176] shown in Table 8 for energy and Table 9 for voltage are seen as consistent. Values of capacitance less than about 5 pF are very difficult to create, since stray capacitance cannot be eliminated. In addition, stray inductance begins to dominate[165], and its value is hard to reduce below 15 μH. Consequently, discharges from low C-L-R circuits tend to be oscillatory in nature.

The role of circuit resistance comes into play in another manner, again not directly related to the energy distribution in the circuit. In 1951 Roth et al.[166] attempted to measure the energy delivered into the gas directly. Their instrumentation was not fast enough to capture the full event, but with extrapolation of the measured values they inferred that close to 95% of the nominal stored energy was being delivered. Later studies[165] indicated that the actual energy dissipated in the spark generally decreases with increasing resistance, although not monotonically. Despite this, lowest MIE values are not found for lowest circuit resistances. Experimentally, it is found that there is an optimum value of resistance, and that too small a value of resistance in series with the capacitor will lead to excessively high values of energy being needed for ignition[167]. This is because it is not just the delivery of energy that matters, but also the time over which it is delivered. In one study[177], optimum discharge times were found to be ca. 1.2 μs, but a broad-based study of this topic does not exist. For an overdamped circuit, if the effective discharge time τ is taken to be the time required for the response to decay down to 1%, then $\tau = 4.6RC$. This simple relation however does not describe the small-capacitance circuits that lead to the most incendive discharges. According to it, a 50 kΩ resistor would be optimal for a 5 pF capacitance, even though only 50% of the stored energy is delivered into the gap under these conditions[165], compared to 90% with R = 100 Ω.

Rose and Priede[165] examined a wide range of discharge times and found that—with practical values of circuit impedances—at short discharge times (microseconds), the waveform was oscillatory and the spark gap resistance was a constant. But at large discharge times (milliseconds), the waveform was overdamped and the resistance was an inverse function of current, much as found for arcs. The experimental measurements indicated that:

$$R_g I^{1.36} = \text{constant}$$

where R_g = spark gap resistance (Ω), and I = current (A). When using large capacitances (> 1 00 pF), a series resistance > 20 Ω was needed for the waveform to be overdamped; for small capacitance circuits, a general guideline was not given.

The *quality* of the capacitor used can affect greatly the energy losses, especially for higher capacitance values. In one series of experiments, Pidoll[168] showed that the largest losses were found with paper capacitors, smaller losses with plastic-film types, and smallest yet with low-loss pulse capacitors.

Workers researching intrinsic safety of industrial instrumentation systems studied at great length the effects of resistance in both capacitive and inductive discharge circuits but much of this work has been aimed at the break-spark arrangement and these results have been considered in the section above dealing with breaking wires and moving contacts.

SPARK DURATION

The duration of the spark also influences the results. Swett[169] originally showed that an optimum duration of spark discharge exists, and that sparks discharged in a longer or shorter time result in the observed value of MIE rising. Results from a later study by Kono et al.[170] are shown in Figure 57. The data were obtained using 0.3 mm diameter wire electrodes and a gap spacing equal to the quenching distance. An optimum duration of 50 – 60 μs is seen. In another study, using 1 mm diameter electrodes and a gap of 1 mm, Kono et al.[171] obtained data showing a flat region for spark durations of 20 – 50 μs, with MIE values rising for spark durations over 50 μs. Kravchenko et al.[172] studied the spark ignition of mixtures of 8.5% methane in air. They found an optimum spark duration of 110 μs under all circumstances. For a resistive circuit, the energy required for ignition was unchanged at over the range from 60 μs (the shortest duration explored) to 110 μs, then increased mono-

tonically with increasing spark duration. For an inductive circuit, however, the 110 µs value was a sharp minimum and both increasing and decreasing spark duration served to raise the energy required for ignition. In experiments with 20% hydrogen in air, they found that the optimum spark duration was only 10 µs. Ziegler and Herweg[173] explored the effect of spark duration on the ignition of methane/air mixtures at an equivalence ratio $\varphi = 0.67$. Using a technique for measuring efficiency of discharge identical to that used by Hertzberg for dust clouds (see Chapter 5), they found that the efficiency increased from 20% for a duration of 20 µs up to 33% for a duration of 200 µs. Beyond 200 µs, a plateau at the same 33% value was seen up to the longest duration explored, 400 µs.

The above results pertain only to tests where stationary electrodes are spaced for optimum ignitability, typically at slightly greater than the quenching distance. In a break-spark, the situation is different, since the gap starts at zero and may still be much smaller than the quenching distance when the bulk of the energy is transferred into the spark. Much longer discharge times are optimal in that arrangement, as discussed above.

Testing is commonly done with DC power, but experiments have also been reported using AC sources. Early work by Wheeler suggested that the minimum igniting current needed for low-frequency AC power sources was the same as the value needed for DC, when the crest value of the AC current was used in the comparison. Subsequent Russian work[129] showed the minimum igniting current rises with frequency until a peak is obtained (ca. 10 kHz for hydrogen/air mixtures), then falls again at higher frequencies. The two factors coming into play are the shorter discharge times being available before a zero-crossing is reached as the frequency is increased, but the ease of re-striking an arc as the de-ionization time is shortened. Later, much more

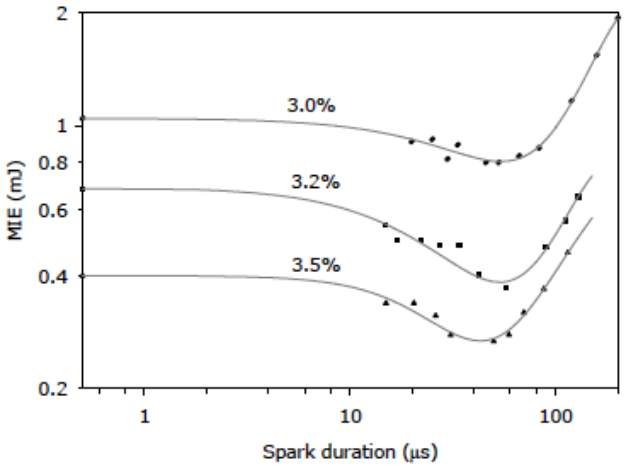

Figure 57 Effect of spark duration on MIE for several concentrations of propane in air
(Copyright The Combustion Institute, used by permission)

detailed studies were undertaken by Kono et al.[174]. They found that there was an optimum frequency which varied on other test conditions, but tended to be around 100 – 200 kHz. At both lower and higher frequencies, the ignition propensity decreased. They then expanded the study to a train of two pulses, representing the igniting effect of a single cycle of sine wave. An optimum pulse duration of around 50 µs was found. Under conditions where the two-pulse method was just sufficient to ignite the mixture, it was found that a single pulse, delivering the same energy as the two separate pulses, did not cause ignition.

Some ignition circuits, both in laboratory experiments and in automotive use, employ an arrangement whereby a capacitor is discharged into the primary side of a step-up transformer. The high voltage from the secondary winding is then directly connected to the spark gap. The combination of the capacitor and the inductance of the primary winding of the transformer forms a *resonant circuit*. Kono et al.[171] determined that an optimum resonant frequency ca. 100 kHz exists for this topology, at least within the context of their experimental arrangement.

When *repetitive sparks* are used, with a cycling rate greater than a certain minimum, the energy discharged by each individual spark can be substantially less than the minimum ignition energy, and yet ignition may still occur. This was demonstrated for methane/air mixtures at a low pressure of 0.2 atm, for which MIE = 6.4 mJ. Repeated sparks with a per-spark energy as low as 0.21 mJ successfully ignited this mixture[175]. Apart from very small volumes where an overall warming effect might be created, the main reason for the enhanced ignitability is because previous sparks have created breakdown products of the fuel gas which are more readily ignitable than the parent gas.

ELECTRODE ARRANGEMENT

If electrodes are placed closer together than the quenching distance, then they will act as a large heat sink in removing heat from the developing flame kernel. Consequently, correct values of the minimum ignition energy can only be determined correctly if the gap width exceeds the quenching distance*. This point was not known in the early days of spark ignition research, and consequently there was no agreement among the MIE values that were published. Figure 58 illustrates the effect of gap size obtained when testing with 2 mm diameter wire electrodes having flat tips[161]. Similar data have been reported by Movilliat and Giltaire[176] for H_2/air and CH_4/air mixtures.

The electrode diameter also influences the minimum energy results. Large electrodes introduce a substantive body into the system to which heat is lost. However, for electrode

* MIE values specific to a breaking-wire or moving-contacts geometry may also be measured, but they should not be expected to be the same as the standard values obtained between fixed electrodes.

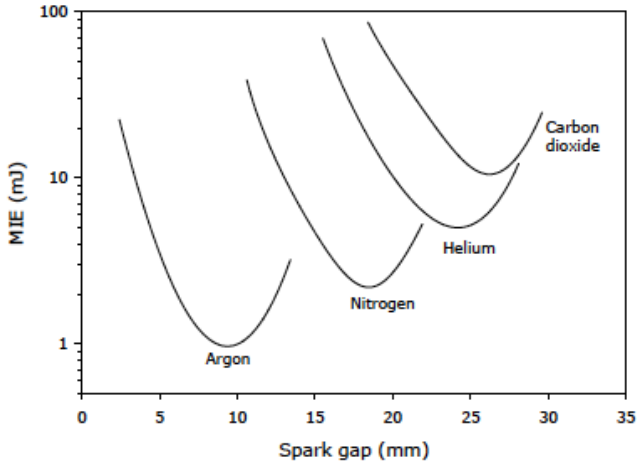

Figure 58 Effect of spark gap size on MIE (stoichiometric propane mixtures with oxygen and various diluents, P = 0.17 atm; 2 mm electrodes with flat tips)

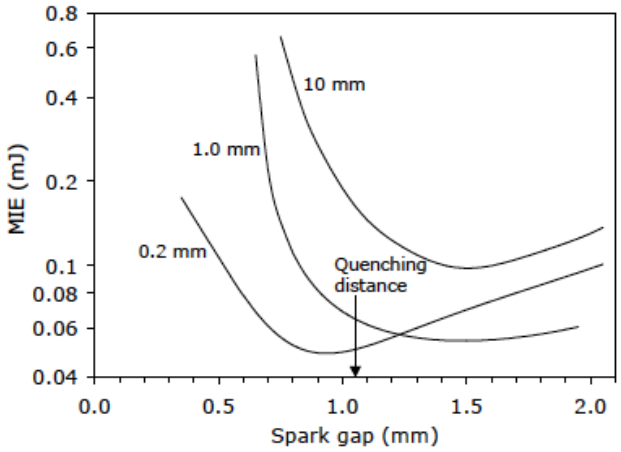

Figure 59 Effect of electrode size (two spherical electrodes) on the ignition of H_2/air

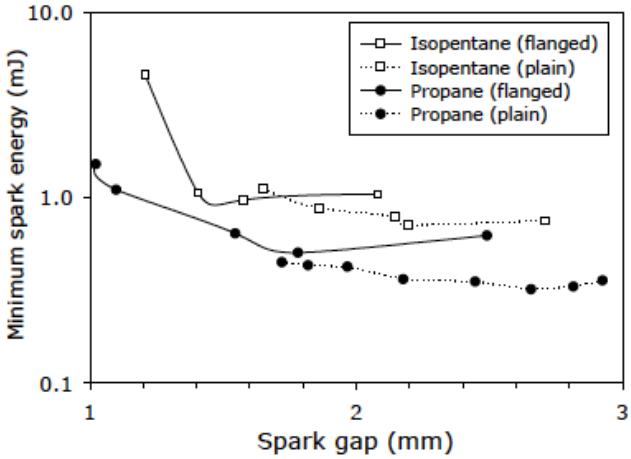

Figure 60 Effect of electrode spacing and construction[180]

diameters below ca. 2 mm, a corona discharge is formed instead of a spark. The diameter which can reliably produce the lowest minimum energy results, thus, tends to be just larger than what is needed for corona discharge to occur. Some results of Rose and Priede[177] on hydrogen are shown in Figure 59. Krämer[178] used spherical electrodes to ignite ammonia/air mixtures and found substantially lower MIE values for 5 mm diameter electrodes than for 15 mm. Kono and Hatori[179] studied the effect of electrode diameter on the ignition of propane/air mixtures in the range 0.05 – 0.8 mm. They found lowest MIE values with the smallest electrode diameter. Table 8 gives further examples of the diameter effect.

Matters are further complicated because the optimum spark gap is a function of *pressure*; limited testing at sub-ambient pressures[157] indicates that for low pressures the optimum gap size is roughly $\propto 1/P$.

The extreme sensitivity of results to gap size can be avoided if flanged* electrodes are used. Flanged electrodes also allow the simultaneous determination of the quenching distance, since if the gap length is smaller than the quenching distance, a developing flame kernel is physically quenched on the flanges. By contrast, even though heat losses occur to the electrodes, if plain-tip electrodes are spaced closer together than the quenching distance, expansion of a flame kernel is still possible, although the value of energy required increases drastically.

Use of flanged electrodes was explored by Calcote et al.[180] In their tests, they had an asymmetrical arrangement where the negative electrode was flanged, while the positive electrode was a plain 3.2 mm diameter wire with a hemispherical tip. The flange was a stainless steel disc, 12.7 mm diameter and 0.25 mm thick, fitted to the electrode at a distance of 0.25 mm down the shaft from the hemispherical electrode tip. Differences in results between tests using two plain electrodes, versus tests using one flanged electrode

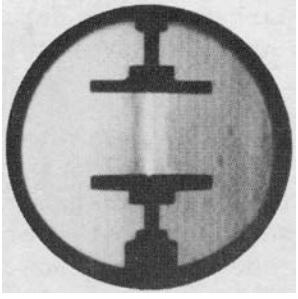

Figure 61 Spark channel developing between two flanged electrodes in a methane/air mixture (time = 50 μs)

* A flanged electrode is one where a glass disc surmounts the end of the wire.

are illustrated for two gases in Figure 60.

Calcote et al. compared the results from tests run under their two conditions. For a large number of gases, a satisfactory correlation was found:

$$MIE_{flanged} = 0.793\, MIE_{plain}^{1.18}$$

where $MIE_{flanged}$ denotes the results for the one flanged/one plain pairing, while MIE_{plain} refers to a pair of plain, hemispherical-tip electrodes; both values are in mJ.

In further studies, the Bureau of Mines found[181] that the most reliable data come from experiments where both electrodes were equipped with 12.7 mm diameter glass flanges (Figure 61). They also found that the best results involved an electrode tip which was flush with the glass disc; Calcote used an electrode which slightly protruded beyond the disc. A non-conductive material such as glass is used, since it can provide thermal quenching without providing a spurious surface for the discharge to wander onto. Under those test conditions, varying the gap width produced results such as illustrated in Figure 62—there is no detectable effect of electrode spacing over a wide range, until a minimum spacing is reached, at which point the ignition energy effectively becomes near-infinite. This critical spacing is identified as the parallel-plate quenching distance, $d_{||}$. If at least one of the electrodes does not have a wide enough flange, then even at small electrodes spacings the developing flame kernel can 'escape sideways' and ignitions, albeit at higher energy remain possible. This is illustrated in Figure 62 for the data points where only one flanged electrode was used, with the second electrode being a fine-point needle. In all of the cases where the electrodes used were not both flanged, a less distinct relation of energy vs. spacing distance has been found and the MIE measurements have been judged to be of poorer repeatability. If very large electrode spacings are used, then the ignition energy needed again starts to rise. Thus, the proper measurements of MIE are made at an electrode spacing just a bit larger than the quenching distance. The electrode arrangement evolved at the Bureau of Mines appears to be unique. Most studies with various other kinds of electrodes show a distinct minimum, not a plateau, in spark gap distance vs. MIE curves.

ELECTRODE MATERIALS

In an early study, Rose and Priede[177] showed that metal used for the spark electrodes has a distinct effect on the MIE. For H_2/air mixture, platinum showed the highest ignition energy, cadmium the lowest, with silver and aluminum giving intermediate results. Later, Ballal and Lefebvre[103] conducted more extensive experiments and proposed the relationship:

$$E_{\min} \propto T_b^{1/4} d^{1/2}$$

where T_b is the boiling point (K) of the electrode and where d is the electrode diameter (m). The boiling-point dependence comes from a known relationship for the ionization of gases. Similar results were obtained by Ziegler et al.[182] The

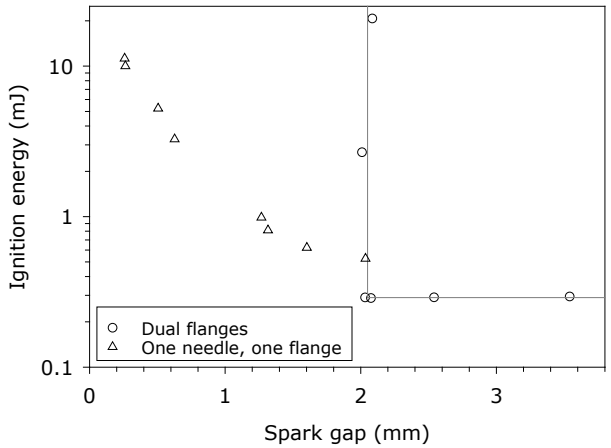

Figure 62 Effect of spark gap on ignition energy for a mixture of 8.3% methane in air (the flanges were 12.7 mm glass discs)

electrodes used by BM for their main studies were made of 1.6 mm diameter stainless steel.

Not surprisingly, if at least one of the electrodes is *heated*, the energy needed for ignition will change. This has been shown in limited testing[183], but not enough studies exist to generalize the trends.

IGNITION IN THE ABSENCE OF EXCITED SPECIES AND HOT-WIRE IGNITIONS OF ALL TYPES

The most common way that a localized source of heating can be created without the presence of excited species is by heating a surface, generally a metal surface. The only other mode that has received some systematic study is one where ignition is caused by a jet of hot, non-flaming gas. Wires that melt (fuse) due to electric heating will generate excited species once an arc is created. Thus, they do not comprise a mode where excited species are absent, however, we treat them directly following the treatment of non-melting wires in order to present all work on hot wires together.

HOT SURFACE IGNITION AND CATALYTIC EFFECTS

In this section we consider hot-surface ignition aspects for pure gases. In many practical cases, hot surface ignitions involve liquid sprays, droplet, or spills. These are considered in Chapter 6. Sir Humphry Davy[98] observed in 1815 that plunging an iron bar "at the highest degree of red heat and at the common degree of white heat" into firedamp (mostly methane)/air mixture did not ignite the mixture. The first scientists to suggest an explanation for this were Mallard and Le Chatelier[49], who in 1880 proposed that while a gas volume directly next to the heated surface does heat up to a high temperature, convective effects quickly sweep it out of that area, where it is cooled down. In other words, they suggested that if the residence time of the heated volume of gas is less than the induction period, ignition is not observed.

By contrast, in an AIT test vessel, all of the surroundings of the gas mixture are at a uniform temperature and any convective motion of the gas mixture does not result in the gas volume 'running away' from the hot surface. Apart from an AIT-testing environment, the 'running away' effect would also be avoided in a stably-stratified environment—for example, a cylinder where only the top surface was heated—but no experiments of this kind have been reported.

Most surfaces are chemically nonreactive, but a few, platinum and palladium for example, provide a catalytic action. Thus, these surfaces behave systematically differently with regards to homogeneous (visible flames) ignitions and also can support heterogeneous (glowing surface) ignitions that are not exhibited by non-catalyst materials. In practical applications, catalysts can be used for either the ignition of a mixture, or for facilitating continuing combustion which would otherwise be impossible. A well-known example of the latter application is the catalytic converter used in current-day automobiles. It provides an extra step of reaction which would not occur if the exhaust gases simply flowed through the same pipe, minus the catalyst.

Experimental studies

In this section, experimental ignition studies will be reviewed where the surfaces studied were primarily non-catalytic. Studies focusing specifically on catalytic effects will be discussed in the following section. The first extensive work on hot-surface ignition was published in 1919 by Prof. Thornton[184], the father of oxygen consumption calorimetry[185]. In his study, he mainly reported the current necessary to cause ignition from an electrically heated wire; temperature was only estimated in a few cases. For many gases, the needed current was roughly independent of the fuel/air ratio over much of the flammable range. For 0.1 mm diameter platinum wires, methane required about 2 A, while gasoline vapors only 0.9 A; all other fuels were intermediate. The metals explored were silver, gold, molybdenum, tungsten, platinum, and iron. For all metal types and for all gases (except H_2 and CO), ignition occurred for the same electric power per unit wire length. In the absence of reliable temperature measurements, however, these results would be difficult to place in context.

In 1927, Coward and Guest[186] studied ignition of natural gas/air mixtures in a large test vessel by heated strips of various metals, with the natural gas being 93.2% methane. They noted that even though the flammability limits (i.e., the range wherein flame propagation fully resulted) were 5.5% to 13.5% for the fuel, mixtures over the range 2.4 – 16% could be "ignited," but such ignitions did not propagate throughout the vessel. One might expect that results would have shown that stoichiometric mixtures are ignitable at the lowest temperatures, with mixtures being progressively fuel-lean or fuel-rich being harder to ignite. Instead, Coward and Guest found a monotonic relation for most metals tried: the lowest temperatures required were at the lowest fuel concentration, with progressively higher temperatures needed for richer mixtures. For copper, gold, Monel, nickel, steels of various sorts, and tungsten, temperatures of 1000–1060ºC were required at the LFL, rising to ca. 1070–1200ºC at the UFL. For molybdenum, an opposite trend was found, since the metal itself ignited. Later investigators[187] found that tungsten wires behave similarly to molybdenum in that tungsten also readily oxidizes in air at high temperatures and hot tungsten wires normally do not ignite flammable gas atmospheres until the metal itself ignites; this phenomenon is further discussed under *Fused wires*, below.

Vogt[188] used 0.2 mm wires, stretched horizontally, and measured the electric current, rather than wire temperature. His results are shown for methane in Figure 63 and hydrogen in Figure 64. For platinum wires igniting methane, over the concentration range of 8 – 12%, the wires fused, but no ignitions were obtained. In most cases, leaner mixtures were more easily ignitable, but there was not a strong effect of fuel concentration. Vogt's results for platinum wires were the opposite from those of Coward and Guest: he also found that it is most difficult to ignite methane near its stoichiometric concentration, but elsewhere in his experiments the mixtures ignited more easily with platinum than with any other metal. The test conditions, however, were not identical, and wires of different materials heated by the same current will not attain identical temperatures. Vogt conducted a more limited test series to measure the temperatures and found these results for 8% methane/air mixtures: tungsten 1530ºC; Nichrome 1430ºC; nickel 1390ºC; and platinum 1290ºC. Thus, the ranking order was only reversed for nickel vs. Nichrome when temperature, rather than current, was taken as the independent variable.

Vogt concluded that the differences among the metals are due to chemical and not due to physical (e.g., thermal or electrical conductivity) factors. He tested tinned 0.2 mm iron wires and found that they readily ignited methane/air mixtures, whereas an untinned 0.2 mm iron wire fused without igniting. There was also a fuel effect, in that the conclusion with respect to tinning was reversed when testing hydrogen mixtures—tinned wires made ignition harder, not easier. Vogt also observed that copper wires could not ignite methane mixtures, even for large wire sizes. In these explorations, the largest conductor he used was a 6 5 mm wide strip, which fused but did not ignite the mixture. Very low circuit voltages (< 5 V) were needed so that an incendive spark would not be emitted upon fusing the wire[*]. Vogt's finding with regards to inability of copper wires to ignite methane/air mixtures was confirmed by Powell[189], although, as stated above, Coward and Guest could obtain

[*] This strategy has normally not been used by other researchers. Consequently, when a hot wire ignites a gas mixture upon fusing, it is commonly ignited from the spark caused by opening the circuit.

ignitions of natural gas even though they used narrower (12.7 mm wide, by 1 mm thick) copper strips. It is unclear if the small amount of non-methane constituents was crucial to the outcome or whether some other experimental factors governed.

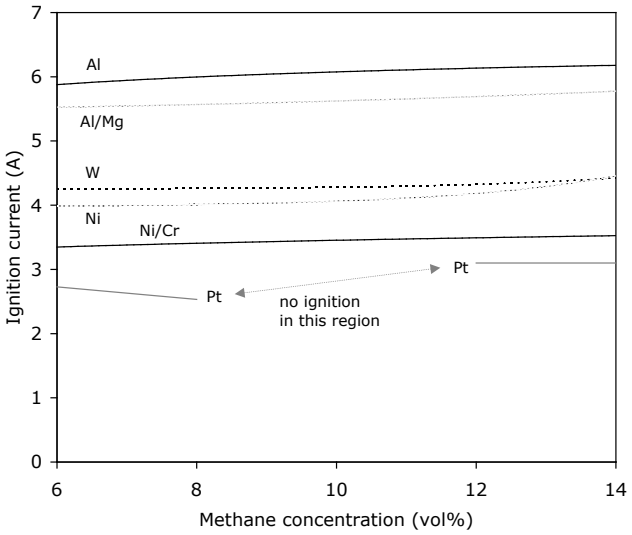

Figure 63 Ignition of methane/air mixtures by 0.2 mm wires of various materials

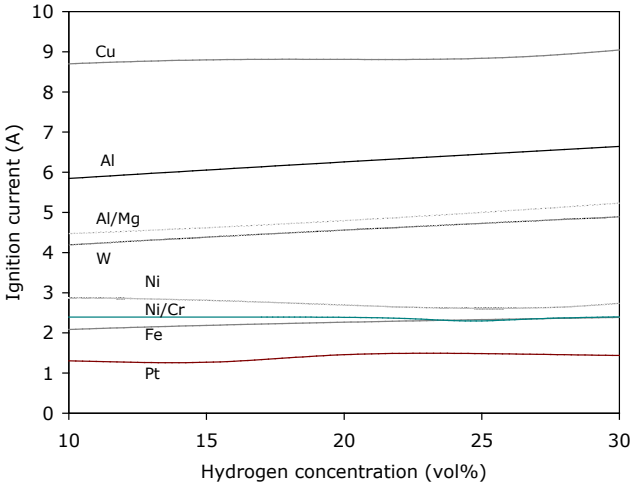

Figure 64 Ignition of hydrogen/air mixtures by 0.2 mm wires of various materials

Kuchta and Cato[248] ignited mixtures using a 10 mm diameter Nichrome rod, with the mixtures being at their most-readily ignitable (but unspecified) concentrations. Their results were: hexane 682ºC, octane 671ºC, and decane 660ºC. Duarte and Drysdale[190] measured the ignitability of a 3% propane mixture in air using a 5 mm Nichrome strip. In their experiments, they located the strip in the bottom of a groove and found a modest geometric effect in the results. The ignition temperature without a groove was 900ºC; in the deepest groove (40 mm) the temperature dropped to 820ºC, with intermediate values for smaller depths. Other experiments with Nichrome wires were conducted by Vanpée and Bruszak[249] who use a 1 mm wire, 90 mm long (Figure 65). Several trends of temperature with equivalence ratio are seen, but the majority of the fuel gases showed only a small dependence on equivalence ratio. Markworth and Schebsdat[191] ignited CS_2/air mixtures with an overheated, wirewound resistor of 6.5 mm diameter and 20 mm length. They found that ignition temperature increased notably with fuel concentration, going from 250ºC at 1% up to 365ºC at 9%. Diethyl ether/air mixtures showed the opposite trend, with temperatures decreasing with increasing concentration over the range 6 – 15%; for concentrations of 15 – 30%, a plateau region was found.

Ignition of gases from heated tungsten surfaces do not require ignition of the metal itself if the hot body is something bigger than a small wire. Cutler[192] used an 11.1 mm wide heated tungsten strip and obtained the results shown in Figure 66. The experiment was unusual in that he provided a brief pulse of heating, instead of keeping a strip at a constant temperature, thus, his results are hard to compare to other workers', although some additional transient heating data were also obtained by Adomeit[193].

In the case of ignition by incandescent particles, the *sphere* is a suitable geometry to study. Also, in such cases the sphere will usually be moving through the flammable atmosphere, so flow velocity must be considered. Experimentally, work on spheres is unique, since in all of the other geometrical arrangements, the surface is electrically heated. For a sphere, on the other hand, experimentalists invariably have taken the approach that in practical cases a sphere will be ejected from some source and then proceed to cool in the atmosphere—it will not be maintained at a fixed temperature electrically. Thus, one will expect that much higher (initial) temperatures will be needed for a sphere to ignite a given atmosphere than would be the case for an electrically

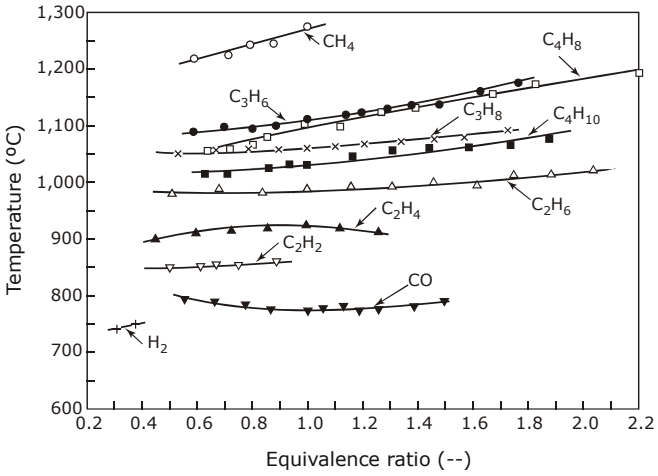

Figure 65 Temperatures needed to ignite various gas/air mixtures using a 1 mm Nichrome wire

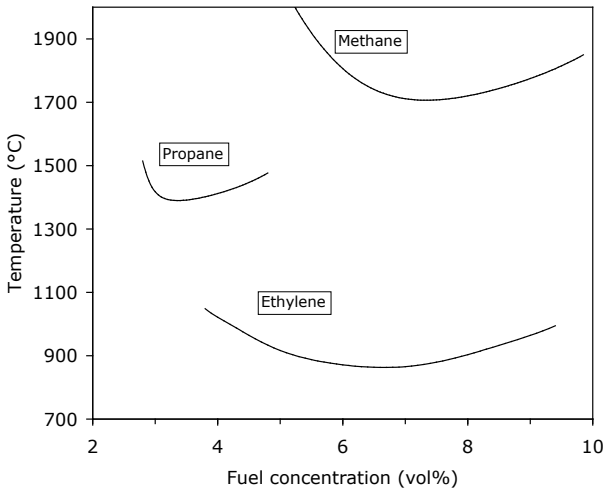

Figure 66 The ignition of gas mixtures in air using a transiently heated tungsten strip

heated body of the same size. Silver[194] and Paterson[195] were the first to study this problem at Glasgow University. For a large variety of materials—aluminum, alundum, nickel, platinum, quartz, slate, titanium dioxide, etc.—the effect of material type was found to be minimal. Newly made platinum spheres were less effective in igniting than other materials; however, the results for aged platinum spheres were essentially identical to all the other materials tried. For a 10% H_2/air mixture, ignition temperature was 900ºC for 0.5 mm diameter spheres and 800ºC for 2.0 mm spheres. Pentane/air mixtures in the range 1.5 to 5% showed 1150ºC for 2 mm diameter and 1030ºC for 4.0 mm. In general, the minimum ignition temperature varied inversely with sphere diameter over the range studied, 0.5 to 5.5 mm. Methane/air mixtures could not be ignited at temperatures up to 1200ºC. For lean mixtures, the necessary temperature for ignition increased very steeply with sphere velocity over the range 10 – 60 m s^{-1}. For a given sphere velocity, higher (but lean) fuel concentrations resulted in lower ignition temperatures being necessary. The temperature of the fuel/air mixture itself did not affect the results, when varied over a range of 200ºC. The researchers did not compare the outcome in the same experimental rig with zero velocity particles. Tolson[196] used an exploding wire technique, which creates an electric arc that disintegrates and scatters tiny metal particles and found that microgram-size particles can ignite methane/air mixtures when they are at temperatures on the order of 3000ºC. Aluminum, iron, copper, and graphite particles ignited the gas mixtures readily, but it was much more difficult to ignite with tin, lead or zinc, and perhaps impossible to get methane/air ignitions with cadmium. Except for aluminum (which most readily caused ignitions, but does not have the highest boiling point), the results otherwise indicate that the incendivity of metal particles is roughly proportional to their boiling points (cadmium's T_b is 767ºC, while zinc's is 907ºC). It was possible, however, to ignite hydrogen/air mixtures by intense laser-energy vaporization of cadmium wires. Tolson did not make particle size measurements, so the results cannot be related to theory.

The effect of *air velocity* was studied by Mullins et al.[197] for pentane/air mixtures ignited with a heated 6.4 mm stainless steel rod. Figure 67 shows that for flow velocities less than about 30 m s^{-1} (which is a substantial value!), the effect is minor. On the other hand, for some hydraulic fluid vapors, it has been found that the surface temperature needed for ignition increases starting at flow velocities barely above zero[198].

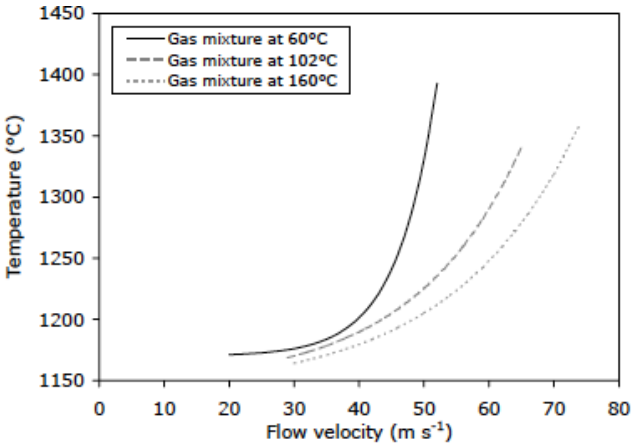

Figure 67 The temperature of a 6.4 mm stainless steel rod needed to ignite stoichiometric pentane-air mixtures of various initial temperatures

Geometric variables influencing natural convection were found to have an influence in experimental studies by Bull[210]. In confining a mixture between an upper hot plate and a parallel cold plate below it, he found that when the spacing became less than 50 mm, exceedingly high hot-plate temperatures became necessary to ignite hexane mixtures having less than 4% fuel concentration. For richer mixtures, the plate spacing had no effect. Hamer et al.[199] tested the rotors of industrial electric motors as a potential source of hot-surface ignition for flammable atmospheres. Atmospheres containing heptane, hexane, or tetrafluoroethylene required hot-surface temperatures 72 – 122ºC above the AIT of the particular vapor for ignition to occur with a locked rotor. With rotor rotating, it proved impossible to ignite any of the mixtures, up to the maximum attainable equipment temperature of ca. 350ºC. As in nearly all of its characteristics, diethyl ether was anomalous, in that its hot surface ignition temperature was 180ºC, essentially the same as its AIT value. With a rotating rotor, it ignited at 229ºC. The environment inside an electric motor is a highly enclosed one, with a marked similarity to an AIT tester, thus it is not surprising that locked-rotor temperatures only about 100ºC higher than the AIT were recorded. The authors note that it was very difficult to make accurate temperature measurements and that, consequently, the actual

rotor temperatures were probably higher than the measurements indicated. The authors also concluded that "any air movement inhibits ignition" in such geometries.

There are almost no studies on *ignition times* for hot-surface ignitions. In one small study, Rae et al.[204] examined the effect of stoichiometry on ignition time of methane from heated surfaces. They found minimum times at $\varphi \approx 1$, with concentrations further away from $\varphi = 1$ showing progressively longer ignition times.

Size effect is clearly a major factor in hot-surface ignitions and a number of workers endeavored to capture the essence of this variable. Bartels[200] showed that there is a size effect, but that the effect is not large once the surfaces are centimeter- and not millimeter-sized. But his results (Table 10) also show that hot-surface ignition temperatures for the larger cylinder sizes approach the AIT values.

Table 10 Hot-surface ignition temperatures for cylinders of several diameters and materials

Fuel	AIT (ºC)	Hot-cylinder ignition temp. (ºC)		
		60 mm brass	38 mm glass	51 mm glass
diethyl ether	195	239	235	227
dimethoxymethane	237			327
heptane	223			302

Powell[189] attempted to generalize the size effect on the minimum temperature needed for a hot body to cause ignition. His conclusions (Figure 68) show that for bodies with a size greater than about 10 mm, the effect of size becomes nearly insignificant. For bodies of size < 1 mm, for example, mechanical sparks, there is an extremely steep relation between size and minimum temperature. Most experimental ignition temperature data reported for individual gases tend to imply an accuracy which is not borne out when data from several investigators are compared. Thus, Powell's representation of results simply according to IEC 'Groups' of gases* has a merit of realism. Group I comprises methane alone. Group IIA has gases with MESG > 0.9 mm (e.g., propane, heptane, methanol, etc.). Group IIB has gases for which 0.5 < MESG < 0.9 mm; it includes ethylene, ethylene oxide, pentane, etc.). Group IIC pertains to MESG < 0.5 mm and comprises only acetylene, carbon disulfide, and hydrogen. An examination of the data discussed by Powell does not make clear the basis for the very steep rise in the trendlines of Figure 68 for very small sizes. It appears Powell intermixed results for hot-particle ignitions with those for hot wires and surfaces. That would appear to be hard to justify, because small particles cool very rapidly, and an initial temperature will have decreased greatly by the time the induction period is over. Duarte and Rohatgi[201] undertook a review of original literature addressed at the same question. They only found reliable data for $d \geq 1.6$ mm; at this size and greater the effect of size on the required temperature was moderate, not steep.

The quantitative effect of surface dimension on the required temperature for ignition is not particularly clear from a plot such as Powell's, especially in view of the steepness of the curves. Müller[202] obtained data on the ignition of town gas/air mixtures showing that straight lines can be plotted if a semi-log graph is used and if the hot surface area, not lineal dimension is used. Scaling according to diameter or thickness, in fact, is a rather poor idea, since for many heated bodies used in experiments the biggest dimension, by far, is their length and presumably the whole length presents a surface available for reaction. Müller's data are shown in Figure 69, as are more recent results from HSE for other gases[203]. The results of Rae et al.[204] on methane are shown in a plot of this kind in Figure 70. A reasonably good fit is seen, except for the smallest areas tested. A configuration where the ceiling is heated is the only stably-stratified geometry and would, in principle, be free of convective effects. This should lead to the lowest ignition temperatures. Rae et al. did not find this, and it appears that this is because they did not create a true ceiling geometry, but rather inserted a heated surface, face-down, but below the actual ceiling of the chamber. Such a configuration is not stably stratified and hot gases will still move convectively. Rae et al. also explored higher methane concentrations and results showed increasing ignition temperatures with increasing concentrations, up to the highest value tested (13%). Ignition temperatures were about 100ºC higher at 13% than at 6%.

Kuchta[50] subsequently illustrated the straight-line relationship for a number of other vapors (Figure 71). The functional relationship represented by all of the straight lines is:

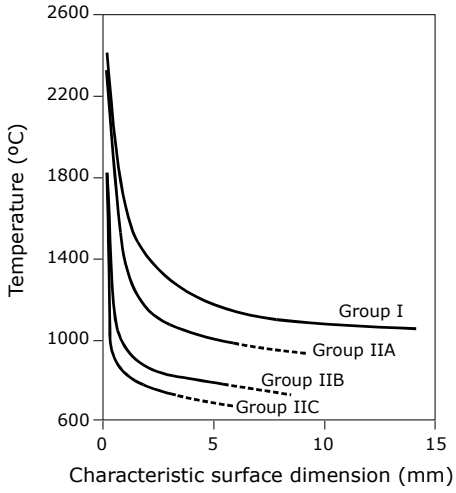

Figure 68 General trends for ignition of gases from hot surfaces

* The IEC Groups of gases are discussed in Chapter 12.

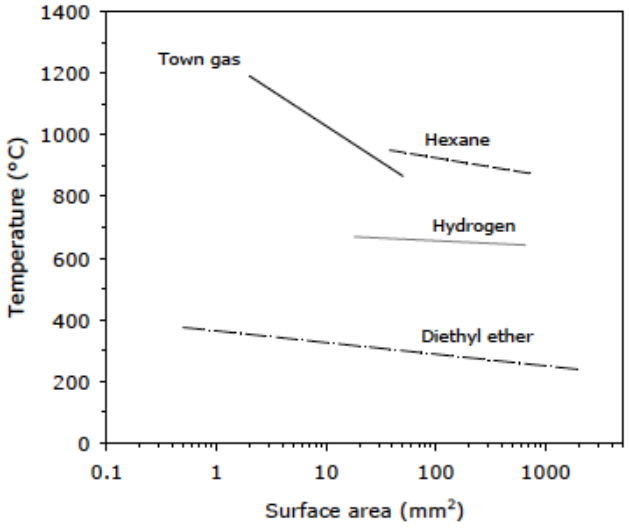

Figure 70 Effect of hot surface area on ignition of several fuel gas/air mixtures

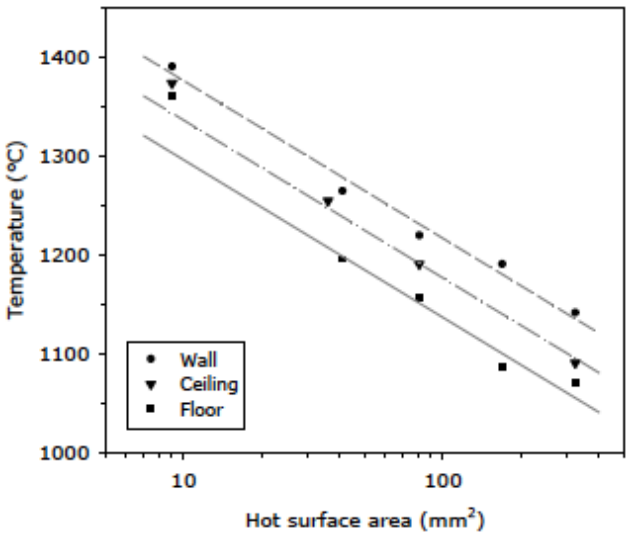

Figure 69 Effect of hot surface area and orientation on ignition of mixtures of 6% methane in air

$$T_{ig} = a - b \ln A$$

where A = surface area (cm^2) and a and b are different constants for each fuel. The data in Figure 71 show two distinct behaviors. JP-6 and *n*-hexane exhibit kinked curves, with a strong discontinuity at ca. 90 c m^2. For these fuels, cool-flame ignition is possible, and this is observed if the vessel size is large enough. Motor oil does not show cool flame ignition, while the other fuels were not tested with large enough heated areas to assess their trends. It is interesting to note that there is no discontinuity at the boundary between heated rods and heated vessels. This finding, in fact, denotes that there is a continuum of 'enclosedness,' with AIT test vessels being at one extreme and heated wires at the other.

The size effect on ignition time was explored for methane/air mixtures by Sano and Yamashita[79] using a computation model. They found a roughly similar relation for time as did Powell for temperature—size mattered little, once it exceeded about 10 mm; for very small sizes, the effect was quite large.

Oxygen concentration may have an effect on h ot-surface ignition, but there is little information on it apart from a study by Khalturinsky and Berlin[205] who used a 2.1 mm diameter heated cylinder, 21 m m long. Their results (Figure 72) indicate a strong effect up to about 40%, with no further effect at greater oxygen concentrations.

The *surface material* used makes a strong effect on catalytic ignitions, but it is also a factor for flaming ignitions from hot surfaces. This has historically been explored mostly in connection with autoignition tests for liquids, and details in Chapter 6 should be consulted. Bannister et al.[206] provide an explanation based on ionic effect. In their theory, the thermoelectric (Seebeck) effect at the hot surface increases the electron density and provides a negatively charged surface which polarizes oxygen molecules in the air, with the resulting induced O_2 dipole serving to promote rupture of

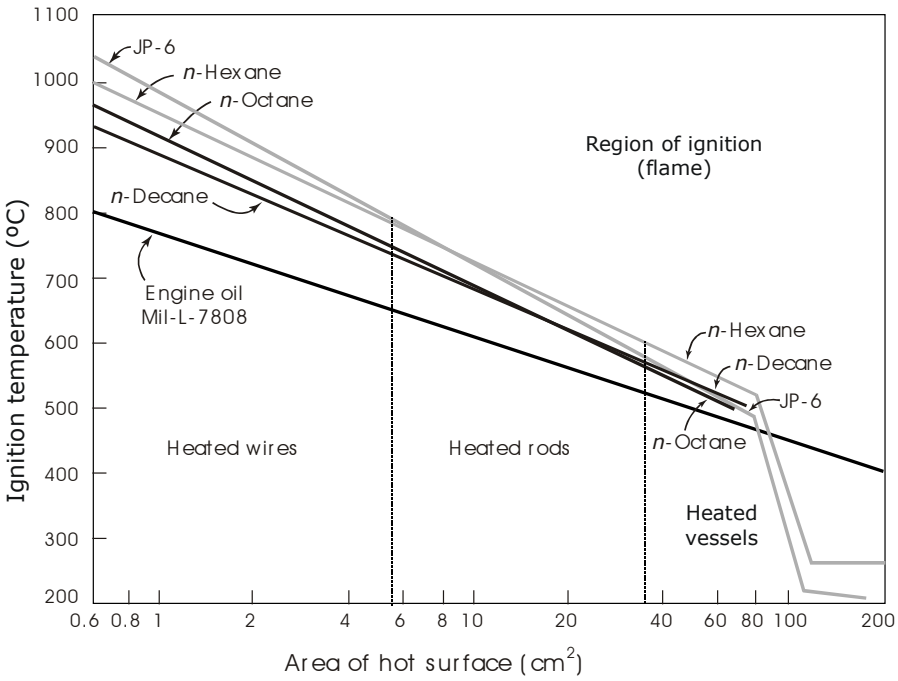

Figure 71 Ignition of vapors from hot surfaces: the effect of surface area

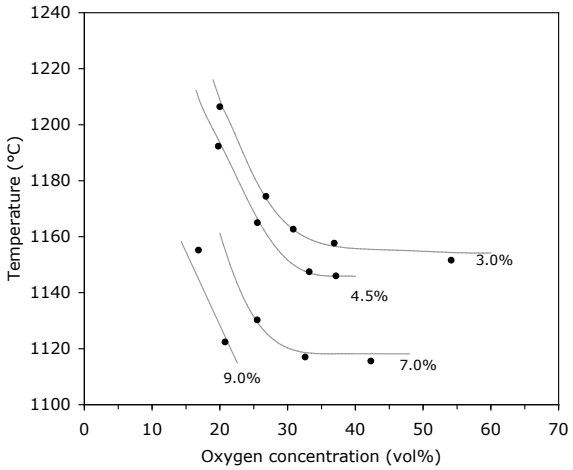

Figure 72 Effect of oxygen concentration on the hot-surface ignition temperature of various concentrations of methyl methacrylate vapor in air
(Copyright Elsevier, used by permission)

Table 11 Effect of surface material according to the theory of Bannister

Surface	Seebeck coefficient (μV K^{-1})		Ignition temp.
	At 25°C	At 300°C	
quartz	NA	NA	lowest
iron	+10	+8	
titanium	+5	+2	
zinc	+2		
aluminum	–1.6	–2.2	
platinum	–5.3	–11.6	highest

C–H bonds. Consequently, the more positive the Seebeck coefficient the more readily will ignition occur. Table 11 indicates that ignition trends are related to the Seebeck coefficient for metals. Non-metals do not have a Seebeck coefficient and Bannister provides another explanation why a quartz surface is expected to be negatively charged.

The effects of *gravity* were studied by Nagata et al.[207] on methane mixtures, who found that the results were identical in microgravity and in normal gravity, if the oxidizer was air. If the oxidizer was O_2, however, then ignition in microgravity was substantially faster than in normal gravity.

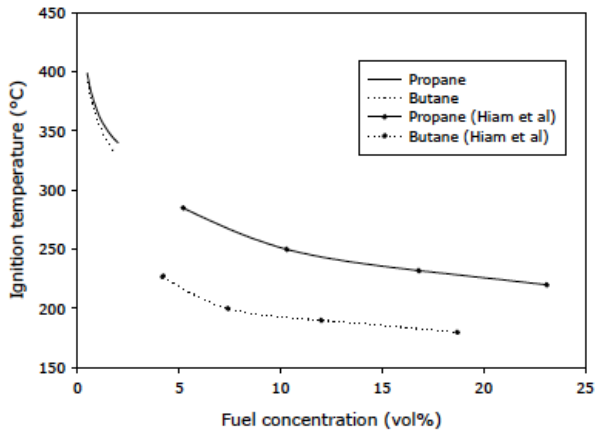

Figure 73 Platinum wire ignition of propane and butane

Catalytic (surface) ignition

Coward and Guest[186] were the first investigators to explore the effects of catalytic materials, but they only examined catalyst effects on gas-phase ignitions, rather than studying the surface-ignition phenomenon. Fundamentally, a catalyst functions by lowering the activation energy required for a reaction to occur. But the sequence of events comprising a surface (also called glowing, or heterogeneous) ignition is rather complex and there are five steps involved in the catalytic reaction process[208]:

(1) diffusion of the reactants to the catalyst surface
(2) adsorption of reactant molecules onto the surface, forming a catalyst-reactant molecule complex
(3) a chemical reaction, which may be between two adsorbed molecules or between an adsorbed molecule and one in the gas phase
(4) desorption of the products from the surface
(5) diffusion of the products back into the gas stream.

Cho and Law[208] examined the catalytic ignition of six fuels over a thin, heated platinum wire at near-zero flow velocity; increasing velocities had the effect of slightly raising the ignition temperature, therefore a very low, 'creeping-flow' velocity was used. Fuel, oxygen, and nitrogen were independently introduced in these experiments and, therefore, the O_2/N_2 ratio was not limited only to its atmospheric value. They found that the fuels fell into two groups: those whose ignition temperature dropped with increasing fuel concentration, and those which rose with increasing fuel concentration. The dropping-temperature fuels were propane (C_3H_8) and butane (C_4H_{10}). The rising-temperature fuels were carbon monoxide (CO), hydrogen (H_2), ethylene (C_2H_4), and propylene (C_3H_6).

The results for propane and butane are shown in Figure 73. The results are presented using fuel concentration as the main variable since it was demonstrated that varying oxygen in the range 4 – 20% had nearly no effect on the results. Since this is true, it can also be realized that plots against the equivalence ratio φ fail to give a single curve expressing the results. It is also interesting to observe that, when plotted against φ, the ignition temperature relationship does not change at $\varphi = 1$. In both the fuel-lean and the fuel-rich regimes, ignition temperature continues to decrease with increasing φ, although oxygen concentration never disappears as the second parameter. Figure 73 also shows some older data obtained by Hiam et al.[209] on propane and butane at higher concentrations. These authors used a 0.1 mm platinum wire coiled into a helix shape. Their propane data appear to be almost an extension of Cho and Law's, but the butane data are clearly lower than found by Cho and Law.

The remaining fuels all show a second type of behavior (Figure 74). With these fuels, the ignition temperature monotonically *increases* with fuel concentration. However, each fuel reaches a near-plateau value, and further fuel concentration increases do little to raise the ignition temperature. Unlike for the first group, where ignition temperature plotted against O_2 showed little variation (except very near to the $\varphi = 1$ value), for the second group of fuels the ignition temperature monotonically decreases with increasing O_2 concentration in the fuel-lean regime. The fuel-rich regime was not sufficiently explored for the second group of fuels.

Cho and Law concluded from the results, first, that catalytic ignition cannot be represented by any generalized Arrhenius form of reaction rate such as $c_f^a c_{ox}^b \exp(-E/RT)$ even for general powers a, b of the concentrations of fuel (c_f) and oxygen (c_{ox}). They also pointed out that the interaction of some very simple molecules with surfaces has been quantitatively studied at sub-ambient pressures, but that there is nearly no systematic information on interactions of common fuels with surfaces at atmospheric pressure. Qualitatively, they observed that data exist showing that the ranking of the adsorption strength of the molecules studied goes as:

$$O_2 > C_3H_6 > C_2H_4 > CO > H_2 >> C_4H_{10} \approx C_3H_8$$

The grouping of the fuels according to surface adsorption strength, then, corresponds to the two groups of ignition results, with propane and butane being difficult to adsorb since a C–H bond must be broken, rather than a C=C bond. Oxygen is more strongly surface-bonded than any of the fuels. In the case of propane fuel, most of the surface sites will be occupied by oxygen molecules and propane molecules will have difficulty getting adsorbed. Thus, reactivity will increase if a greater abundance of fuel is provided. Increasing oxygen however is not expected to change the reactions, since the surface is mainly populated by oxygen molecules. This qualitatively explains why increasing propane concentration lowers the ignition temperature, but increasing oxygen concentration does not change it. Other organic molecules which do not have C=C bonds, e.g., methane[211] and hexane[210], behave similarly to propane. Deutschmann et al.[211] consider that the adsorption strengths of CO and H_2 are greater than of oxygen, thus, at low temperatures the surface is going to be populated largely by fuel molecules, in the case of these fuels. Despite this difference in interpretation, the experimental trends observed by them are identical to those of Cho and Law.

In the case of propylene and other fuels of the second group, the adsorption strengths of the fuel are of the same order of magnitude as that of oxygen. Thus, it means that fuel and oxygen will be competing for surface sites. So, for lean mixtures, the effect on temperature should be similar whether the concentration of fuel is raised or the concentration of oxygen is lowered. The experimental results bear out this hypothesis.

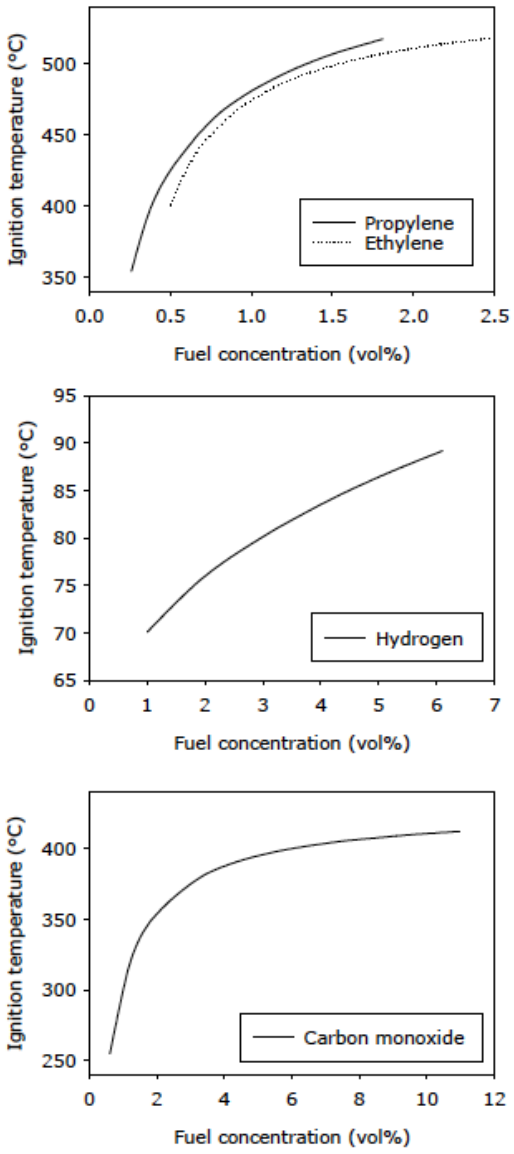

Figure 74 Platinum wire ignition of other fuels

Song and coworkers[212] constructed a test rig where a gas stream impinged upon a heated platinum foil ('stagnation flow' condition). In that arrangement, the size of the foil is immaterial, since it is much larger than the reaction zone of the gas mixture. In their experiments, they were able to separately identify homogeneous and heterogeneous ignition. Homogeneous ignition was evidenced by a visible flame; heterogeneous ignition was noted by a change in the power consumption of the electrically heated foil. Figure 75 shows their results. The 'flammability limits' for heterogeneous ignition were found to be much broader than for normal flaming ignition: for methane, these were 3 – 74%, in comparison to 5 – 15%. Over a substantial middle portion of the heterogeneous ignition range, a behavior was found which the authors dubbed 'autotherm.' In that range of concentrations, removing the electrical power from the platinum foil did not cause the combustion to stop.

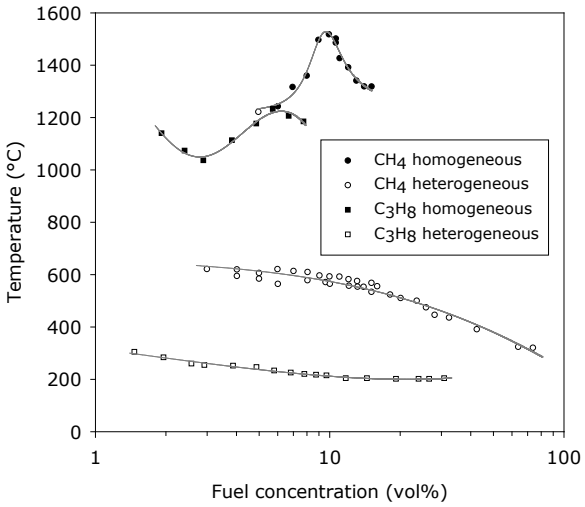

Figure 75 Platinum foil ignition temperatures for stagnation flow geometry of methane and propane

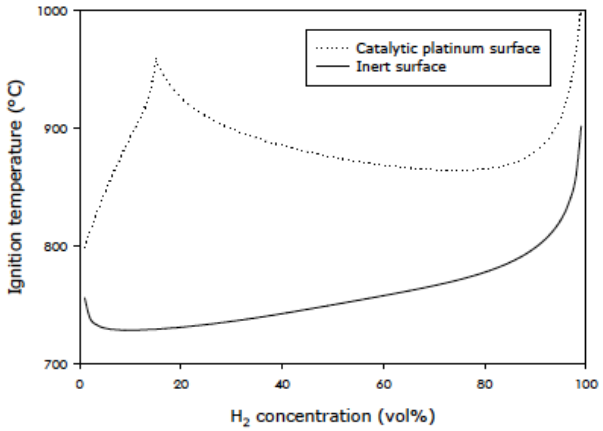

Figure 76 Ignition temperatures necessary for gas-phase ignition of hydrogen/air mixtures

Methane is a difficult to ignite gas, and early experiments[186] suggested a curiosity: for mixtures very close to stoichiometric, substantially higher temperatures of a platinum surface are needed than for mixtures with $\varphi < 0.9$ or $\varphi > 1.1$. For many chemical reactions, the condition of the mixture being near-stoichiometric is one that results the $\varphi = 1$ condition occur the most easily, thus, all sorts of chemical explanations were attempted to elucidate this anomaly. A good explanation did not come until careful experiments were done by Griffin and Pfefferle in 1990[213]. They found that gas-phase and surface ignitions must be considered separately and that, furthermore, these two forms of ignition may interact in order to create anomalous-seeming results. The anomaly stems from transient heat losses, since the heating time for a solid surface is much greater than the time scale according to which chemical reactions take place. Once a suitable experimental arrangement was developed, the authors found that surface ignition (glowing), temperatures ranged from 575ºC at $\varphi = 0.5$ to 545ºC at $\varphi = 1.5$, with no jumps in between. For gas-phase ignitions (flaming), the temperatures ranged from 1120ºC at $\varphi = 0.5$, to 1320ºC at $\varphi = 1.0$, to 1410ºC at $\varphi = 1.5$, with the range again being smooth and continuous. In neither case is there a jump at $\varphi = 1.0$. A surface ignition was possible even for the lowest value of φ explored, 0.025, although the temperature required was not reported. The authors also reported some data for surface ignition temperatures of ethane/air mixture; generally, temperatures about 240ºC lower than corresponding ones for methane were found. Over the range 76 – 250 μm, the wire diameter used did not influence the results.

The effect of using an inert versus a catalytic surface for flaming ignition of hydrogen was explored by Bui et al.[214]. Figure 76 shows how a catalytic surface interferes with a gas-phase ignition; also, compare these values to the vastly lower values shown in Figure 74 for glowing ignition of hydrogen. For inert surfaces, very similar results to those of Bui that are shown in Figure 76 were also obtained by Enomoto et al.[215]. However, they found increased temperatures with a platinum surface only for highly fuel-lean conditions. For mixture ratios with $\varphi > 0.4$, their platinum results were indistinguishable from the their inert surface results; possibly this was due to a lesser catalytic activity of their platinum surface.

The effect of oxygen concentration has been explored only to a very limited extent. Cho[216] obtained the CO data shown in Figure 77; he also reported a small amount of scattered data for propane.

Rogowski and Pitt[217] explored the ignition of various gas jets on the platinum covered surface of a catalytic room heater. The jet was 100% fuel, while the heater was situated in normal room air. For propane, they found that ignition occurred without any heating, the catalytic surface being at 21ºC. The most common application of hot surface ignition is for igniting modern gas furnaces and gas clothes dryers, wherein a silicon carbide *glow bar* is heated electrically. Such an arrangement has been found to be more reliable than the historically-used gas pilot; advice on practical troubleshooting of such ignition systems has been published[218].

Theories

Semenov theory. A simple thermal theory can be used to explain the minimum temperature T_c which a sphere of radius r must have in order to ignite a gas mixture flowing past it. The sphere is taken to have a given initial temperature and it is not supplied with electric heating. Assume that the temperature drops from T_c at the surface of the sphere to the ambient T_o in a small distance L. The area of this heated gas layer is approximately $4\pi r^2$ and the volume of the thin

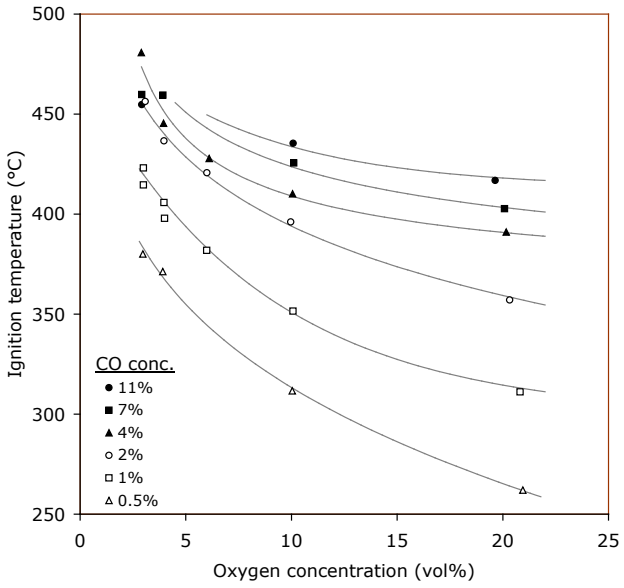

Figure 77 Effect of oxygen concentration on the catalytic ignition of CO

layer is $4\pi r^2 L$. If we assume a first-order reaction, then the HRR of the layer is

$$\rho QA(4\pi r^2 L)\, e^{-E/RT_c}$$

The conductive heat loss is

$$4\pi r^2 \frac{\lambda}{L}(T_c - T_o)$$

Equating the HRR to the heat loss gives:

$$\rho QA\left(4\pi r^2 L\right) e^{-E/RT_c} = 4\pi r^2 \frac{\lambda}{L}(T_c - T_o)$$

The heat transfer can be expressed by means of the nondimensional Nusselt number Nu. The general definition of Nu is:

$$Nu = D\frac{h}{\lambda}$$

where D = critical dimension (m) and h is the heat transfer coefficient (W m^{-2} K^{-1}). For a sphere, $D = 2r$. The heat transfer coefficient is defined as the thermal conductivity, divided by the thermal boundary layer thickness:

$$h = \frac{\lambda}{\delta_t}$$

In the present case, the thermal boundary layer thickness, by assumption, was L. Putting these together, we can replace L by $2r$/Nu, giving

$$\rho QA\; e^{-E/RT_c} = \frac{\lambda}{L^2}(T_c - T_o) = \frac{\lambda\, Nu^2}{4r^2}(T_c - T_o)$$

Or

$$e^{-E/RT_c} = \frac{\lambda\, Nu^2}{4r^2 \rho QA}(T_c - T_o)$$

By taking logs of both sides,

$$\ln\left[e^{-E/RT_c}\right] = \ln\left[\frac{\lambda\, Nu^2}{4\rho QA}\right] + \ln\left(\frac{T_c - T_o}{r^2}\right)$$

$$\ln\left(\frac{T_c - T_o}{r^2}\right) = -\frac{E}{R}\frac{1}{T_c} - \ln\left[\frac{\lambda\, Nu^2}{4\rho QA}\right]$$

Thus, by plotting experimental data with $1/T_c$ on the x-axis and $\ln\left(\frac{T_c - T_o}{r^2}\right)$ on the y-axis, a straight line will be obtained with a slope of $-E/R$ if simple, single-step kinetics, in fact, controls the ignition process. Ashman and Büchler[219] presented a theory which is variant of the above.

Laurendeau theory. Semenov's theory does not address the details of the heat losses from the hot surface, which are important in establishing data trends. Thus, Laurendeau[220] proposed a theory for hot-body ignitions that includes stagnant gas, natural convection, and forced convection possibilities. Laurendeau starts from the postulate of van't Hoff, who considered that ignition at a hot surface can be defined as the moment at which the net heat flow at the surface is zero. To understand the physical basis for this criterion, it is helpful to consider Figure 78. If a volume of gas is not ignited, then heat is being delivered from the hot surface to the gas. Thus, the heat flow is into the gas, and the temperature gradient at the surface is negative. If a gas is already ignited, then heat from combustion is available to be delivered into the boundary surface; thus the temperature gradient at the surface is positive. The condition where the temperature gradient is zero represents no net heat flow (adiabatic condition) and corresponds to the ignition event. Of course, the theory could not be used if the hot surface were so hot that its temperature would exceed the flame temperature of the gas mixture.

Laurendeau assumes that the surface is convectively cooled, i.e.,

$$\dot{q}''_{x=0} = \frac{\lambda\, Nu}{L}(T_w - T_o)$$

where T_w is the temperature at the wall (K) and T_o is the temperature of the surrounding gas (K). By equating this value to the heat transfer due to combustion, an ignition criterion is obtained:

$$\left(\frac{\theta_w - 1}{\theta_w}\right)^2 \theta_w^{n/2} e^{E^*/\theta_w} = \frac{2D_1 D_2}{E^*}$$

where $_w = T_w/T_o$, $E^* = E/RT_o$, and two Damköhler numbers D_1 and D_2 are defined as:

$$D_1 = A\left(\frac{P}{RT_o}\right)^{n-1} \frac{X_o^{m_o} L^2}{\alpha\, Nu}$$

$$D_2 = \frac{X_f^{m_f} Q}{C_p T_o}$$

X_o = mole fraction of oxidizer, X_f = mole fraction of fuel, the reaction rate is defined to be:

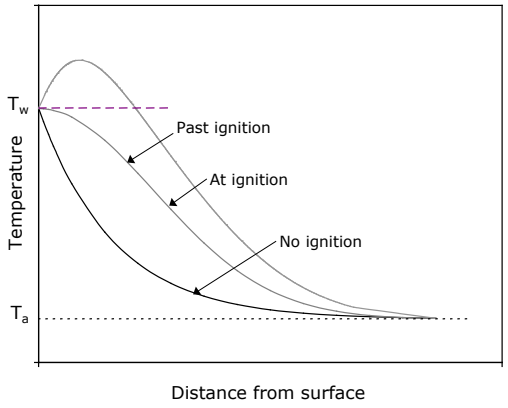

Figure 78 Temperature distribution near the heated wall

$$\dot{w} = -X_f^{m_f} X_o^{m_o} A e^{-E/RT}$$

$$n = m_f + m_o$$

α = thermal diffusivity ($m^2\ s^{-1}$), and L = characteristic dimension (m). The evaluation of Nu depends on the flow conditions. If flow is assumed not to be turbulent, then

Nu = constant	stagnant
$Nu \propto L^{3/4}(T_w - T_o)^{1/4} P^{1/2}$	natural convection
$Nu \propto L^{1/2} u^{1/2} P^{1/2}$	forced convection

where u = flow velocity ($m\ s^{-1}$). For the combustion of hydrocarbons, $n = 2$ is commonly the order of the reaction. Furthermore, the effect of T_w is mostly concentrated in the exponential term; thus, dropping the other factors containing T_w, one obtains:

$\ln(P^2 L^2) \propto E/RT_w$	stagnant
$\ln(PL^{1/2}) \propto E/RT_w$	natural convection
$\ln(PL/u) \propto E/RT_w$	forced convection

The application of the theory to Cutler's data[221] is shown in Figure 79. When plotting 2 ln (L) as a function of $1/T_w$, the results for stagnant conditions should fall along a straight line whose slope is E/R. For methane, an appropriate value of E/R is 25,000. The solid line in Figure 79 shows that the three lowest-temperature points follow this relationship. Why do the others not? The reason is that at high strip temperatures, it is no longer appropriate to assume stagnant conditions—elevated metal temperatures induce natural convection in the gas atmosphere. For pure natural convection, the slope would be 25,000 if 0.5 ln (L), instead of 2 ln (L) were plotted on the y-axis. In other words, if the y-axis remains 2 ln (L), then data points should follow a line of $4E/R$. The dotted line bears this conclusion out, and indicates that points following that line must be considered as being in a natural convection flow, not in a stagnant gas.

Laurendeau's theory does less well when applied to Kuchta's data[67,248]. Figure 80 shows that at higher temperatures, the same slope of 25,000 (note that, for convenience, the x-axis variable is plotted as $1000/T_w$) is found. But at lower temperatures, the slope is roughly 10,000, which is neither 2× nor 4× the high-temperature slope. It is of some interest to observe that the break in slope for Cutler's data is at 1800ºC, while for Kuchta's data it is at 700ºC. Both values are much higher than the regime in which cool flames occur.

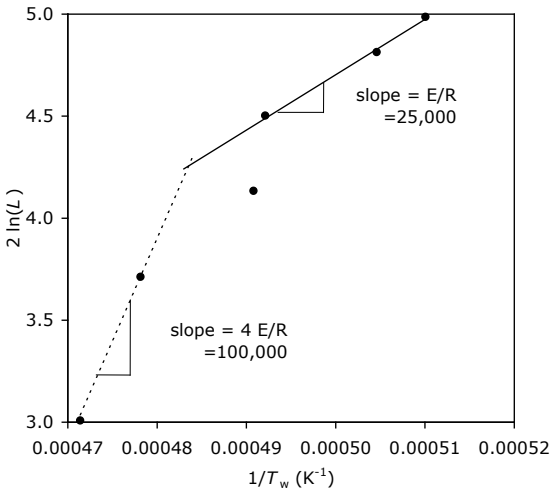

Figure 79 Laurendeau theory applied to Cutler's data: hot-metal-strip ignition of 7% methane/air mixtures; L = width of strip (mm)
(Copyright The Combustion Institute, used by permission)

Kumagai and Kimura[222] obtained a large amount of data for hot-wire ignition of town gas. According to Laurendeau, for forced convection, the correlating function should be $\ln(L/u)$. This did not collapse their data, but the data can be collapsed by a more general treatment of the Reynolds number. In general, the heat transfer coefficient[223] is proportional to:

$$h_c \propto \frac{(Lu)^k}{L}$$

Laurendeau's suggested correlation form implies $k = 0.5$. Collapse of data onto a single line was possible by taking $k = 0.25$, in other words, by plotting $\ln(L^2/(uL)^{1/2})$, as shown in Figure 81.

Ono et al.[224] studied the natural convection case for a number of gases. Applying a modification of Frank-Kamenetskii theory, they were able to correlate their experimental data according to:

$$\ln(P^{n-1} L^{1/2}) = C_1/T_w + C_2$$

This equation differs from Laurendeau's in that (a) a constant term C_2 is added; and (b) a variable order of reaction n is assumed. Their data for propane gave $n = 2$, but methane, ethanol and diethyl ether gave $n = 1.7$. The additive term was seen to become important for temperatures greater than

about 1300 K; for such temperatures, a straight line is no longer found and the additive term accounts for the curvature. The conclusion with regards to Laurendeau's theory and related theories is that while they are tractable, they do not offer any notable improvement in correlating experimental data over the plots based on area as correlating variable, discussed above. Perhaps it is too much to expect significant accuracy from Laurendeau's simple theory when applied to electrically heated bodies—it must be kept in mind that it does not include any heat-balance term for the electrical power supplied.

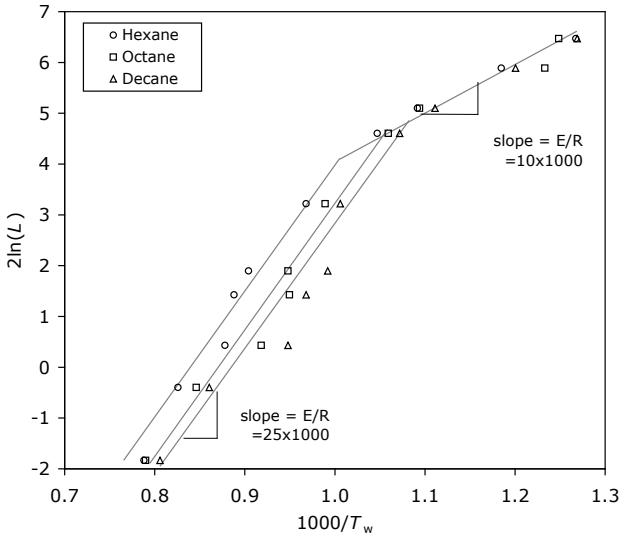

Figure 80 Laurendeau theory applied to Kuchta's data: hot Nichrome or Inconel wires

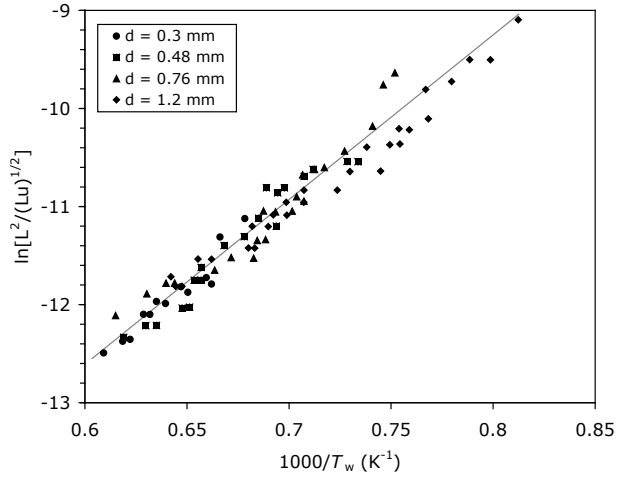

Figure 81 Correlation of forced-convection results of Kumagai and Kimura for hot wires in town gas

Other theories. A model was developed by Goyal et al. that endeavors to predict hot-sphere ignition temperatures from fundamental chemical kinetics data[225]. Sharma and Sirignano[226,227] constructed an elaborate model and obtained some numerical solutions with it. Their calculations showed the expected behavior—smaller size or higher velocity of the hot body require higher temperatures for ignition to be attained, but no closed-form solutions were derived. Cairnie et al.[228] proposed another model requiring significant computational effort. Boczek et al.[229] developed a theory for the ignition of a hydrogen-air mixture by a stationary hot sphere. They considered a single-step Arrhenius reaction in the gas phase and solved the problem numerically. A minimum particle diameter of 8 μm was predicted necessary to ignite an 8% hydrogen/air mixture. Toong[230] developed a theory for the ignition of gases by an infinitely-large plate, i.e., a laminar boundary layer solution for a gas flowing past a hot plate where the sides and the end of the plate are infinitely far away. In principle, solutions of this problem could make a good comparison for the infinite-size asymptote obtained from studies of finite-size objects. In practice, however, closed-form solutions or approximations were not obtained for Toong's theory that would be needed to make a comparison. Chen and Faeth[231] further developed the laminar boundary layer theory. Their theoretical calculations showed a large dependence on the Arrhenius parameters, but actual correlation to experimental data was not attempted. A number of authors have proposed ignition theories for *catalytic surfaces*, which may be heated or not. The one by Fakheri[232] is among the most ambitious; he also provides an extensive review of previous work on the topic. The problem generally modeled is one of forced convection over a long catalytic plate; this is relevant to some cases of purposeful combustion but is not a particularly common geometry for accidental ignitions.

FUSED WIRE IGNITION

In 1922, Ilsley and Hooker[233] studied the ignition of natural gas/air mixtures by heated 22 AWG (0.643 mm) copper and iron wires. They found that ignition took place only if the wires fused. Since two different metals could be brought up to just below their melting temperature without ignition taking place, yet ignition would occur upon fusing, the findings were suggestive that more than simply a hot-surface temperature effect was involved. Later, Shepherd and Wheeler[234] conducted more extensive experiments using platinum and tungsten wires. They found that the platinum wire needed to be heated to 1200 – 1300ºC, which was below the fusing temperature of the metal; ignitions with tungsten wires could be obtained far below the melting point. Subsequently, Davies[235] discovered that very thin (0.127 mm) gold wires only ignited methane/air mixtures upon fusing (T_m = 1064ºC). Repeating his experiments with platinum wires, he found that when the wire was heated to about 600ºC, the temperature took an abrupt jump to 1600ºC. This signified a heterogeneous ignition. The wire was then heated to its melting point (T_m = 1768ºC) by applying further electric power, but a gas-phase ignition never occurred. Davies concluded that when gas-phase ignitions did occur, it was because fusing of the wire caused a spark to appear and to ionize the gas mixture, and that these

should not properly be considered hot-surface ignitions. In further experiments, Davies found that heterogeneous ignition was strongly dependent on the nature and history of the platinum surface—fresh wires did not show a low-temperature heterogeneous ignition, only ones which were 'pre-conditioned' did.

Very thin (0.127 – 0.16 mm) copper wires were used by Silver[236] in 5% diethyl ether/air mixtures. Fusing the wires did not lead to any ignitions. However, when he used a slightly smaller (0.114 mm) wire, but configured as a long (0.3 m) spiral, he obtained an ignition even without fusing the wire. Wires of 0.33 – 0.63 mm diameter did lead to ignition, but only after fusing. Silver also showed that small (5A or less) glass cartridge type fuses (with glass removed) did not lead to ignitions of diethyl ether/air mixtures when fusing. Zborovszky[237,238] conducted constant-current tests using various wires (Table 12). Whether or not ignition took place after fusing was found to be dependent on the duration of the spark discharge caused by fusing. If the duration was 16 μs or less, there was no ignition, while durations of 70 μs or more did lead to ignition; intermediate values were not examined. In testing tungsten wire, Shepherd and found a special phenomenon taking place. Ignition could be achieved with very low currents if they waited for the wire to oxidize. As it oxidized, it lost thickness and eventually the tungsten itself ignited and flamed. At that point, the gas mixture would become ignited. Under these conditions, 0.065 mm wires required only 1.04 A for ignition, while 0.1 mm wires needed 1.56 A. Although copper does not ignite in this type of experiment, Zborovszky[237] found that with copper wires there was also an oxidation effect, which could lead to thermal runaway. If the wire temperature was raised above ca. 950ºC, then the wire started to undergo a runaway condition, leading to fusing. At temperatures below this value, the wire could be maintained at a given temperature without appreciably changing with time, without fusing, and without ignition. In her experiments on copper wires, ignition versus non-ignition cases showed a color difference. After the experiment, the wires which both fused and caused ignition were lavender or dark lavender in color, while ones which fused but with no ignition were grey. In her tungsten wire tests, Zborovszky found that ignition could be achieved without fusing, and with as little as 3.5 A, but this took 1174 s. In all her other experiments, ignition took place in 260 s or less, and was later followed by fusing. Thus, for tungsten wires the ignition mechanism was determined to be hot surface, with the subsequent fusing and arcing playing no role in the ignition process.

Lewis and von Elbe[70] considered that the minimum energy for fused-wire ignition should be the same as for spark ignition, but corrected for the energy needed to heat up the wire. Using the experimental results of Stout and Jones[239], they plotted MIE as a function of the heat sink variable ρVC (density × volume × heat capacity) for the wire and found that the energy extrapolated to $\rho VC = 0$ was very close to MIE as determined from spark ignition experiments; for higher values of ρVC, MIE increased linearly with ρVC.

Table 12 Zborovszky's results on the ignition of 8.3% methane in air by heated wires

Wire	Diameter (mm)	Current needed for ignition (A)	Must fuse for ignition to occur
copper (100 mm long)	0.254	*	
	0.327	*	
	0.381	46	yes
	0.508	32	yes
	0.635	80	yes
beryllium/copper (80 mm long)	0.178	4.25	yes
	0.38	11	no
tungsten (11 mm long)	0.178	4.5	yes
	0.178	3.5	no
tungsten (80 mm long)	0.178	4.25	yes
	0.38	9 – 12	no
* wire fused, but no ignitions obtained			

Craven and Foster[240] claimed that ignitions from fused wires occur because, when a wire fuses, hot metal particles are ejected into the gas volume and these particles present a large surface area in contact with the gas. Furthermore, a larger gas kernel becomes effectively 'seeded' with such particles. But Zborovszky showed that such special assumptions are unnecessary by conducting two parallel experiments—in one case ignition took place upon fusing of the wire. In the second case, wires of the same diameter (0.635 mm) and the same electrical current (79.3 A) were used, but two wires were originally butted together, then quickly separated at a speed matching that at which fused wire ends separate. This experiment likewise led to ignition, leading Zborovszky to conclude that the ignition mode in fused-wire experiments is simply normal spark ignition. She did document that multiple flame kernels could be observed in some wire fusing experiments, but evidently these do not play a crucial role. The spark discharge produced 5 – 20 mJ in her experiments, and this energy sufficed for ignition.

A comprehensive recent study[241] by Takahashi and coworkers explored the effect of a wide variety of fused wires on the ignitability of a methane/air mixture at room pressure and temperature. This type of experiment is carried out by selecting a DC or AC power supply of a given voltage. A wire of a given metal type, diameter and length is then connected to the power supply. A current recording circuit determines the total current which flowed through the wire, up to the point that the wire fails due to fusing. The total power delivered is simply determined as the integral over time of the voltage times the current. By monitoring the current, the authors were able to elucidate the *time* element in such ignitions. For mixtures at the LFL, ignition occurred during the wire's heating-up period, before fusing. But for mixtures at the UFL, ignition corresponded to the

fusing event. This difference implies that less heating energy must be delivered for ignition at the LFL than at the UFL. Within certain broad ranges, the results did not depend significantly on the diameter of the wire nor on the voltage used for fusing. A very high voltage (100 VAC), however, was found to cause such a vigorous scattering of particles that results had poor repeatability. Takahashi also found that a different ignition mode occurred if the voltage was low enough so that a long preheat time occurred before fusing. In such cases, they believe that the fuel gas is able to decompose prior to ignition and that the subsequent ignition, effectively, represents a different fuel. When tungsten wires were fused under long-preheat conditions, an additional phenomenon was observed. The actual ignition was preceded by observable chemiluminescence, which is attributed to a tungsten-carbon reaction. Under such conditions, the UFL was increased from 16.3% to ca. 17.5%. Takahashi's main conclusion was that metals of high melting point, such as molybdenum (T_m = 2892 K), and tungsten (T_m = 3663 K) give higher UFL values than do low melting point metals, such as copper (T_m = 1357 K), Nichrome (T_m = 1673 K), or platinum (T_m = 2043 K). A limited exploration with copper wires indicated that fusing of an 0.3 mm diameter wire was never sufficient to cause ignition; copper wire of 0.5 mm diameter was able to cause ignition, but only by using a very large amount of energy. Thus, for the purposes of conducting standard, conservative tests, only the high melting point metals should be used. When various exceptional ignition modes were excluded, the flammability limits for methane/air under fused-wire ignition conditions were found to be 4.6% to 16.3%, which is slightly broader than the 5.0% to 15.0% spark-ignition range reported by Coward and Jones[242]. The authors consider this to be insignificantly different, since a German test method (DIN 51 649 Part 1) employing an apparatus similar to Coward and Jones, but with somewhat different dimensions, gives a flammable range of 4.4% to 16.5%.

When a current-carrying wire is fused, the diameter of the *droplets* formed normally does not exceed the wire diameter[237].

IGNITION BY HOT, NON-FLAMING GASES AND MESG

There are a number of safety problems where the ignition problem is as shown schematically in Figure 82. Two chambers are connected by a narrow passage. The primary chamber has a flammable atmosphere and an explosion takes place there. It is desired to prevent an explosion in the secondary chamber, which also may contain a flammable atmosphere. With this arrangement, the ignition in the secondary chamber may be due to:

- a jet of hot gases expelled into it
- a flame expelled into it
- hot particles expelled into it.

Ignition by flames was already considered earlier in this Chapter, while ignition from small hot particles moving through a narrow passage has only been studied to a limited extent and it is considered in Chapter 12 under explosionproof enclosures. The phenomenon which generally tends to govern ignition in practical situations of this kind is a jet of hot, non-flaming gases and this mechanism will now be considered. The problem is typically important in chemical manufacturing plants, where electrical equipment, even under failure conditions, must be prevented from igniting flammable atmospheres. In such equipment, it may be impractical to insist on zero gaps at junctures such as mating flanges, and finite-size gaps can be permitted, if it is reasonably certain that an explosion will not be initiated through this path. In safety regulations, this is done by limiting the size of the gap to a prescribed maximum size, called the MESG (maximum experimental safe gap).

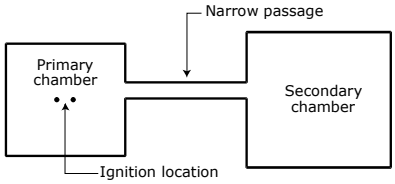

Figure 82 Basic geometry of the secondary chamber ignition

A jet of hot, but non-flaming gases has the ability to act as a pilot for igniting a mixture. The earliest investigations of this phenomenon were by Wolfhard and coworkers. In one study[243], using jets of hot air or nitrogen, they showed that mixtures of hydrocarbon gases in air required very high temperatures for ignition, typically 900 – 1100ºC. The flow rate of the hot gas jet, however, had nearly no effect. The effect of oxygen percent in the atmosphere was negligible, for concentrations > 21%, and modest for concentrations between the MOC and 21%. Using a jet of nitrogen to ignite H_2/air mixtures[244] required a temperature less than 755ºC; a temperature of 870ºC sufficed for a hot air jet to ignite a CO/air mixture. Later, they examined[245] methane/oxygen/nitrogen jets escaping through a narrow channel into an 'outer' methane/air atmosphere. They first determined that gaps smaller than 3 mm in diameter would not pass through a methane/air flame, but ignition of a flammable 'outer' mixture could still occur due to the issuing hot gas jet. When the gap diameter became less than about 2.75 mm, hot-gas-jet ignition became impossible, unless the escaping jet's composition contained more than 21% oxygen. For gaps below about 0.5 mm, even highly oxygen-enriched jets were unable to cause ignition. For methane/21% O_2/nitrogen jets escaping into an outer atmosphere where the fuel was a mixture of CO and H_2, however, a much smaller gap of 1.2 mm was required to prevent ignition. The problem has another size variable, the length of the channel. Functionally, this corresponds to the width of the flanges containing the gap. The longer the gap length, the greater the cooling effect that might be expected on the jet. Thus, for lengths greater than about 5 – 10 mm, it was found that increasing gap length increased the minimum oxygen concentration of jet required for ignition to occur. However, it was found that very short gaps (< 5 mm) made

ignition more, not less, difficult. This is because flows emerging from short channels diverge rapidly, with attendant cooling.

In other experiments, Wolfhard et al.[246] documented that a stoichiometric hydrogen/air 'inner' mixture was more incendive than a stoichiometric methane/air mixture. They also deduced that shock waves do not play a role in igniting the outer mixture. Vanpée and Wolfhard[247] showed that there is quite a good correlation (but not a straight line relation) between the gas-jet ignition temperature and an unusually-defined limit flame temperature of a particular fuel gas. The limit flame temperature (see Chapter 3) is normally defined as the flame temperature at the LFL, but Vanpée and Wolfhard defined it as the flame temperature when a stoichiometric fuel/oxygen mixture is diluted with sufficient nitrogen so as to be at extinction.

In a study encompassing a variety of fuels, Kuchta and Cato[248] found that the lowest temperatures were required when the fuel/air mass ratio exceeded about 0.5. At a fuel/air ratio of 0.25, igniting temperatures were about 50ºC higher. The results are hard to present in some universal way because ignition temperatures decrease with increasing jet diameter[249]. This relation appears to be monotonic and does not show a minimum. The authors also studied several permutations of the basic situation of discharging a hot-air jet into a flammable atmosphere:

- a hot-air jet is discharged into a volume of pure fuel (without an oxidizer).
- a hot-nitrogen jet is discharged into a flammable atmosphere.

These test conditions likewise led to a plethora of disaggregated results. Qualitatively, however, the authors observed some important effects. As an example, injecting a hot nitrogen jet from a 17 mm diameter hole into CO/air mixtures produced no visible phenomena if the jet temperature was below 750ºC. But when the jet temperature was between 750 and 875ºC, a luminous column appeared in the CO/air mixture. The color was generally deep blue at the base of the column, progressing to green further downstream. The length of the column increased with temperature and reached about 250 mm at 875ºC. For temperatures in excess of this value, flame originated at a location roughly corresponding to the tip of the luminous column. This flame then propagated throughout the vessel, denoting a true ignition of the mixture. With the exception of hydrogen mixtures, lowering the *pressure* of the system caused an increase in the ignition temperature, but the effect was not large until pressure dropped to ca. 0.2 atm. Methane[250] generally behaved in a different manner from other fuels. Flaming ignition without a preceding luminous column occurred if the methane concentration in the target atmosphere was ≥6%. But for methane concentrations in the range of 1.5 – 5.5%, a bright luminous column was seen, but no flaming ignition. Some typical laminar-jet ignition data obtained by BM are shown in Figure 83.

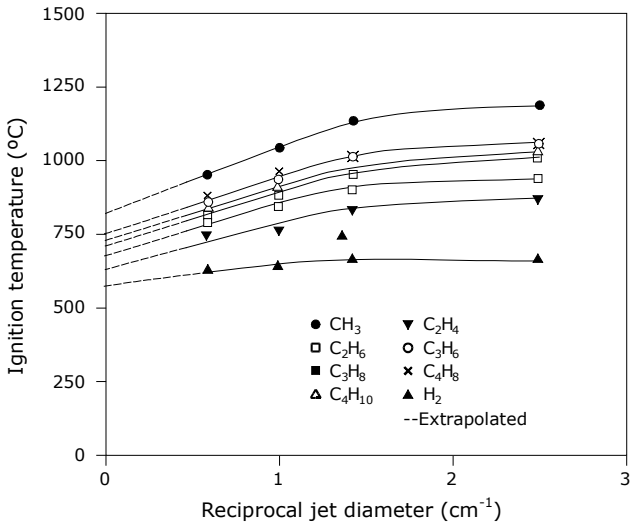

Figure 83 The effect of jet diameter on ignition with a laminar hot-gas jet[250]

For a given diameter of hot source, the temperatures of hot gas jets needed for ignition are always higher than the temperature of a hot, non-catalytic wire[251].

The above discussion was limited to laminar jets. Turbulent-jet ignition temperatures are generally higher than those for laminar jets. For turbulent jets, it has been shown that ignition, if it occurs, tends to occur at about 10 mm away from the exit[252]. A theory has also been proposed for the turbulent jet case[252], but it does not lead to closed-form solutions. The exit velocity of the gases (and whether they are laminar or turbulent) will, of course, be affected by the pressure developed in the primary chamber, thus, the fluid-mechanical regimes within the primary chamber must be considered next.

Upon an explosion in the primary chamber, the pressure in it will rise significantly, and an increase of roughly six-fold is common[253]. The role of pressure in the primary chamber is important, complicated, and not necessarily intuitive. Thibault et al.[254] explained that, as the outflow velocity from the primary chamber is increased, progressively three different regimes are encountered:

(1) A laminar flow regime, where the MESG pertinent to the narrow passage corresponds to the conventionally-measured quenching distance.
(2) A turbulent-mixing controlled regime, where turbulent mixing of the combustion products at the entrance to the secondary chamber causes the temperature of the jet entering the secondary chamber to drop. Consequently, increased pressure in the primary chamber (and flow velocity into the secondary chamber) lead to larger spacings being sufficient for quenching.
(3) A gas-dynamic regime, where flow is sonic at the inlet into the secondary chamber. In this regime, quenching distances are about an order of magnitude greater than

Table 13 Effect of flange breadth on the MESG of methane in air

Flange breadth (mm)	MESG (mm)
3	0.7
5	0.85
8	0.9
10	0.9
12.5	0.975
15	1.0
25	1.15
50	1.3
75	1.35

the MESG values for that particular mixture. An overpressure in the primary chamber of only about 0.8 atm can suffice to cause sonic outflow.

The highest pressure and velocity are developed if the ignition source is located at the center of the primary chamber. As a consequence of this, the safest *location* for the ignition source in the internal chamber is at the center and the least safe is near the flanges. Experiments where the igniter was located in different locations within the primary chamber will generally yield quite different results. For example, in some early tests, Walls et al.[131] found that a circular orifice of 5.1 mm diameter (in a 3 mm thick wall) was required for ignition of a methane/air mixture, whereas its MESG is reported as 1.14 mm when measured in current-day test equipment. Larsen and Eckhoff[255] showed that for gap sizes slightly greater than the MESG, there is only a very small range of igniter-to-gap spacings for which propagation can occur. Maekawa and Takeichi[256] demonstrated that when the igniter was located in the center of the primary chamber and not close to the flange, values of MESG were found which were higher than the quenching distance. Smith[257] studied the igniter location effect for methane/air mixtures in three different vessels and found that the effect ranged from negligible to about 30%; the effect was generally largest for very small flange breadths (< 6 mm). Phillips[258] directly studied the effect of flow velocities when the igniter location was changed.

Most of the MESG studies have used small spark ignition sources, since the application of the results is typically to electric-control equipment that only uses small currents. But if ignition in the first chamber is from a large arc, then smaller gaps are needed in order to avoid transmitting the explosion into the second chamber. Bartels[259] found, for a limited number of tests, that the required gap size dropped with increasing arc current. Additional data have been presented by Birtwhistle and coworkers[260,261].

The annular space between the flanges through which the primary chamber gases escape has three dimensions. The MESG itself corresponds to the smallest dimension, but the other two dimensions can affect the outcome and, thereby, have an effect on the MESG value. Phillips[262] documented that the MESG value increases with increasing flange breadth (i.e., the distance along the flow stream), up to a very wide 50 mm flange (Table 13). Riddlestone and Nethercot[263] also published similar data. Maekawa and Taeichi[256] showed that, under some circumstances the distance along third dimension (perpendicular to the gap and to the flow velocity) can also affect MESG values.

Brown et al.[264] showed that the volume of the space wherein the explosion originates must have a certain minimum size (ca. 900 mL for H_2) so that an incorrectly high value of MESG would not be reported (Figure 84).

Later investigators found that curves typically have a 'knee' at a much smaller volume. For instance, Redeker[265] provided data which provides the basis for the selection of a 20 mL internal test volume by PTB, the German safety testing organization (Figure 85). Redeker also showed that for the values to reach a constant asymptote, the secondary chamber must be configured as a pressure-relieving (constant-pressure) chamber. If the secondary chamber is sealed, then a constant plateau is not obtained, but that latter situation would not likely pertain to actual industrial explosions.

Phillips[266] attempted to create a model to predict MESG values. Basically, the exiting jet is cooled by air being entrained into it, while its temperature is raised by reactions. It is assumed that at the issuing gap there is zero fuel fraction. Now, in the outside atmosphere, combustible gas is present and this is being entrained, along with air. Thus, a competition is set up between cooling and heating. Phillips showed that the maximum entrainment rate is proportional to a group of constants representing the fuel, primarily its reaction rate. A plot of this 'fuel chemistry' variable against the MESG showed a good relationship, but Phillips did not

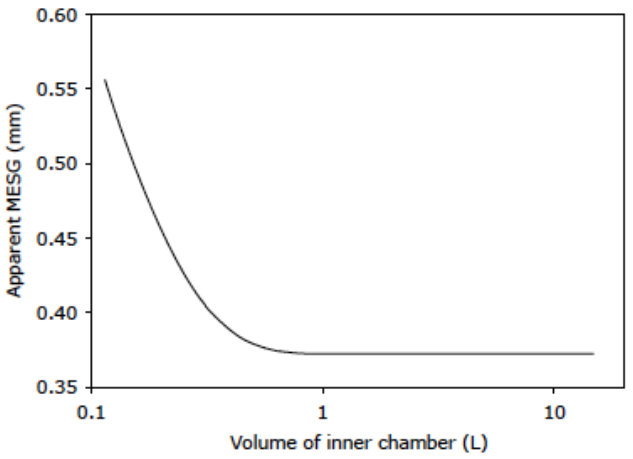

Figure 84 Brown's results on the effect of volume of the space wherein the explosion originates on the apparent MESG of mixtures of 29.6% H_2 in air (determined at the 50% probability level)

present verifiable computational details, and his theory has been criticized by Prof. Roger Strehlow as being unacceptably oversimplified[267]. Lunn[268] also attempted to relate the MESG to chemical structure. Qualitatively, he found it depended on the initial decomposition of the fuel molecule at pre-ignition temperatures, especially the bonds that were susceptible to earliest attack and the products which were being formed. Such considerations, however, did not lead to numeric predictions or correlations. In general, MESG values are lowest for gases which have unsaturated bonds (C=C or C C), since these tend to be least stable. Burgess and Hertzberg[269] proposed that MESG will be governed by the dimensionless ratio LFL/C_{st}, where C_{st} = stoichiometric fuel concentration (vol%). Unfortunately, checking this relation for a number of substances listed in Table 1 of Chapter 15 reveals that a correlation is non-existent.

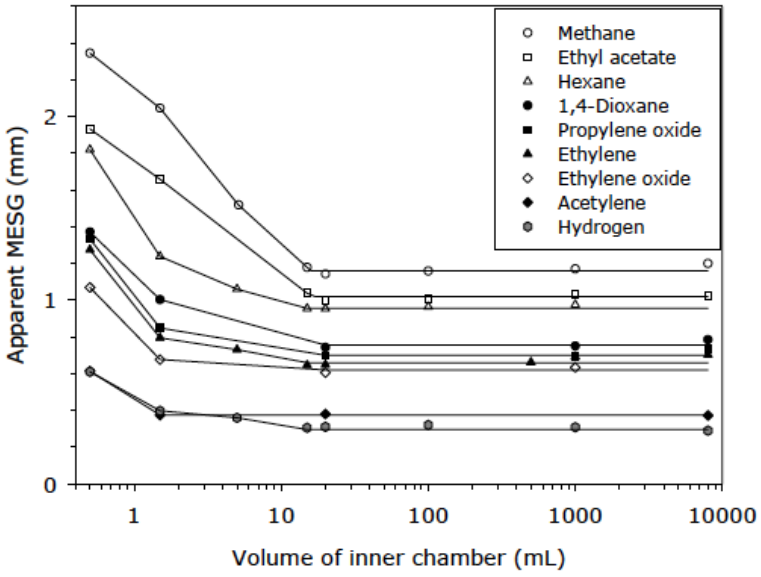

Figure 86 Redeker's results on the effect of volume of inner chamber on the apparent MESG (flange width = 25 mm in all cases)

If the flanges are heated, as by continued flame activity in the inner chamber, the effective MESG value will decrease. This dependence on *temperature* was documented by James[270] for the case of natural gas/air mixtures (Figure 86). In systems at elevated pressure, *pressure*[262] has an effect on the MESG, as illustrated in Figure 87. The curves for the three gases are quite similar and can be well represented by:

$$\frac{MESG}{MESG_{1\,atm}} = 0.13 + \frac{0.86}{P}$$

where P = total pressure (atm). *Humidity* has a negligible effect on results[271].

The MESG is normally quite a bit smaller than the minimum quenching diameter. This is because the quenching diameter is determined for a stagnant mixture, while in MESG testing an explosion is created in the inner chamber, which expels gases at high velocity. Helwig and Nabert[272] showed that for 20 common gases and vapors the relation:

$$MESG = 0.5\,d_{II}$$

is obeyed very closely (Figure 88), with only CS_2 showing a discrepancy. However, there are other exceptions. Wolfhard and Bruszak[245] found for a configuration where the inner volume comprised a nitric oxide/hydrogen mixture while the outer volume contained methane/air that MESG = 0.7 mm while d_{II} = 15 mm, which is a ratio of 0.062. Redeker[265] showed that values of MESG and the quenching distance would become identical, to within experimental error, if the MESG were measured using an inner chamber of very small dimensions instead of the 20 m L or larger volume that is needed for standard testing. This can be seen by noting that the data points in Figure 85 for the smallest test vessel are close to the published values of d_{II}.

The *test apparatus* used makes a difference. The values of MESG as determined by the UL's Westerberg apparatus (details of the test apparatuses are given at the end of this Chapter) are sometimes similar to the UK results and sometimes grossly different. The disparities were originally examined by Strehlow et al.[267], later by Phillips[273], and finally by Bartkus[422]. Strehlow conducted some modeling of explosions in the Westerberg apparatus, in the 20 mL HSE sphere and in the 8 L UK sphere. These results were inconclusive, but did point out a strong role of the flange configuration: in the UL test, the breadth (i.e., the travel distance for the escaping gases) of the flange is 19 mm, while it is 25 mm in both UK tests. Phillips considered it a serious draw-

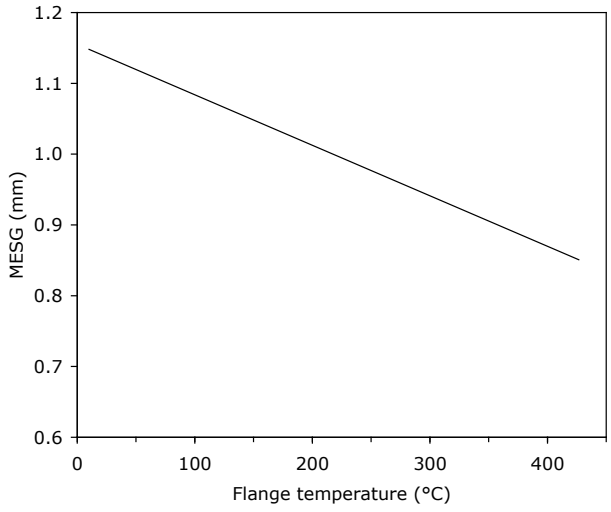

Figure 85 Effect of elevated temperature on effective MESG for the case of natural gas/air mixtures

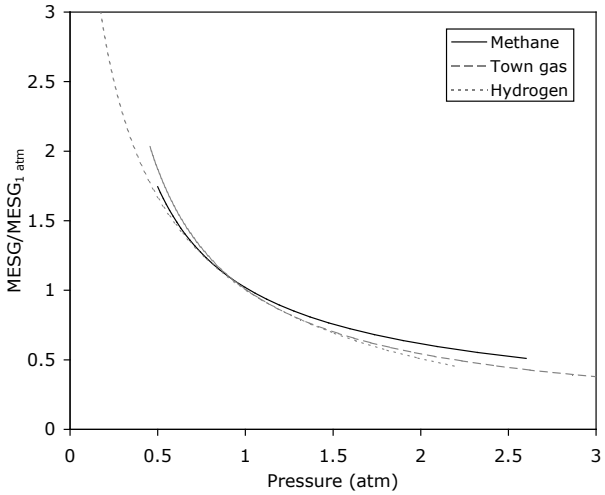

Figure 87 Effect of pressure on MESG

back of the UL rig that the secondary chamber is smaller in volume than the primary and consequently, the environment there becomes strongly vitiated by the entering gas jet. This has a pronounced effect only if the fuel has a low AIT, in which a spurious autoignition can occur in the secondary chamber due to the hot vitiated gases. Bartkus considered Phillips' hypothesis to be validated by further testing at UL, where new tests were run with the volume of the primary chamber reduced by 30%. This resulted in the MESG for hydrogen rising from 0.086 mm to 0.23 mm and for diethyl ether from 0.30 to 0.64 mm. Other values were unaltered by UL, despite their questionable status. Figure 89 shows a comparison of results; the UL values for hydrogen and diethyl ether are the corrected ones. Acetylene, ammonia, and carbon disulfide are clearly strong outliers and have not been corrected. Generally, only a very weak dependence on AIT can be seen, so effects other than a low-temperature

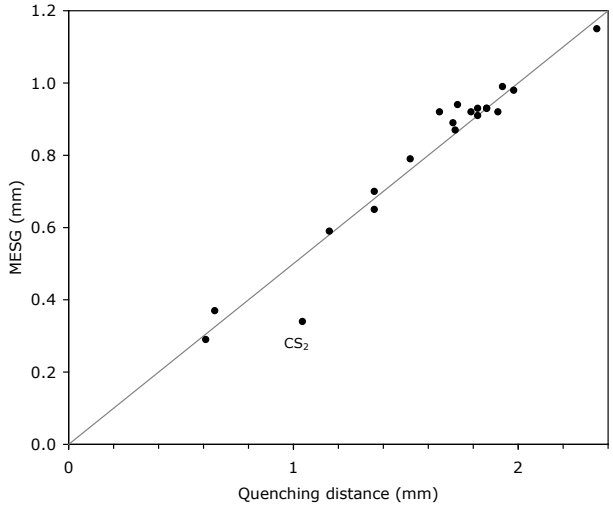

Figure 88 Relation between quenching distance and MESG

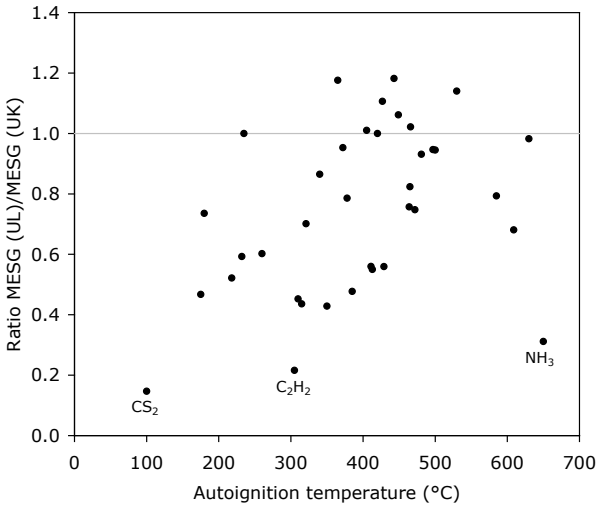

Figure 89 Comparison of MESG values obtained by the UL procedure and by the UK procedure

autoignition in the secondary chamber appear to be dominating. Britton[274] considers that the IEC/PTB apparatus should be used and that the UL apparatus is poorly designed. He pointed out that MESG data are mostly used for designing small electrical instrumentation cabinets and that creating pressure piling and bulk heating in the test system grossly misrepresents the intended use of the data.

As was pointed out by Slack and Woodhead[275], there is a relation between the MESG and the MIE. For industrial safety applications, the results of testing are often reported not in energy units but simply as the minimum value of current—'*minimum igniting current*'—needed for ignition. Figure 90 shows the results from PTB[272]. Their correlation line is:

$$MESG = 0.022 \times MIC^{0.87}$$

The correlation between MESG and MIC is used in the IEC scheme for design of electrical equipment for hazardous locations (Chapter 12). In there, the value of MIC is reported as the 'MIC ratio,' which is the MIC for the desired substance, divided by the MIC for methane. By using only the ratio, it was felt that some interlaboratory discrepancies would be eliminated. The MIC for methane is determined as 85 mA at PTB. Note that MIC values are even more test-apparatus-dependent than MESG values. The German researchers concluded that the UK values reported using the HSE Break-flash Apparatus No. 3 can be related to the PTB values as:

$$MIC_{HSE} = 2.17 \times MIC_{PTB}$$

The PTB values are the ones of more general interest, since their test apparatus was the one adopted as an international standard by IEC. Bartels and Howes[276] showed that values of the MIC, as determined in the IEC/PTB breakflash apparatus, decrease with increasing pressure, oxygen concentration, or temperature. A limited amount of data obtained by

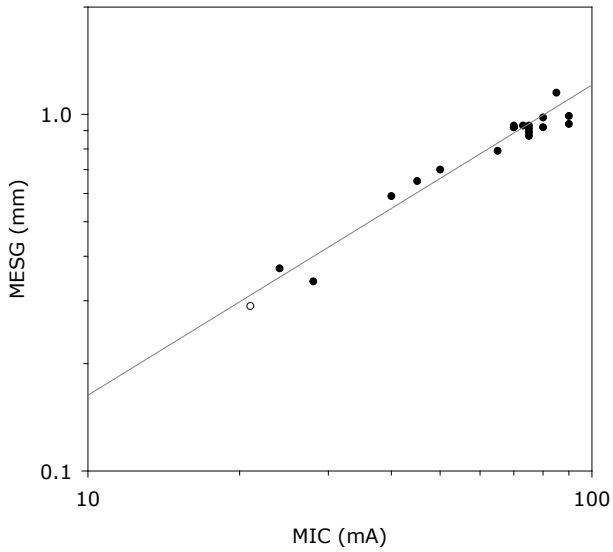

Figure 90 Relation between MESG and MIC using German data from PTB

Zborovszky[237] pertinent to the pressure effect suggests that $MIC \propto \frac{1}{P}$. Raising the oxygen concentration[277] from 21% to 35% causes the MIC to decrease by about 3×.

MESG data are compiled in Chapter 15. Brandes et al.[278] proposed a method for estimating the MESG of *mixtures* of gases.

IGNITION BY LASER ENERGY

The ignition of gases by lasers can be in one of six ways[156,279]:

(1) direct thermal heating of gas
(2) photochemical excitation of gas (photodisssociation)
(3) laser-induced breakdown (spark) of gas; a subcategory of this termed resonant breakdown is possible but has been demonstrated only for some unusual gases.
(4) radiative heating of small particles in the atmosphere
(5) laser-induced breakdown of gas aided by presence of small particles
(6) laser-induced heating of particles of explosives.

The last possible mode is very specialized and will not be considered. The modes that depend on direct use of laser energy to produce a spark kernel (#2 and #3) are inefficient—the bulk of the energy is not absorbed by the gaseous medium. Ignition by simple heating of a solid target (i.e., dust particle) can be much more efficient, and ignition by that mechanism requires much lower heat fluxes. With laser energy it is possible to initiate detonations, not just deflagrations, and Ronney[156] reviewed this topic.

DIRECT THERMAL HEATING OF GAS

Thermal heating is typically feasible if suitable molecules are present that can effectively absorb radiation at the laser wavelength. Trott[280] provided extensive data for ignitions in this mode on low-pressure (11 – 13 kPa) fuel/air mixtures using ethylene, methanol, ethanol, dimethyl ether, *p*-dioxane, *n*-propyl nitrate, and *iso*-propyl nitrate. The laser wavelengths used were 9.2 – 10.8 μm in his experiments. Successful thermal ignitions were also reported for $SF_6/CH_4/O_2$ mixtures from CO_2 laser radiation[281]; even though methane and oxygen are transparent to laser radiation, SF_6 does absorb and this suffices. The temperatures the gas needs to attain for ignition to occur are much higher using laser heating than using conventional heating arrangements. Trott typically found that T_{ig} values were 200 – 500ºC higher than standard AIT values. Apparent activation energies, however, as computed from $\ln(t_{ig})$ versus $1/T$ plots, were nearly the same as reported in conventional experiments.

PHOTOCHEMICAL EXCITATION OF GAS

If sufficient UV radiation is imposed, molecular oxygen can be dissociated into atomic oxygen. This creates the initial radicals needed to start a chain reaction, and combustion can then begin. Photochemical excitation was already studied by Norrish[282] in 1964, who used a photoflash tube for his experiments, before lasers for this purpose were available.

LASER-INDUCED BREAKDOWN OF GAS

Extremely intense laser radiation can cause a gas to break down in the form of a plasma, visible as a spark which, under the right circumstances, can be incendive. The irradiance needed (10^{11} – 10^{12} kW m^{-2}) is several orders of magnitude greater than necessary for ignition by directing laser energy onto a target surface or particle, with actual gas ignition then resulting from the elevated temperature of the target. Several groups[283,284] studied the effect of the wavelength of the laser used on the energy needed for ignition, but clear trends were not found. In laser-spark ignition, a plasma is created that has extremely high temperatures (100,000 to 1,000,000 K), along with high local pressures (ca. 10^3 atm) and a concomitant shock wave[291]. The laser pulse duration needed for ignition is very short. As an example, Phuoc[285] ignited stoichiometric methane/air mixtures at ambient pressure using pulse lengths of 5.5 ns. Because of the short duration, the energy needed was only 7.5 mJ. Detonable mixtures can be detonated by laser-induced breakdown. When atmospheric pressure is varied, Lee and Knystautas[286] showed for equimolar C_2H_2/O_2 mixtures that an inverse energy/pressure relation exists that characterizes the boundary between deflagrations and detonations.

In describing the ignition of methane/air mixtures, Phuoc and White[291] observed that initially a loud 'crack' is heard upon the breakdown of the gas and the formation of a spark channel, the kernel then grows and is followed later by a burst of blue flame enveloping the spark. For producing a spark (as contrasted to an incendive spark), about 2.5 mJ was found to be needed at 1 atm, with greater energies at

lower pressures. For sparks to be incendive at 1 atm, about 4 mJ was needed; this is about an order of magnitude greater than for ignition from a capacitive-discharge spark. Also, unlike for capacitive discharge spark ignitions, the minimum energy was found at rather high methane concentrations of 10 – 14%. In their experiments, where Phuoc and White had incendive results with irradiances of $10^{13} – 10^{14}$ kW m^{-2}, the corresponding beam powers were $10^6 – 10^7$ W and beam diameters were ca. 17 μm. For a spark kernel to continue growing and lead to ignition, a minimum size of ca. 0.4 mm was needed in the short axis; the kernels were cylindrical or ellipsoidal, and lengths were about double the width.

The sparks created by laser breakdown differ from sparks produced by capacitive discharge primarily in two ways: (1) the laser-induced plasma is hotter and of shorter duration than from spark discharge; and (2) heat transfer and flow effects due to metal electrodes are absent. Despite these differences, the energy required for ignition through laser-induced breakdown of gases is roughly similar to the MIE found in capacitive discharge testing. In an early study, working in a low-pressure regime ($0.2 \leq P \leq 0.4$ atm), Weinberg and Wilson[287] found the energy required for methane ignition by the laser mechanism was within about a factor of 3 to the value found at the same pressure in capacitive discharge testing. More recently, Lim et al.[288] conducted tests at 1 atm and found that there is a strong effect of pulse duration. Figure 91 shows that using shorter pulses (picosecond duration) more energy is required than for longer duration (nanosecond) pulses. The same trend was found by Syage et al.[289], who tested hydrogen/air mixtures. By extrapolating from their experiments with theoretical modeling, they showed that, while pulse durations on the order of 10 μs give MIE values about 10× higher than do capacitive sparks, pulses of 1000 μs give laser-ignition values similar to the capacitive ones. The latter is an exceedingly long time, however, and it is not clear if this a realistic extrapolation. Under many test conditions, the energy required for breakdown is inversely proportional to pressure, at least over a range of about 0.1 – 10 atm[290].

There is no detectable delay period between initiation of the beam pulse and spark breakdown if short-wavelength (ca. 1 μm or less) radiation is used. For long-wavelength radiation, e.g., a CO_2 laser at 10.6 μm, delay may be detectable[290].

Since one mode of ignition with laser radiation involves an electron cascade process, environments leading to the presence of initial electrons facilitate ignition; this includes the presence of impurities such as aerosols or low-ionization potential organic vapors[291].

A hybrid technique has also been used[292], whereby laser energy is focused onto a 'beam dump.' The latter is an open conical cavity where multiple reflections of the beam energy occur from the walls, with the energy being mostly deposited into the gas phase near the point of the cavity. The walls aid the focusing of energy in this case, but do not directly act as a hot-surface ignition source.

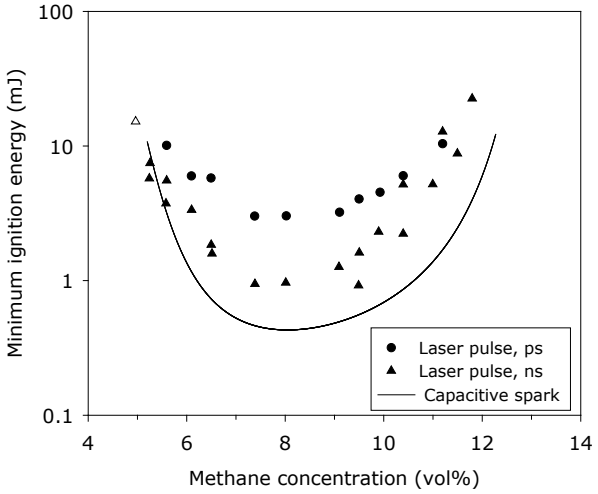

Figure 91 Effect of laser pulse duration on MIE for methane/air mixtures at 1 atm pressure

RADIATIVE HEATING OF SMALL PARTICLES IN THE ATMOSPHERE

If a gas mixture contains some suspended particles and a laser beam is hits a particle, under certain circumstances the heating can ignite the flammable gas mixture. This mode of ignition is considered to have potential for accidental ignitions, since laser measuring and sensing devices are more actively being introduced into manufacturing and extractive industries. Two types of target particles, in general, may be involved—combustible and non-combustible. Dubaniewicz et al.[293] explored this mode of ignition for methane/air mixtures. In their experiments, they used an optic fiber to deliver laser energy to particles which were adhered to the end of the fiber. Smaller fiber diameters were found to require less energy, with an 0.2 mm fiber requiring typically less than 1 W. Calculations showed that the non-combustible iron oxide particles used as targets heat up to roughly 1500 K in the ignition process. Bituminous coal particles (combustible) required more power than black iron oxide (Fe_3O_4) particles (non-combustible); this is attributable to the higher radiant absorptivity of the iron oxide particles. The same authors[294] also explored the ignition of hydrogen/air mixtures by laser beams impinging on coal dust particles. Their data, along with those of Carleton et al.[299], Zhang[295], Bothe[296], and Tortoishell[297] are shown in Figure 92. The role of very small particles is not fully clear. Experimental ignition data from other investigators exist down to very small particle sizes (Figure 92), but Tortoishell[297] reported in his study that he failed to ignite particles smaller than 0.25 mm diameter because the particles tended to vaporize, rather than to cause an ignition. Furthermore, in his

study he observed that combustible particles of any size decomposed without causing ignition.

When the area of the target becomes large compared to the quenching distance of the fuel, an area effect should disappear. Adler et al.[298] measured the minimum heat flux needed using large-size, inert targets and their results are shown in Table 14. If the target itself is combustible, lower heat fluxes are sufficient for ignition. For small charcoal particles in a carbon disulfide mixture, the authors found that 9 kW m^{-2} sufficed; large charcoal particles are themselves ignited by laser heating and do not make a viable target.

Generally, the optimally-ignitable gas concentration is lower with laser heating of target particles, than it is with spark ignition. For example, the optimal concentration for methane was found to be 5 – 6%, versus 8.3% for spark ignition testing.

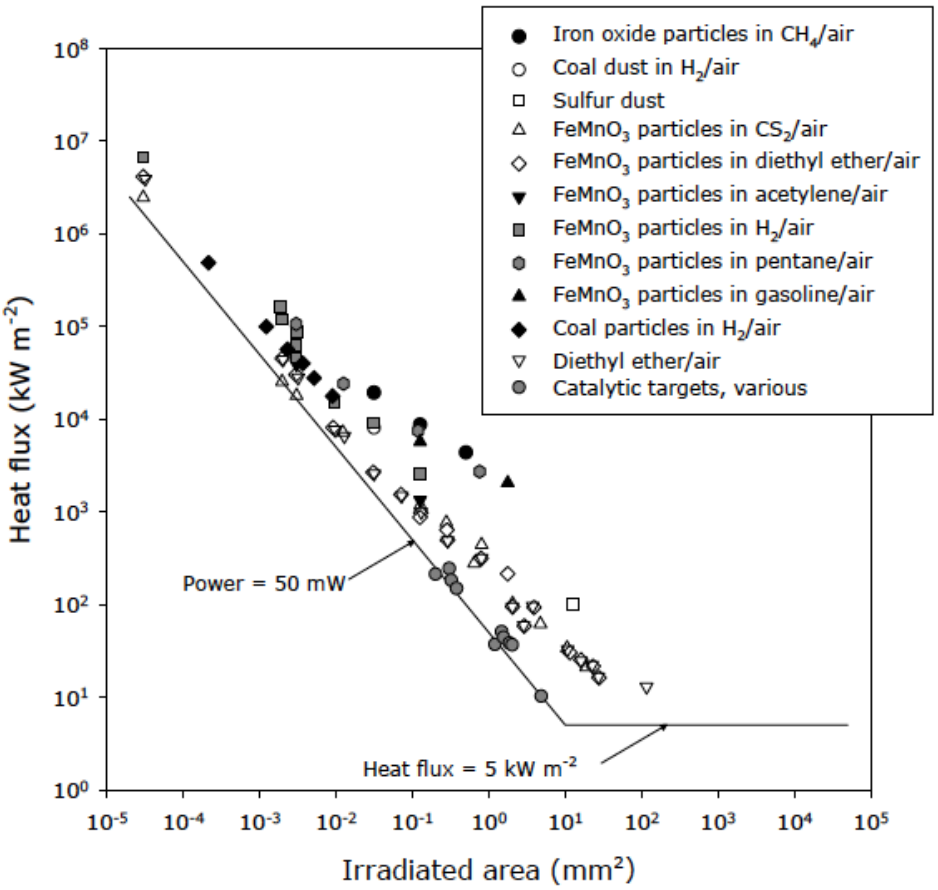

Figure 92 Summary of data on minimum laser heat flux required for ignition of gases by heating of solid target particles

Carleton et al.[299] examined the effect of varying oxygen concentrations over the range 15 – 28% and concluded that the effects were minor. They also explored the effect of the chemical nature of the fuel gas. These results are shown in Table 15. The target powder was chosen because it led to lowest power ignitions; coals, carbon black, and black toner particles generally needed higher power for ignition. Visually, it was found that ignition occurs above the target, not directly adjacent to it. The authors also reported that, with very small beams "the target appears seriously disturbed by the beam and a hole is instantaneously drilled into the target at the hot spot." Quite evidently, a target cannot be raised to a high temperature for a sufficiently long time to ignite a gas atmosphere if it has vaporized; however, general guidelines for conditions under which vaporization occurs were not evolved. The ignition power results shown in Table 15 are roughly correlated to MESG, especially for the 400 μm fiber tests, with the exceptions of hydrogen, propane, and 2-propanol.

Table 14 Minimum heat flux needed for ignition using large, inert targets

Fuel	Min. heat flux (kW m^{-2})
carbon disulfide	22
hydrogen	80
ethylene	87
diethyl ether	90
propane	110
pentane	112
methane	167

In the case of dust clouds, a separate target and combustible gas mixture are not needed, since ignition can be obtained by absorption of radiation by particles of the dust cloud. Carleton et al. also obtained some results in dust clouds; these generally proved to be harder to ignite than targets in gas atmospheres. For example, a minimum ignition power of 1.9 W was found for a starch target in gas atmospheres, but this rose to 4.0 W for a starch target in a starch-dust atmosphere. Additional work is considered in Chapter 5.

The data summary shown in Figure 92 indicates that no ignitions occur at power levels less than about 50 mW. Based on this, the European Commission has selected a 35 mW level as intrinsically safe[299]. The heat flux $\propto$ 1/area relation holds over a very wide range of target areas, but clearly, as the heat flux is decreased and the area is increased, eventually a finite limit for the heat flux must be

Table 15 Effect of chemical nature of fuel for laser ignitions of $FeMnO_3$ targets

Gas	Conc. at min. ignition power (vol%)	Min. ignition power for 62.5 µm fiber (W)	Min. ignition power for 400 µm fiber (W)
carbon disulfide	1.5	0.050	0.149
diethyl ether	12.0	0.089	0.127
acetylene	25.0	0.110	0.167
hydrogen	10.0	0.140	0.331
ethylene	7.0	0.202	0.494

2-propanol	4.5	0.273	0.660
methyl ether	8.0	0.280	NA
methane	5.0	0.304	1.125
n-pentane	3.0	0.315	0.847
* tested at 110ºC			

reached. The Commission guidelines set forth 5 kW m^{-2} as the minimum heat flux below which ignitions are not expected. For gases other than diethyl ether and CS_2, the Commission criteria would offer a very large safety factor.

It is not a trivial task to explain why a 'power' limit exists in Figure 92. Carleton and Weinberg[300] proposed that the breakpoint separating the 'power' limit from the 'heat flux' limit should correspond to a size of the quenching distance for the gas. If the area over which the energy is deposited is smaller than the quenching distance, then the actual area has no role in the problem, since the energy from the entire area can be used in heating the flame kernel. For diethyl ether, the quenching distance is about 2 mm, while for CS_2 it is around 0.5 mm. For most other gases, it is generally 1 – 2 mm. Thus, according to this reasoning, the breakpoint should be at about 0.5 – 2 mm, or at an area of roughly 1 mm^2. In Figure 92, the breakpoint is found at ≈ 10 mm^2, but this value very much depends on data points taken to define the 'heat flux' limit, and latter, as mentioned above, is highly uncertain. Thus, given the fact that the experimental data span 8 orders of magnitude, agreement to within a factor of 10 seems entirely reasonable.

Based on data for large-area ignitions, Carleton et al. found an inverse correlation between the temperature of the target and the AIT of the gas. For silicon carbide targets (the only ones for which these data were provided), a relation was derived:

$$\theta_{ig} = 6.876\theta_a - 1.778\times10^{-2}\theta_a^2 + 1.392\times10^{-5}\theta_a^3$$

where $\theta_{ig} = (T_{ig} - T_o)$, T_{ig} = surface temperature at ignition (K), T_o = ambient temperature (K), $\theta_a = (AIT - T_o)$, and AIT = autoignition temperature (K). The relation, along with experimental data, are shown in Figure 93. Apart from ethylene and hydrogen, the relation fits the data rather well. The authors attributed the divergent behavior of the latter two gases to their exceptionally high laminar flame velocities. A number of mathematical theories[279,301,302] have been offered, but the solutions have been solely computational in nature and closed-form approximations were not offered. Note that at much higher laser irradiances than shown in Figure 92 (ca. 10^{11} kW m^{-2}) it is possible to achieve direct ignition of gases without converting the energy into thermal heating of a solid target; this mode was discussed above.

LASER-INDUCED BREAKDOWN OF GAS AIDED BY PRESENCE OF SMALL PARTICLES

This is, effectively, a combined mode of action and it requires much less power than breakdown without the presence of particles. Kingdon and Weinberg[303] explored this mode by focusing the laser beam sufficiently to cause a breakdown of the gas, but at the same time introducing particles into the focal region. In this mode, high heat fluxes are not required to break down the gas, and the authors considered the breakdown threshold to be smaller than they could measure. The actual energy needed for ignition in this mode turned out to be of the same order of magnitude (0.5 mJ) as the MIE for spark ignition (0.2 mJ) when igniting methane/air mixtures The proviso is that the energy which must be considered is the net energy developed in the plasma, not the gross energy supplied from the laser.

Flammability limits

Assuming that a substance shows an exothermic behavior due to oxidation and not due to self-decomposition, polymerization, or another form of a unary reaction, then it is evident that if an atmosphere contains 100% fuel or 100% oxidizer, no ignition and no fire can occur. What may not be necessarily evident is that the fuel/oxidizer ratio has to be within certain bounds, or else ignition is impossible, even if the 'fire triangle' is met, that is, fuel, oxidizer, and source of ignition are all present.

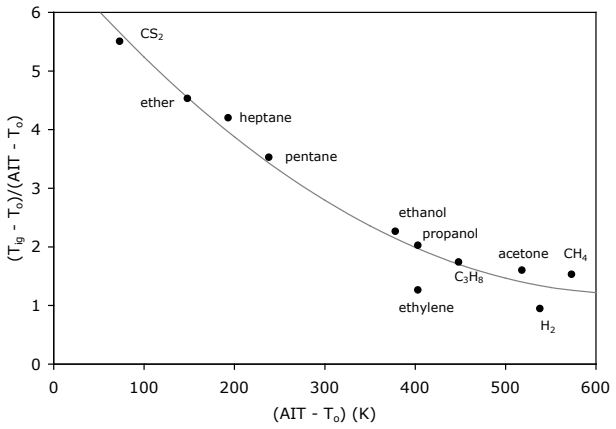

Figure 93 Relation between AIT and target surface temperature for ignition of gases by laser radiation heating of target surfaces

Qualitatively, the reason for the existence of flammability limits is because—apart from 'cool flames'—a flame of very low temperature cannot be sustained. The lowest possible flame temperature describes the minimum temperature below which reaction kinetics become so slow that rapid oxidation, i.e., flames, cannot occur. In the definition, it is important to realize that a continuous combustion is described, not a momentary phenomenon. Thus, a flammability limit can theoretically be considered to be a state at which a 1-dimensional, planar, premixed flame in an infinite medium becomes impossible. In addition to reaction kinetics, heat losses also come into play in any practical combustion situation.

The concept of *flammability*, as applied to gas mixtures, is more specific than is what is used in general in the English language. A mixture is flammable if a flame can *propagate* through it. Thus, if a local heat source, when applied to a mixture, results in combustion which does not propagate through the volume of the gas, the mixture is considered *non-flammable*. But if a heat source is introduced into a fuel/oxidizer mixture through which propagation cannot occur, a local 'cap' of flame may nonetheless be visible. The upper and the lower *flammability limits*[*], then, refer to the lowest and highest fuel concentration, by volume, for which the mixture is flammable. More precisely, the LFL is defined as the value half-way between the lowest concentration at which flame propagation occurred, and the highest concentration at which it did not. The UFL is defined in a similar manner. As with most aspects of ignition, the concept of flammability limits is not absolute, but rather depends on the details of the test apparatus by which the determination is made. Flammability limits are pertinent only to *premixed* fuel/oxidizer atmospheres; the concept is not meaningful if a volume contains significant spatial concentration non-uniformities.

The concept of flammability limits is applied only to normal flames. *Catalytic combustion* can take place outside of the normal flammability limits, since the process does not entail a flame propagation but rather a surface reaction. Thus, for example, the flammability limits of hydrogen in air are 4.0 – 75%, but using a platinum catalyst[304], combustion can be sustained over 1.0 – 80%.

Mixtures can come in a wide range of complexity, but commonly will be a fuel-oxygen-nitrogen mixture. Data presentation becomes somewhat complex, since a *ternary* system must be considered. Figure 94 shows the BM results for methane-oxygen-nitrogen on a triangular plot[51]. The flammable region is the fin-shaped area inside. A few geometric constructions are of interest in this kind of plot. To determine the minimum O_2 concentration which can result in a flammable mixture, given the worst-case fuel and N_2 percentages, a line is drawn that is tangent to the fin and parallel to the 'C-N' axis. This tangent line is seen to correspond to O_2 = 12%. By referring to the other coordinates at the point of tangency, it is found that CH_4 = 8%, and N_2 = 80%. The ratio of O_2 to N_2 in air is fixed at 0.2095/0.7905. Thus, a line labeled "air" is drawn which represents the line upon which any fuel/air mixture must be located, unless O_2 or N_2 are introduced into the system separately, not in their in-air ratio.

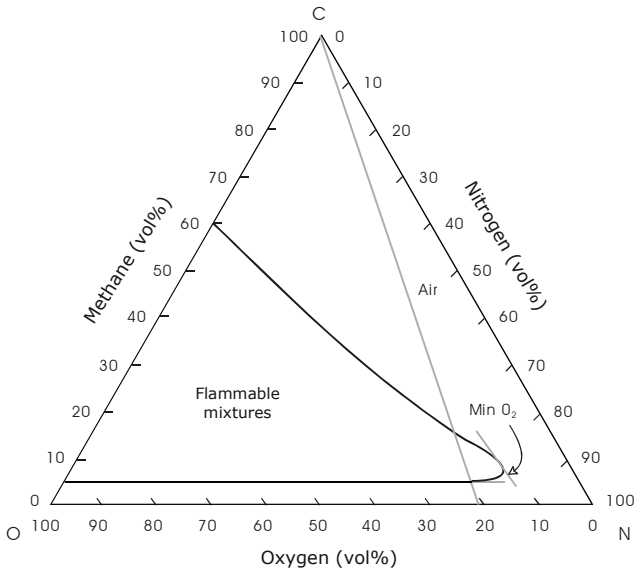

Figure 94 The flammability limits for the methane-oxygen-nitrogen system[51]

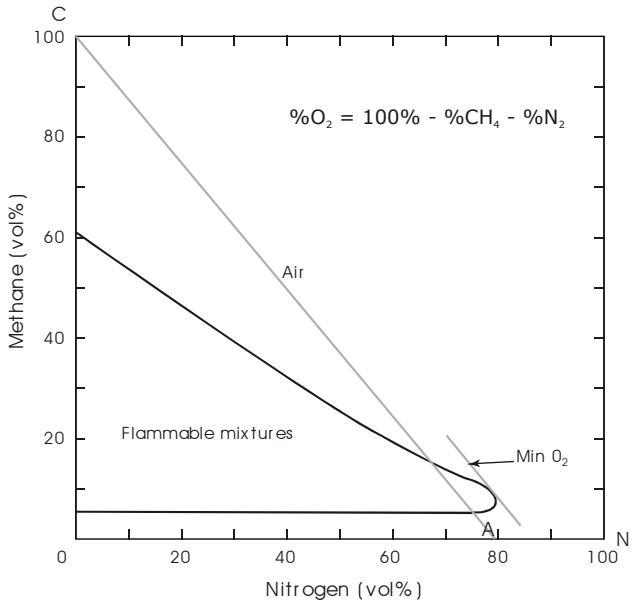

Figure 95 The methane-oxygen-nitrogen system represented on a two-axis plot[51]

[*] Older literature often refers to these as *explosion limits*. This terminology is not preferred today, partly because of the realization that, close to the limits, the gas mixture may be flammable, but it burns slowly and is hardly 'explosive.'

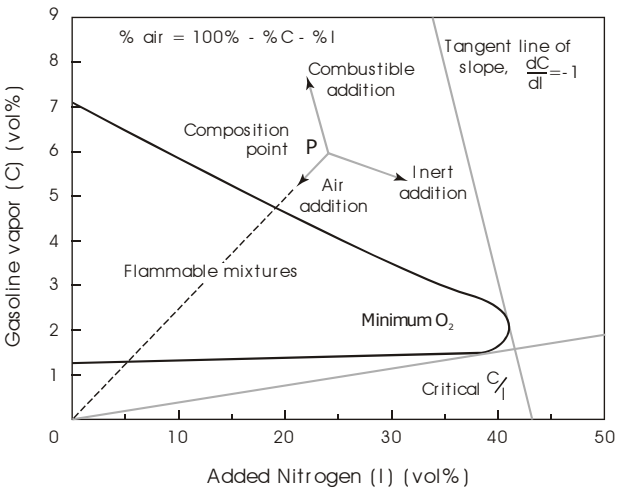

Figure 96 Flammability diagram for 100/130 grade aviation gasoline[50]

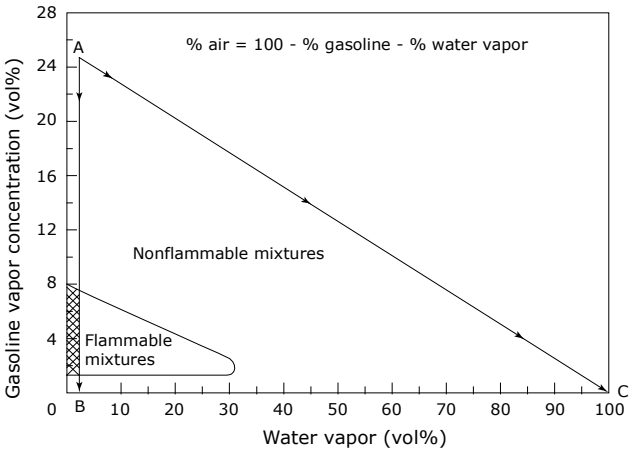

Figure 97 Flammability diagram of the gasoline vapor-air-water vapor system[51]

Since fuel + O_2 + N_2 must equal 100% in the system, this means that if, say the percent of CH_4 and N_2 are known, the oxygen value is pre-determined and cannot vary. Thus, it is possible to make a two-axis plot of the same data, as shown in Figure 95. A similar two-axis plot could be made by using CH_4 and oxygen as the two explicit quantities.

Some practical problems arise where inerting is being considered. It is assumed that fuel concentration will be originally plentiful, but that nitrogen will be added to the system until the mixture is no longer flammable. In a practical case, the atmosphere would be measured with a gas analyzer reading percent O_2. A diagram showing fuel vapor on the y-axis and *added* nitrogen on the x-axis is then convenient (Figure 96). In such a diagram, the minimum O_2 value is found by first drawing a line at the slope of dC/dI = -1, and finding the point at which it is tangent to the 'nose' of the curve. At this point of contact, the fuel vapor (C) and the added nitrogen (I) percents can be found on the graph. The percent of air is then = 100 – percent C – percent I. Having obtained the percent air, multiplying by 0.2095 gives the oxygen percent. Also illustrated in Figure 96 is an arbitrary point P. Suppose a certain amount of nitrogen has already been added, and the composition is now at point P. From this point, three lines are shown. If more fuel vapors are added, the point P will shift along the line marked "Combustible addition." Similarly, if more air or more nitrogen are added, the point will shift along the other two directions. Note that the line for fuel addition has the slope of dC/dI = –1, while the line for air addition goes between P and the origin of the graph.

Table 16 Effect of methane concentration on the pressure rise sustained upon ignition

Methane in air (vol%)	Pressure rise (atm)
5.0	0.06
5.5	0.7
6.0	3.9
8.0	6.5
10.0	7.5

Quaternary mixtures are encountered in some practical circumstances. Zabetakis illustrates the case of a gasoline tank which is to be cleaned by pressure-washing with either water or steam[51]. This involves gasoline–O_2–N_2–H_2O vapor, and such a quaternary system is rather difficult to graph. A simplification can be made if the O_2/N_2 ratio is always invariant, as it is in normal air. Figure 97 shows such a representation. Suppose the original mixture, upon draining the liquid from the tank, contains 24% gasoline vapor at a temperature of 21ºC. If the air has 100% RH at this temperature, its water-vapor content is 2.5 vol%. Point B denotes this water vapor content. Point A then denotes a mixture which is 2.5% water vapor, 24% gasoline vapor, and the rest being air. If pressure-washing with water is done, then the operation will introduce additional air which is at 21ºC and is saturated with water vapor (along with some liquid water). Thus, the mixture will start moving in a straight line from point A and eventually approach point B. But by doing this, it will pass through the flammable region; thus an explosion is possible, if a spark ignition occurs. Now consider what happens if steam is used for cleaning. Pure steam is point C. Steam contains 100% water and thus the mixture composition will move in a straight line from point A to point C, a route which does not pass through the flammable region; thus an explosion is precluded. The above analysis ignores the effect of temperature on the LFL, which is reasonable here since the temperature rise is not high and line A-C does not pass close to the flammable region.

The lower flammability limit (LFL) in air and in pure oxygen are normally found to be identical. This can be understood easily. Under lean conditions, there is a surplus of air. Therefore, air is acting as a diluent. But the heat capacities

of oxygen and nitrogen are very similar. Therefore, the two gases can be viewed as interchangeable, for purposes of absorbing heat through dilution.

The term flammability limits suggests that there is a sharp demarcation between combustion and non-combustion, as the fuel gas concentration is changed. This is partly true, and the exact value is highly dependent on both the test apparatus and the criteria selected. The latter issues are addressed under Test Methods at the end of the Chapter, but the sharpness or lack thereof can be considered in the context of some experimental data[305]. Table 16 shows the pressure rise recorded when methane/air mixtures were ignited in a 120 L sphere. The LFL for methane is normally quoted as 5.5%. It can be seen that some combustion activity (although small) is registered for smaller concentrations and, conversely, at 5.5% there is a 'slight' explosion, rather than the full-force explosion achievable with richer mixtures.

Example We want to find out how much propane can leak out into a 1200 m^3 space before the LFL is reached. In this example, we will assume that the propane is evenly distributed although, as seen later, this would often be a poor assumption in practical cases. The LFL of C_3H_8 is 2.1 vol% and its molar mass is 44.1. We use the ideal gas law:

$$PV = nRT = \left(\frac{m}{M}\right)RT$$

where for this calculation it is convenient to use the following self-consistent set of units: m = mass (g), P = pressure (atm), M = molar mass (g mol^{-1}), R = 82.1 10^{-6} m^3 atm K^{-1} mol^{-1}, and T = temperature (K). The total pressure = 1 atm, but the pressure of C_3H_8 is at the LFL is 2.1% of that, or 0.021 atm. The mass m which corresponds to the LFL is computed as:

$$m = \frac{VPM}{RT} = \frac{1200 \times 0.021 \times 44.1}{82.1 \times 10^{-6} \times 293} = 46.2 \times 10^3 \text{ g} = 46.2 \text{ kg}$$

This is not a small leak, but would more closely correspond to a sizeable broken cylinder.

THEORY

It has proven to be quite difficult to evolve a good theory of flammability limits. The difficulties arise because the problem is intrinsically a dynamic one: not only must flame propagation be quantified, but mechanisms must be described which may only be second-order effects with regard to flame velocities of stoichiometric mixtures, yet assume a dominant role for limit mixtures.

The limits of flammability occur because, as with any ignition phenomenon, there is a balance between heat generation and heat losses. The heat loss mechanisms are:

(a) natural convection
(b) wall losses
(c) radiation
(d) selective, diffusional demixing
(e) flow gradient effects (flame stretch).

The first two attempts to formulate a quantitative theory were in 1957. Spalding[306] focused on radiative losses, while Mayer[106] added convective losses. It, however, turns out that the dominant mechanisms are (a) and (e). Hertzberg presented a unified theory[307] whereby each of the mechanisms is unraveled in turn. For the LFL in horizontal propagation, Hertzberg performs a force balance at the flame, defining a combustion force as the gradient of the kinetic energy (KE) across the flame:

$$\text{combustion force} = \frac{\Delta(KE)}{\Delta x} = \frac{\rho_b S_b^2/2 - \rho_u S_u^2/2}{\alpha / S_u} = \frac{S_u^3}{2\alpha}\left(\frac{\rho_u}{\rho_b}\right)(\rho_u - \rho_b)$$

where u denotes unburned mixture and b denotes burned. The combustion force is then set equal to the buoyancy force, which is:

$$\text{buoyancy force} = (\rho_u - \rho_b)g$$

Setting these expressions equal to each other allows us to solve for S_u, the flame velocity at the LFL:

$$S_u = \left[2\alpha g \frac{\rho_b}{\rho_u}\right]^{1/3}$$

For many gases, $\alpha \approx 0.55 \times 10^{-4}$ m^2 s^{-1}, and at near-limit conditions $\rho_b / \rho_u \approx 1/5$, giving $S_u \approx 0.06$ m s^{-1}. To determine the LFL then requires that a computation be made of the laminar flame velocity S_L as a function of the equivalence ratio φ. The LFL then corresponds to that value of φ at which the limiting-value S_u is identical to S_L (φ). Experimentally, for many gases S_L (φ) $\approx$ 0.06 – 0.08 m s^{-1} at the LFL, confirming that the theory is in the right order of magnitude.

For upward propagation, Hertzberg extends the theory and determines that the value of φ must be sought at which S_L (φ) = $S_{u\uparrow}$, with

$$S_{u\uparrow} = \left[\frac{3}{16}\left(\frac{\rho_u - \rho_b}{\rho_u + \rho_b}\right)\right]^{1/3} \approx \frac{1}{2}\left[2\alpha g \frac{\rho_b}{\rho_u}\right]^{1/3}$$

or, in other words, upward propagation corresponds to a value of S_L (φ) which is ½ that for horizontal propagation. For methane/air mixtures, the theory predicts that the lean limit occurs at S_u = 0.06 m s^{-1} for horizontal propagation and 0.03 m s^{-1} for upward propagation. These correspond to fuel volume fractions of 5.3% and 4.8%, respectively. Since the measured values are 5.4% and 5.0%, the agreement is quite close. Hertzberg also derives a theoretical expression for the downward propagation LFL, but since this is always the highest of the three and therefore of less interest in fire safety concerns, we refer the reader to the original study for its details.

Hertzberg later extended his theory[308] to encompass the effect (b), which is of importance when small-diameter tubes are used. Radiation losses, mechanism (c), were found to be unimportant in terrestrial flames, but possibly

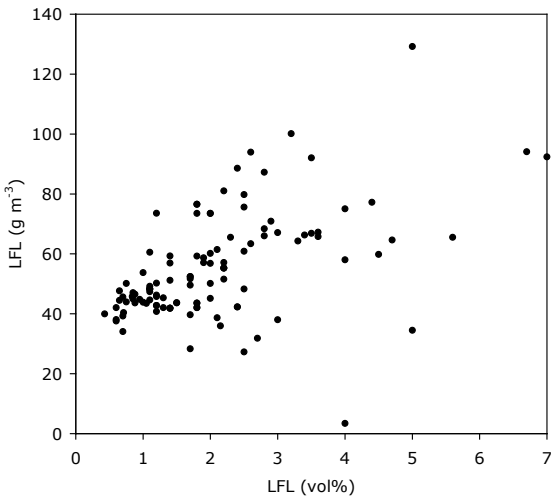

Figure 98 The relation between LFL (volume units) and LFL (mass units) for a number of simple organic molecules

crucial in determining flammability limits at microgravity conditions[309]. Selective diffusional demixing is an effect which comes into play when fuel molecules are much smaller or much larger than molecules of air (or other media present). Hertzberg provides correction factors which cover these cases[309]. In the final part of this theory[310], Hertzberg provides additional considerations of mechanism (e). While Hertzberg's theory is sound, in that it accounts for most of the important flame effects, its engineering applicability is limited, because it is normally much easier to measure the LFL of a mixture directly than to accurately compute a S_L (φ) curve.

Since the same chemistry governs both flammability limits and laminar burning velocity, Westbrook[311] proposed that the flammability limit corresponds to a laminar burning velocity $S_L \approx 0.05$ m s^{-1}. Any mechanisms which would reduce S_L below this value would also quench the flame. Law and Egolfopoulos[312] compiled a large collection of data to this point, but their results disproved the utility of the proposed criterion. The mean value was indeed not far from 0.05 m s^{-1}, but the range of S_L at the LFL was found to be 0.005 – 4.38 m s^{-1}. Instead, they determined that what stays roughly constant at the lean flammability limit is the adiabatic flame temperature, which was between 1450 and 1520 K for all of the mixtures that they examined. This conclusion, they point out, does not apply to the rich limit, nor to systems where halogenated species are present.

In current-day work, a number of authors[313,314] have shown that computational schemes which take into account both reaction kinetics and heat losses are able to correctly predict flammability limits for arbitrary mixtures, but the computations are laborious and the computed results do not lead to phenomenological insights.

FLAMMABILITY LIMITS IN MASS UNITS

To solve practical problems, it is sometimes convenient to express the fuel amount on a mass, rather than the volume, basis. The conversion can be made knowing the general relation for converting from a mole-fraction Y_1 to a mass-fraction X_1. For simplicity, here we illustrate with only 2 components, which we can identify as 1 = fuel, 2 = air:

$$X_1 = \frac{M_1 Y_1}{M_1 Y_1 + M_2 Y_2}$$

Since mol% and vol% are identical, we only need to convert from percent to fractions. Thus, for example, since propane has an LFL of 2.1 vol%, $Y_1 = 0.021$. Everything which is not propane must be air, thus $Y_2 = 0.979$. The molar mass of air = 28.96, thus

$$X_1 = \frac{44.1 \times 0.021}{44.1 \times 0.021 + 28.96 \times 0.979} = 0.032$$

Thus, the LFL of propane can be expressed as 3.2 mass%.

Sometimes the opposite operation needs to be performed, converting mass% to vol%. For such cases, the formula is:

$$Y_1 = \frac{X_1 / M_1}{X_1 / M_1 + X_2 / M_2}$$

where again we have illustrated only two components, but the generalization to more can easily be made.

Fuel mass, expressed as a percent of total mass, is only occasionally used. What is much more common is an expression of fuel mass as a *concentration*, i.e, fuel mass, per total system volume:

$$LFL_{(mass)} = \frac{LFL}{100 - LFL} \times \frac{1000\,M}{24.46}$$

where 24.46 is the molar volume at 25ºC. The factor (100 – LFL) will generally be ≈ 100, at least within the experimental error of LFL measurements. Thus, a suitable expression is:

$$LFL_{(mass)} \approx LFL \times \frac{10\,M}{24.46}$$

Thus, for example, propane has LFL_{25} = 2.1 vol%, and this is converted to a concentration of 38.7 g m^{-3} using the exact equation or 37.9 g m^{-3} using the simplified. Some authors[51] use a factor of 22.41, instead of 24.46, to obtain values at 0ºC, instead of 25ºC; but since combustion processes normally take place in environments closer to 25ºC than to 0ºC, the 24.46 factor is more realistic. Figure 98 shows the relation for a wide variety of organic molecules containing only C, H, O, and N atoms. The bulk of data in volume units span a range from about 0.5 to 4%, a range of 8:1. In mass units, the range collapses to 30 to 90 g m^{-3}, a span of only 3:1. The figure also suggests that, in the absence of any other information, assuming that LFL ≈ 50 g m^{-3}, is not a bad assumption. Halogenated molecules (not shown on the figure) have values much in excess of that, so the estimate is fairly conservative, since the only data points below

50 g m^{-3} are generally ones which are well-studied and not likely to need estimation.

The utility of expressing the LFL on a mass-concentration basis is shown in another way in Figure 99. This illustrates this for *n*-alkanes (straight-chain alkanes, e.g., methane, ethane, propane, etc.) the LFL is nearly.

ESTIMATION OF FLAMMABILITY LIMITS

When measured data are not available, various methods have been proposed for estimating flammability limits. There is no 'best' method; what method, if any, is appropriate, will depend totally on the user's needs and the information that is already available or can be obtainable. Thus, a number of estimation rules published in the literature are summarized below. As with all estimating rules, none are as good as a reliable test result on the substance itself.

Zabetakis[51] suggests that the LFL *for alkane-series hydrocarbons* (that is, fuels with a formula of C_nH_{2n+2}), can be estimated at 25ºC as:

$$LFL \approx 0.55\, C_{st}$$

where C_{st} = stoichiometric concentration (vol%) of the fuel in air, and the equation for computing C_{st} has been given in Chapter 3. That equation assumes that the real products will be the standard products and that no incomplete combustion products (CO, soot, etc.) will be produced. For alkane-series hydrocarbons, the general combustion reaction expression simplifies to:

$$C_cH_{2c+2} + \frac{1}{2}(3c+1)(O_2 + 3.77N_2) \rightarrow$$

$$cCO_2 + (c+1)H_2O + \frac{1}{2}(3c+1)(3.77N_2)$$

Thus the mole (or volume) fraction of fuel in air is

$$= \frac{1}{1+(1.5n+0.5)(4.77)}$$

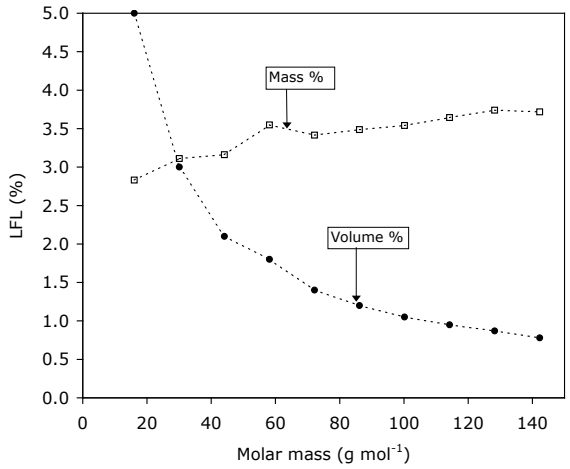

Figure 99 Straight-chain alkanes: the effect of computing LFL on a mass basis

and converted to percent becomes:

$$C_{st} = \frac{100}{1+(1.5n+0.5)(4.77)}$$

As an example, *n*-decane is $C_{10}H_{22}$. Its C_{st} = 1.33% and the estimated LFL would be 0.73%. The actual LFL is 0.75%, so the agreement is very good. While approximately correct results may often be obtained, nonetheless the estimating formula cannot be assumed to apply to hydrocarbons other than the alkane series. For example, if it were applied to acetylene, an LFL of 4.2% would be computed. The actual LFL = 2 .5%, so a l arge, unconservative error would be made.

Using a larger data set than Zabetakis, Pintar[315] proposed a slightly better fit for LFL of hydrocarbons:

$$LFL \approx 0.512\, C_{st}$$

The same expression is also a good approximation for *esters* (substances with the formula $C_nH_{2n-1}OOC_mH_{2m+1}$), but the user must take care to correctly balance the reaction for combustion of the fuels.

For *alcohols* (which have the general formula $C_nH_{2n+1}OH$), *ethers* ($C_nH_{2n+1}OC_mH_{2m+1}$), and *aldehydes* and *ketones* (C_nHC_nO) the LFL_{25} can be estimated as[51]:

$$LFL \approx 0.5\, C_{st}$$

The advantage of such an approximation is that no experimental data are required. It only requires knowing the value of C_{st}, which can always be computed, if the formula of the substance is known.

Hilado[316] proposed that the LFL can in general be approximated as:

$$LFL = A \cdot C_{st}$$

where the constant *A* assumes the following values:

C, H, O compounds	0.537
amines	0.692
chlorides	0.609
dichlorides	0.716
bromides	1.147
sulfur-containing compounds	0.577

He also proposed a rule for the UFL, but it does not exhibit much generality.

Shimy[317] proposed estimating rules for some of the more common families of organic compounds (Table 17).

Some investigators have advocated developing estimating schemes that are universal, i.e., independent of a particular organic family. Kanury[318] attempted to do this on a theoretical basis, but the results were not encouraging. Other investigators have met with more success by taking a purely empirical approach. Firth et al.[319] suggested that the LFL can be estimated as:

$$LFL \approx k / \Delta h_c^l$$

Table 17 Estimating rules proposed by Shimy

Compounds	LFL	UFL
n-alkanes, *n*-alkenes	6/c + 0.2	60/h + c/20 + 2.2
iso-alkanes, *iso*-alkenes	6/c + 0.1	60/h + 2.3
benzene series	8/c	86/(2h_r +h')
alcohols	8/c – 0.7	(80 – 2h)/2c + 3
c – number of carbon atoms h – number of hydrogen atoms h' – number of hydrogen atoms not in radicals h_r – number of hydrogen atoms in radicals		

where k is a constant and Δh_c^l = net heat of combustion (kJ mol^{-1}) and is taken to be a positive number. Figure 100 shows that this relation is acceptable only if significant outliers can be tolerated; it can also be shown that the suggestion[336] to use values of the heat of combustion on a per-mass basis does not give better results. Suzuki[320] proposed another formula based on the heat of combustion but cautioned that its applicability extends to compounds containing only C, H, and O atoms. Hshieh[321] extended the scheme to include compounds containing Si and halogen atoms. His relation is:

$$LFL = 1145\left(\Delta h_c^l\right)^{-0.8} - 0.38$$

Hshieh's method can be considered the best of these, but still only fair accuracy is to be expected. Hshieh found 95% confidence intervals of about 0.5 vol%. Since many substances show an LFL of 1.0 vol% or less, the accuracy is clearly limited; consequently, such methods should only be used for rough estimating purposes.

Pintar[315] suggested that a relation between LFL and flash point be considered as another estimating method:

$$LFL = 100 \times \frac{P(T_{FP} - 3)}{P}$$

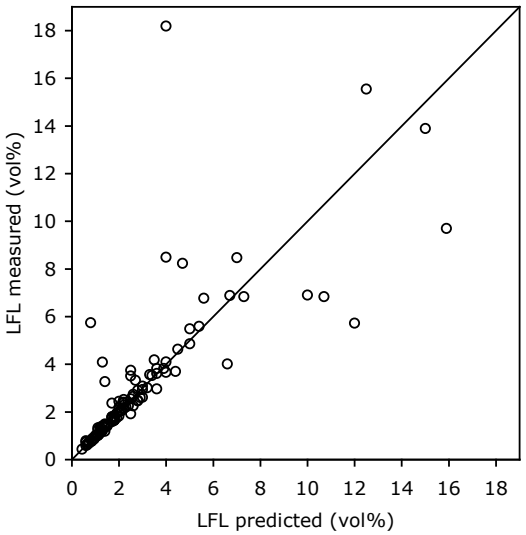

Figure 100 The prediction of the LFL by the method of Firth et al.

where $P(T_{FP} - 3)$ = vapor pressure (Pa) at a temperature 3ºC lower than the flash point, and P = total pressure (Pa). He empirically determined that better results are obtained if the value at $T_{FP} - 3$ is used, instead of at T_{FP}. The converse problem, of predicting the flash point from the LFL is considered in Chapter 6.

The simplest estimating formula[322] for the UFL is:

$$UFL \approx 3.3\, C_{st}$$

although there is a very large amount of scatter. Pintar[315] recommends the similar formula:

$$UFL \approx 3.8\, C_{st}$$

While all estimating methods for UFL give only very rough results, Pintar points out that the results from this simple rule are almost as good as from the DIPPR method. For *alkane-series hydrocarbons*, again, when LFL_{25} is known, the upper flammability limit may be estimated as:

$$UFL \approx 6.5\sqrt{LFL}$$

The UFL often cannot reasonably be predicted on the basis of simple rules because values can vary widely even for isomers. As an example, considering substances with the formula C_3H_6O, the UFL for propionaldehyde is 17%, but for propylene oxide it is 37%.

Monakhov[323] offers approximate methods for computing the LFL and the UFL.

$$LFL \approx \frac{100}{a\beta + b}$$

and

$$UFL \approx \frac{100}{c\beta + d}$$

where

$$\beta = n_C + n_S + \frac{n_H - n_X}{4} - \frac{n_O}{2}$$

with n_C being the number of carbon atoms in the fuel molecule, n_S sulfur, n_H hydrogen, n_O oxygen, and n_X denoting any halogen (F, Cl, Br, I) atoms. The values of the other constants are: a = 8.684; b = 4.679. The upper-limit constants depend on the value of β. For $\beta \le 7.5$, c = 1.55 and d = 0.56. For $\beta > 7.5$, c = 0.768 and d = 6.554. This relation is applicable to a wider range of fuels, including ones with oxygen, sulfur, and halogen atoms. For many compounds, the values predicted are reasonable. As an example, for phthalic anhydride ($C_8H_4O_3$), the predicted LFL is 1.4%, compared to the actual value of 1.2%. But it likewise should not be applied to such 'badly behaved' gases as acetylene, where unreasonable values would be predicted.

For hydrocarbons, in some cases, the UFL of a straight-chain ('normal') compound will be known but not the values for the branched-chain ('iso-') isomer (or vice versa). For such cases, Monakhov[323] offers an approximation:

$$\frac{UFL_{iso}}{UFL_n} = \frac{T_{b,iso}}{T_{b,n}}$$

where T_b is the boiling point (K). Monakhov also offers an approximation for the LFL, but examining experimental data it is clear that for most substances the difference between the *iso-* and the *n-* molecule's LFL would be within the experimental data scatter; thus it would appear to be more appropriate to simply assume that $ULF_{iso} \approx ULF_n$.

FLAMMABILITY LIMITS FOR MIXTURES

For mixtures of fuel gases, the lower flammability limit can be computed by Le Chatelier's Law[324], if the LFLs are known for the constituent components:

$$LFL = \frac{100}{\frac{C_1}{LFL_1} + \frac{C_2}{LFL_2} + ... + \frac{C_n}{LFL_n}}$$

where C_1 ... C_n are the concentrations of the n components and LFL_1 ... LFL_n are their respective flammability limits.

Example The LFL of propane is 2.1 vol% and that of butane is 1.8 vol%. For a gas mixture comprising 70% propane and 30% butane, the LFL is computed as:

$$LFL = \frac{100}{\frac{70}{2.1} + \frac{30}{1.8}} = 2.0$$

Chemically, the Law depends on all substances having the same T_{ad} at the LFL condition. As shown in Chapter 3, this is true for most organic fuels, but exceptions do exist. Thus, Le Chatelier's Law is generally accurate when applied to most mixtures[325], except those containing hydrogen, hydrogen sulfide, carbon disulfide, formaldehyde, or acetylenic compounds[326]. The Law *is* obeyed for CO + H_2 mixtures[327]. The Law will normally not be applicable for substances which burn by decomposition, rather than oxidation[336]. Sizable (and unconservative) errors can also be introduced if the Law is applied to halogenated species[136]. For a number of mixtures, Hustad and Sønju[328] demonstrated that, using Le Chatelier's Law, all results were within 20% of the predicted value and 83% were within 10%. Le Chatelier's Law is not restricted to LFL values at room temperature, and can also be applied to elevated temperature data.

Le Chatelier's Law can also be applied to the UFL[329], but more deviations must be expected, even if the fuel mixture does not contain any halogenated species[330]. This is because chemical kinetics plays a stronger role in the UFL.

The more recent *DIPPR method* [331,332] attempts to predict, within the same framework, both the LFL of a single compound, and the LFL of a mixture. According to the method, the LFL (vol%) is estimated as:

$$LFL = \frac{100}{\sum_i \left[X_i \sum_j n_j GF_j \right]}$$

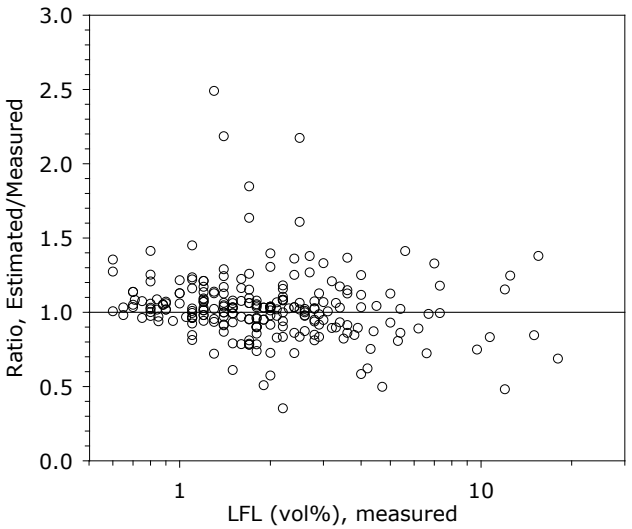

Figure 101 Comparison of LFL predicted according to DIPPR method with experimental results for 241 pure substances

where X_i = mole fraction of gas i in mixture (considering fuels only; air and diluents are ignored); n_j = number of groups of type j in compound i; and GF_j = group factor for group j, to be obtained from Table 18. Negative values denote suppression, rather than combustion, effect. Thus, the computed LFL for pure CCl_4 would be 100/(–8.42), which is a negative number and this denotes a non-flammable compound. For a set of 40 mixtures, Liekhus et al.[332] demonstrated that the DIPPR method showed a mean predicted value that was +0.8%, compared to the experimental results; for the Le Chatelier rule, the mean predicted value was –8.5%. The standard deviation for the DIPPR method was ±12.6%, compared to ±7.6% for the Le Chatelier rule. A comparison of LFL values as estimated by the DIPPR method to measured values is shown in Figure 101. Recently the DIPPR scheme has been extended by Pintar[315], who developed a group-factor method which treats 61 groups, it is known as the *MTU method*, after the Michigan Technological University where the author is based. A separate

Table 18 Group factor values for the DIPPR method

Group	GF

Si	1.3
a – if $n_H \geq n_F$ b – if $n_H < n_F$	

scheme is used by DIPPR for predicting UFL values. That scheme is significantly more complex and can be found in the DIPPR manual[331]. Pintar has also provided an elaborate MTU method for predicting the UFL.

VARIABLES AFFECTING FLAMMABILITY LIMITS

OXYGEN CONCENTRATION

The LFL does not vary with an increase in oxygen concentration, and its value in pure oxygen is generally identical to the value in atmospheres of 21% oxygen[333]. Since the LFL is a fuel-lean condition, excess oxygen is available at 21% and any further excess oxygen is simply acting as a diluent. The molar heat capacities of O_2 and N_2 are similar and, consequently, the LFL value is not changed by going to a 100% oxygen atmosphere. If O_2 concentration is progressively decreased below 21%, then eventually a minimum oxygen concentration is reached; this is discussed in the following section. The UFL, however, greatly increases with oxygen concentration, as shown in Figure 102. The data illustrated are from Kuchta[50], and curve fit is:

$$UFL(oxygen) = 120 - \frac{216}{\sqrt{UFL(air)}}$$

When measured values of the UFL are available in both O_2 and in air, but an estimate of the UFL is desired at some intermediate oxygen concentration, the following equation[323] can be used:

$$UFL = 0.12\left(UFL(oxygen) - UFL(air)\right)\sqrt{x - 21} + UFL(air)$$

where x denotes the vol% of O_2 at which the UFL is to be computed.

PRESSURE

Increasing the initial pressure of the gas mixture generally increases both the LFL and the UFL, as illustrated in Figure 103 for natural gas. The relations can be represented by the formulas:

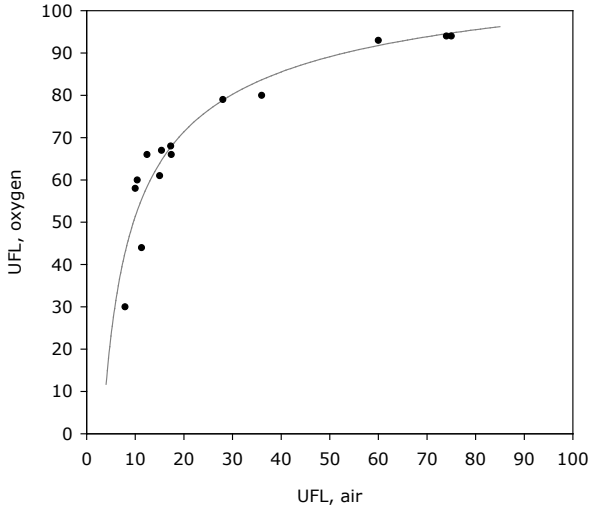

Figure 103 The relation between UFL in air and UFL in oxygen

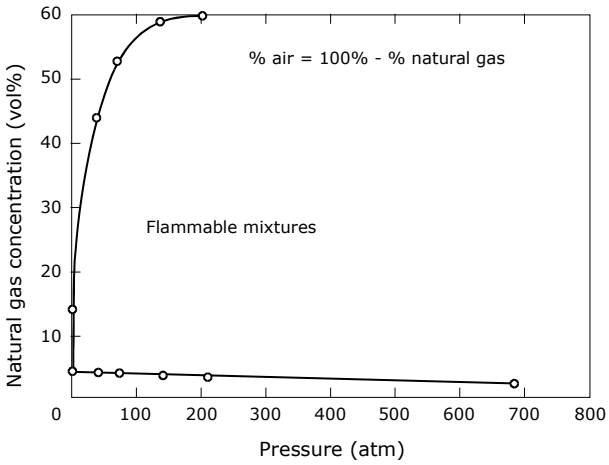

Figure 102 The effect of very high pressures on the flammability limits of natural gas[51]

$$LFL = LFL_a - 0.31\ln P$$
$$UFL = UFL_a + 8.9\ln P$$

where P = pressure (atm) and the subscript a denotes conditions at ambient (1 atm) pressure. Similar expressions are generally not available for different fuels.

A more detailed study on the effects of pressure for methane has been done by Ronney and Wachman[334], who conducted both downward and upward propagation experiments (Figure 104). The downward propagation results show a functional form as indicated in the equation above; the upward propagation results indicate a curvature at very low pressures.

Somewhat different results have been obtained on several other gases by Zabetakis[51] (Figure 105). Here, he found a similar effect as did the other researchers for the LFL, but the UFL results showed a peak at around 0.2 atm pressure. The reason for this is not clear.

Melhem[335] computed flame temperatures for several gases as a function of concentration and pressure and observed that increasing pressure raises the flame temperature for fuel-rich mixtures, but not for lean ones. Thus, if the flame temperature is assumed to be constant at the flammability limits, then the UFL will rise with increasing pressure, but the LFL will not change.

As the pressure is lowered, a *pressure limit* is reached, where the LFL and the UFL become identical, as illustrated in Figure 106[355]. Below this pressure, the propagation of flame becomes impossible. For most combustion reactions, the pressure limit is so low that safety measures cannot be based upon its existence, as shown in Table 19[336]. But for decomposition reactions of unstable substances, not exceeding the pressure limit of the substance sometimes can be a useful safety strategy. Brandes et al.[337] reported data on acetone, ethyl acetate, and hexane vapors at an elevated

Table 19 Pressure limits for several gases and vapors

Substance	Reaction	Pressure limit (atm)
acetylene	combustion in oxygen	< 0.001

ethylene	decomposition, pure fuel	70
propylene	decomposition, pure fuel	1000

temperature of 100ºC. For all these substances, the pressure limit was roughly 3 kPa. For natural gas at room temperature[338], the pressure limit is approximately 6.8 kPa.

The above discussion presumed that certain amounts of fuel gas and air were mixed together, and then the pressure of the system lowered or raised. With vapors of liquids, there is another way that the pressure effect comes in. Suppose a large open container of the liquid is sitting in a closed chamber. Now raise or lower the pressure in this chamber—What will be the effect? Assuming that the temperature remains constant and the total pressure is lowered, the partial pressure of the vapor will remain unchanged, but the partial pressure of air will drop. Thus, mixtures which were too lean at room pressure may become flammable at a lowered pressure; conversely, mixtures within the flammability limits at room pressure may become too rich for combustion. On the assumption that there is not a total-pressure

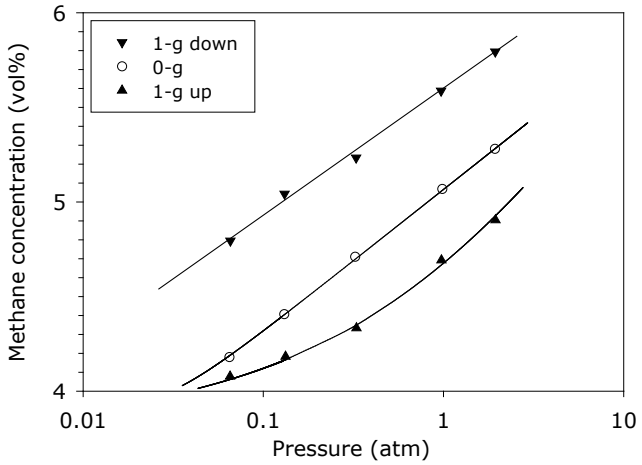

Figure 104 Effect of pressure, gravity, and propagation direction on the LFL of methane

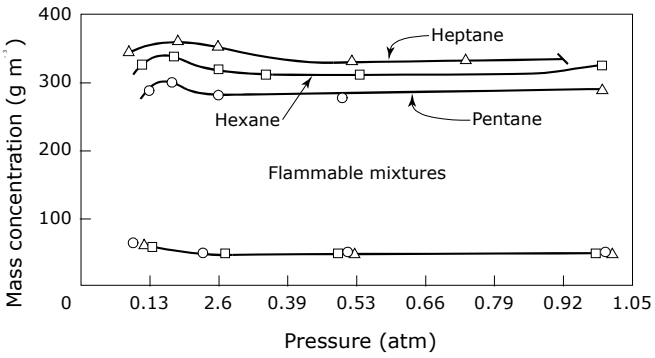

Figure 105 Effect of pressure on the LFL and UFL of several hydrocarbons

effect on the flammability limits (i.e., that the lines in Figure 105 are flat-horizontal), conditions at the new pressure may be computed by simply knowing the vapor pressure of the liquid. Example calculations for a number of common liquids have been published[339].

The *temperature limits of flammability* (explained below), change with total pressure according to the effect considered above. As the system pressure is lowered, both the LTL and the UTL drop downward. This effect is illustrated for aviation fuels in Chapter 14.

TEMPERATURE

The most general formulation of the problem involves a vapor which is in equilibrium with a pool of liquid, so this problem will be analyzed here, even though ignition of liquids is separately considered in Chapter 6. An example is shown for *n*-decane in Figure 107. The fuel vapor concentration is plotted on the right y-axis. Since the vapor con-

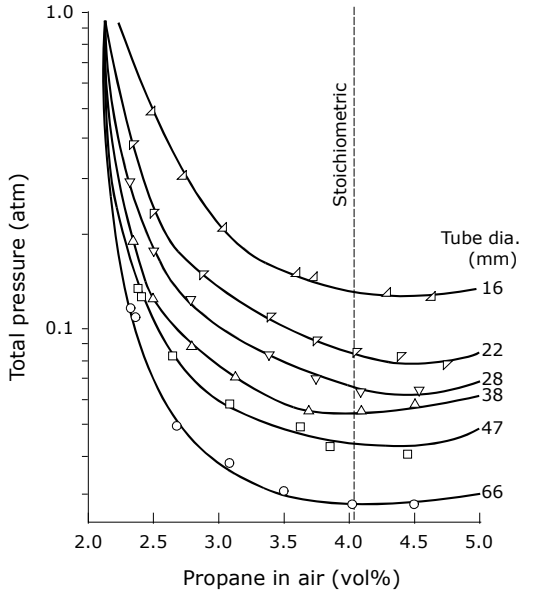

Figure 106 Pressure limits for propane, as a function of tube diameter

centration is related to the vapor pressure through the Ideal Gas Law, the left y-axis is used to denote the fuel vapor pressure. The vapor pressure above a liquid and in equilibrium with it represents the saturated vapor-air mixture and is shown as the steep diagonal line. The region to the left of this line represents an aerosol. It can only be created by mechanically atomizing the fluid into the air, not by simple evaporation from the surface of a liquid. The region to the right of this line represents vapor-air mixtures which are not saturated. Such mixtures can be created if a certain volume of vapor is introduced into a closed space but a liquid pool of the fuel does not exist. For these mixtures, the concentration of fuel vapor is less than what would be reached if a liquid pool were available from which further vaporization could take place.

It will be noted on Figure 107 that the flammable range widens with temperature, i.e., the lower flammability limit decreases and the upper limit increases. The presence of the liquid phase establishes the existence of a special point on each flammability limit vs. temperature line. The point labeled T_L is termed the *lower temperature limit* (LTL), and is the minimum temperature to which the system must be heated for flame propagation to be possible. Similarly, the point labeled T_U is termed the *upper temperature limit* (UTL), and is the maximum temperature to which the system can heated and still show flame propagation. The diagram also points out that cool flames are not encompassed within the standard definition of flammability limits. Note that LTL and UTL are meaningful only under conditions where the fuel vapor is saturated, i.e., it is in equilibrium with a reservoir of liquid. The LTL would be identical to the *flash point* (see Chapter 6), if flash point and flammability limits were measured under identical conditions, which they are not. Figure 108 shows the relation between LTL and the flash point. The LTL values are as reported by Zabetakis[51], while the flash point values (closed-cup) are from various sources. The scatter from a 45º line amounts to no more than the reproducibility of the measurements.

Some examples of LTL and UTL are given in Table 20. It can be seen that for most of the substances either summer or winter ambient temperatures will fall between the LTL and the UTL. Thus, for many common substances, tanks that are not completely full can be anticipated to contain mixtures which can explode, given an ignition source.

As might be expected, there is a probabilistic aspect to temperature limits. Figure 109 shows results from experiments by Vaivads et al.[340] where a 'strong' spark was used. The use of a strong ignition source tends to broaden the probability curves; if a weak spark is used, the LTL and UTL lines are nearly vertical.

For refined petroleum products, the following correlations have been evolved for the LTL and the UTL[341]:

$$\text{LTL} = 0.82\ \ \text{IBP} - 86$$

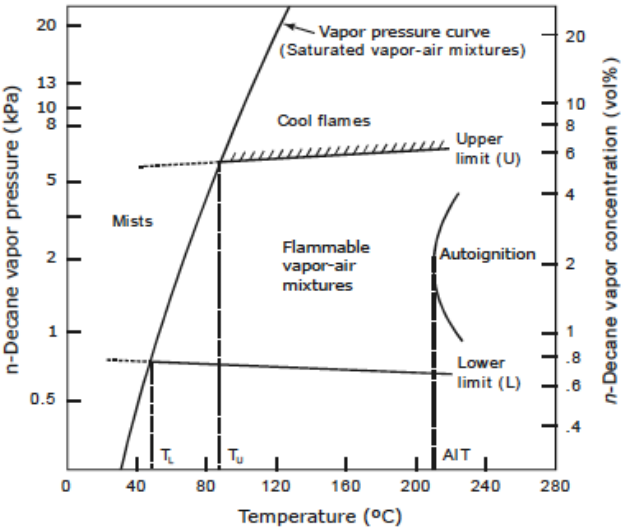

Figure 107 The effect of temperature of the flammability limits of *n*-decane[50]

$$\text{UTL} = 0.70\ \ \text{IBP} - 42$$

where IBP = initial boiling point (ºC), as determined by ASTM D 86[342]. The relations are shown in Figure 110.

In 1925 White[343] observed that, as the mixture temperature is raised, the adiabatic flame temperature at the LFL remains constant. Zabetakis et al.[344] observed that for most hydrocarbons the LFL decreases by about 8% for each 100ºC rise in mixture temperature. By this rule, mixtures containing an infinitesimal concentration of fuel could sustain flame propagation if the temperature were raised to about 25 + 100/0.08 ≈ 1275ºC. This was confirmed by further work at the Bureau of Mines[51], illustrated in Figure 111. The asymptote temperature is seen to be 1300ºC. At a temperature of 1300ºC or higher, even minuscule amounts of fuel gas are thus likely to lead to a propagating fire. A later study by Hustad and Sønju[328] concluded that 1200ºC is a better fit than 1300ºC for the asymptote, however, this

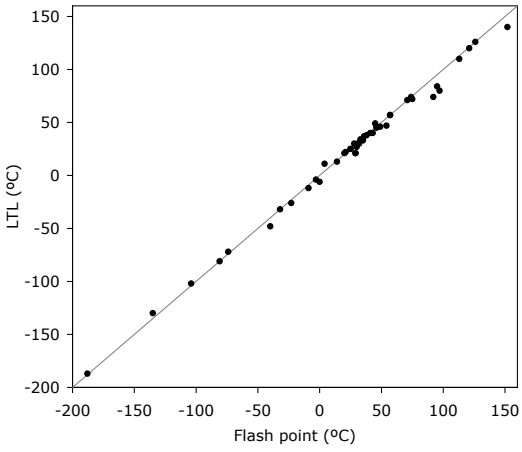

Figure 108 Relation between LTL and flash point

difference is probably within the experimental reproducibility for making flammability limit measurements.

Table 20 The flammable region for some common organic liquids[345]

Substance	Lower limits		Upper limits	
	LFL (vol%)	LTL[a] (C)	UFL (vol%)	UTL (C)
acetone	2.6	-18	12.8	7
benzene	1.4	-12	8.0	16
carbon disulfide	1.0	-30	50	25
cyclohexane	1.3	-17	7.8	15
diethyl ether	1.9	-45	36.5	9
ethanol	3.3	13	19	43
heptane	1.1	-4	6.7	26
methyl ethyl ketone	2	-7	12	22
styrene	1.1	31	6.1	62
toluene	1.3	4	7	37
xylene	1.0	29	7.0	62

[a] – the values are reported by the authors as LTL, but are probably actually flash point measurements.

With this value in hand, if the LFL is known at a temperature T_1 (normally this will be 25ºC), then it can be evaluated at another temperature T_2 according to:

$$LFL_{T_2} = LFL_{T_1}\left(1 - \frac{T_2 - T_1}{1300 - T_1}\right)$$

If T_1 is, in fact, 25ºC, then the expression becomes:

$$\frac{LFL_{T_2}}{LFL_{25}} = 1 - 0.000784\left(T_2 - 25\right)$$

An equation of this form is sometimes known as the *Burgess-Wheeler law*. The asymptote value ought to correspond to the adiabatic flame temperature at the LFL condition. Actual values, shown in Chapter 3, are not far from the value of 1300ºC derived as an asymptote to experimental data.

The general relation above does not hold for hydrogen, and for hydrogen the expression is[328]:

$$\frac{LFL_{T_2}}{LFL_{25}} = 1 - 0.00129\left(T_2 - 25\right)$$

The general relationship above will also not hold if the substance starts to *decompose* at elevated temperatures. Thus, Schrödter[346] showed for ethyl acetate and methanol that the diminution in the LFL with increasing temperature tends to stop or be reversed at a temperature close to the decomposition temperature (325ºC for ethyl acetate, 300ºC for methanol).

For the UFL, BM recommends that the increase with temperature be computed according to:

$$UFL_{T_2} = UFL_{T_1}\left(1 + \frac{T_2 - T_1}{1412 - T_1}\right)$$

If T_1 is 25ºC, then the expression becomes:

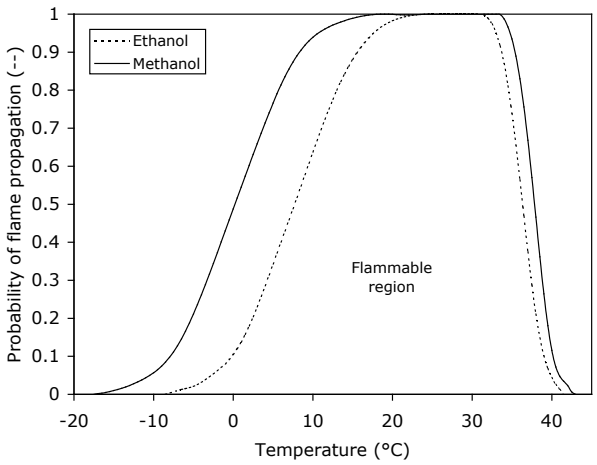

Figure 110 Temperature limits for alcohols expressed on a probabilistic basis, based on experiments using a 'strong' spark source; if a weak spark is used, nearly-vertical lines are found, instead.

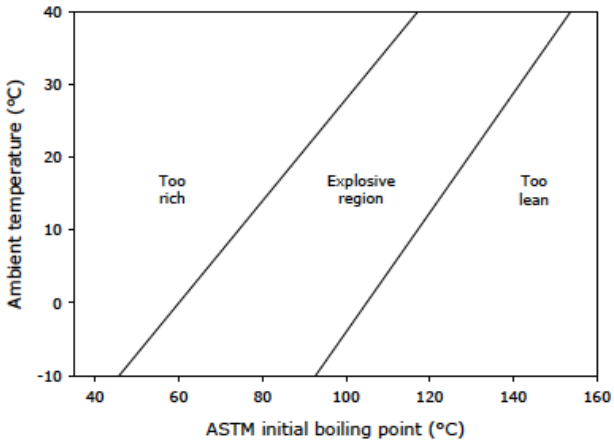

Figure 109 Flammability temperature limits for petroleum products, as a function of ASTM initial boiling point

$$\frac{UFL_{T_2}}{UFL_{25}} = 1 + 0.000721\left(T_2 - 25\right)$$

However, while the predicted temperature effect on the LFL is very similar to the measured data, for the UFL there are substantial discrepancies. Figure 112 shows that even the higher alkanes (hexane, heptane, and octane) do not follow the general relationship. One reason that non-linearities arise is due to cool-flame ignitions with some gases, at some temperatures, and not at others.

VELOCITY

When mixtures are not quiescent, but are flowing at an appreciable velocity, the LFL rises and the UFL falls. Starkman et al.[347] illustrated this with data for propane/air mixtures, but general relations have not been proposed.

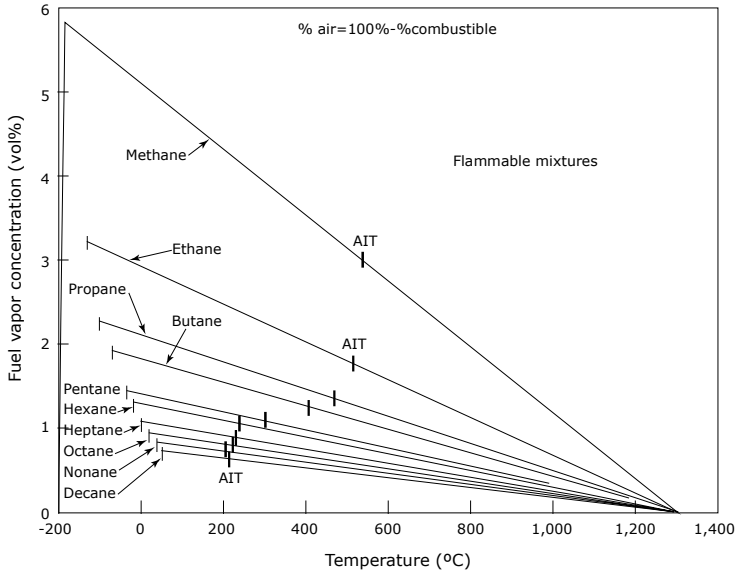

Figure 111 The effect of temperature on the LFL of *n*-alkanes

GRAVITY

Gravity affects the propagation of flame by introducing buoyancy, which distorts the flame shape. Thus, there has been interest in studying flammability limits under zero-gravity conditions. A set of results[334] for methane is shown in Figure 104. The LFL under 0-g conditions lies between the upward and the downward propagation results obtained at 1-g conditions.

For gravity greater than normal, the upward propagation limits, both LFL and UFL, are nearly unchanged. For downward propagation, however, the limits progressively narrow. Downward propagation becomes impossible at any fuel concentration for natural gas/air mixtures at over 100 G[348].

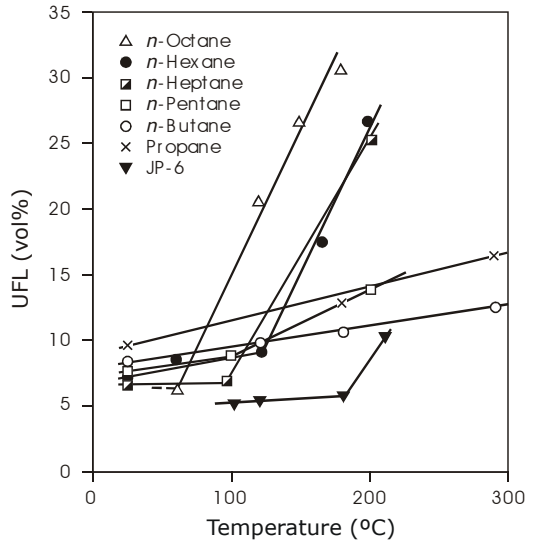

Figure 112 The effect of temperature on the UFL for several hydrocarbons[50]

TURBULENCE AND SLOSHING

For pure gases, a limited amount of data suggests that turbulence narrows the flammability range. When fan-stirring was introduced into a test chamber, it was found that the LFL rose (and the UFL fell) with fan speed and consequently with the turbulence ty[349,350]. The effect requires a sizable stirring speed, however, to become significant. A fan speed of 2000 rpm only increased the LFL by about 0.75 percentage points for methane in air. The narrowing of observed flammability limits has been interpreted as being an MIE effect: if experiments are conducted at the same ignition energy and it requires more energy to ignite mixtures that are either turbulent or have an equivalence ratio far away from stoichiometric, then turbulent mixtures will be observed as having a smaller flammability range. Lovachev[351] reviewed some other, mostly older, studies and concluded that a wide variety of trends have been reported. The effect generally seems small, but it must be remembered that if faith is rigidly (and improperly) placed in tabulated values, then even small effects can lead to flame propagation in 'non-flammable' mixtures.

When a liquid aerosol (mist) is present, increasing turbulence lowers the LFL. Similarly, if the system comprises a part-full reservoir of flammable liquid, sloshing the liquid will lower the LFL of the vapor. This is due to creation of a mist, and the effects are considered in more detail in Chapter 6.

MEASURING APPARATUS

Several factors directly related to the test apparatus design affect the flammability limits. These include the energy of ignition source, the size of the propagation tube, and the direction of flame propagation (upward or downward).

Most of the flammability data reported in the literature has been obtained with the technique developed by the Bureau of Mines (BM). The method is based on a flame tube, and either upward or downward propagation can be measured. It has been determined that the limits for upward propagation are wider, and therefore this is the orientation that BM adopted. This is illustrated in Table 21, where results are given using an early apparatus with a diameter of 75 mm and a length of 1.5 m. Close to the limits, flame cannot travel downward, because buoyancy creates an upward convective current. But upward propagation can remain possible, since buoyancy aids propagation. This is evidenced by the shape of the flame—at the LFL, a downward traveling flame is approximately flat, while an upward traveling flame 'bulges' upward[352]. The effect has also been interpreted in terms of greater flame stretch in downward propagation[70]. Even wider limits would be reported from

flat-flame burners; however, it has been concluded that such results do not correlate to real fire situations and, therefore, flat-flame burners are not used for determining flammability limits. The data of Table 21 show that the UFL values are much more affected by the direction than are the LFL values; indeed for the LFL the differences are mostly within experimental data scatter. For fundamental combustion chemistry studies, downward propagation is preferred precisely because the extra effects of buoyancy do not come into play.

Table 21 Effect of propagation direction on flammability limits[353]

Mixture	Direction	LFL (vol%)	UFL (vol%)
methane/air	upward	5.35	14.85
	horizontal	5.40	13.95
	downward	5.95	13.35
pentane/air	upward	1.42	8.0
	horizontal	1.44	7.45
	downward	1.48	4.64
benzene/air	upward	1.45	7.45
	horizontal	1.46	6.65
	downward	1.48	5.55

Numerical simulations[354] for methane have suggested that, over the pressure range 0.25 – 1.0 atm, tube diameter has a strong influence for diameters < 100 mm, and very little influence for diameters > 200 mm. Since the standard apparatus used by the Bureau of Mines (see below) has a diameter of 50 mm, this suggests that somewhat wider limits might be found in real-scale applications. The reason for the wider limits is because a h igh flame speed is found for higher tube diameters. This flame speed, as measured by Levy[352], is nearly identical to the speed of an air bubble rising in a fluid-filled tube, which increases with tube diameter.

For sub-atmospheric pressures, the tube diameter plays an important role. Simon et al.[355] showed that the lowest mixture pressure at which flame propagation is possible ('pressure limit') depends inversely on the tube diameter (Figure 106). This was determined to be a quenching-diameter effect. The quenching diameter increases with decreasing pressure, and, in fact, the pressure limit corresponds to the reduced-pressure quenching diameter.

The spark energy required to ignite a mixture varies both with the chemical nature of the gases and with the stoichiometry, with mixtures close to $\varphi = 1$ being the easiest to ignite and those farther away requiring progressively greater spark energies. The spark energy specified for the test apparatus may, therefore, influence the exact flammability limits determined.

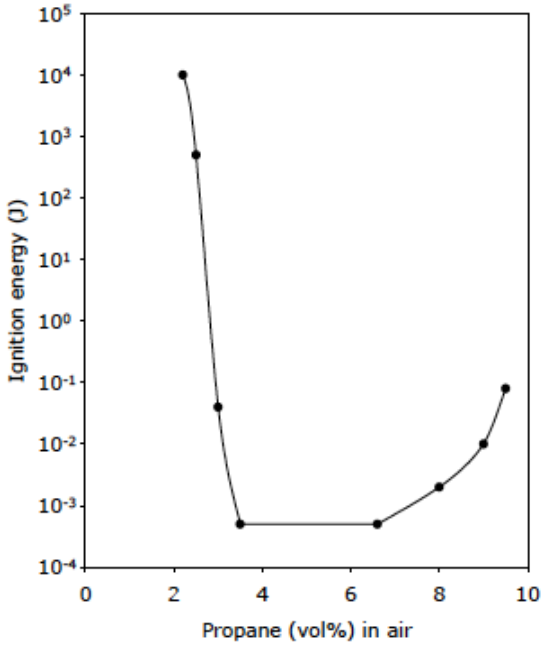

Figure 113 Propane flammability limits as a function of ignition energy, as measured under turbulent conditions in a 1 m^3 sphere

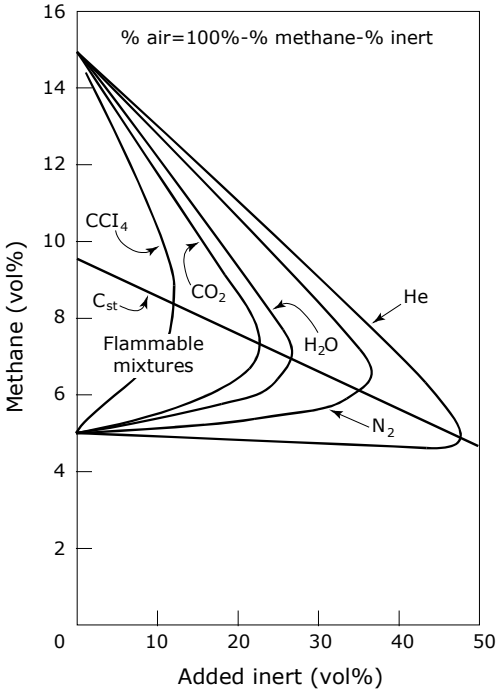

Figure 114 The effect of additives on the flammability limits of methane[344]

IGNITION SOURCE

A small amount of data exists for flammability limits determined by use of igniters other than electric spark discharges. Cashdollar et al.[305] assessed the flammability limits for several gases using pyrotechnic igniters, in addition to electric sparks. For methane, a 1 000 J igniter in a 1 20 L spherical chamber gave LFL results very similar to those obtained with an electric spark. For hydrogen, however, a 5000 J igniter (the smaller igniter was not tested) gave an LFL of 5%, compared to 6.5% found using spark ignition. But hydrogen was considered to be an anomaly, since its results are highly dependent on test apparatus details and on the exact experimental definition of LFL adopted. If very large ignition sources are used, significant turbulence is created, which tends to lower the LFL; in addition, sizable flame volumes are presented within the chamber, making the results perforce dependent on igniter characteristics. Pellmont[356] measured the ignition energy dependence of propane/air mixtures under turbulent conditions in a 1 m^3 sphere. His results (Figure 113) show that a huge increase in igniter energy is needed to sizably lower the LFL, but the moderate increases in igniter energy raise the UFL. Bartknecht[357] showed similar data for methane, indicating that very large ignition sources are needed to sizably widen the flammability limits.

ADDITIVES

Inert additives (that is, substances which are neither fuels nor oxidizers), are sometimes added to mixtures in order to decrease their flammable limits or to make the mixture entirely outside the range of flammability.

For inert additives, the effect is proportional, in the first approximation, to their heat capacities. The heat capacities, at 298 K and 1 atm, of some inert additives are given in Table 22.

Experimental data indeed show that the effectiveness of inert additives is in the order:

$$CO_2 > H_2O > N_2 > He > Ar.$$

Since their C_p values are identical, the effectiveness of Ar and He would have been estimated to be identical, but experimentally it is found that Ar is more effective than He. Molecules with halogen atoms (e.g., F, Cl, Br) are not inert, since their action contributes to chain termination, not simply dilution. Thus, halogenated compounds such as CCl_4 are more effective than their C_p values would suggest.

From Figure 114 it can be seen that, for moderate amounts of inert additives, the effect is mainly on the UFL. All of the additives are able to make a mixture non-flammable if added in sufficient quantities. However, adding lesser amounts of N_2 has negligible effect on the LFL, while adding less than 45% of helium actually decreases the lower limit of methane.

For most hydrocarbon gases, nitrogen in the amount of 40 – 50 vol% must be added to a fuel/air mixture in order to make them 'non-flammable,' that is, to prevent flame propagation. These are very high amounts, whereas much lower concentrations are sufficient when using many halogen-containing ('halon') gases. The most popular and effective of these, however, have been banned due to environmental ozone considerations.

MINIMUM OXYGEN CONCENTRATION FOR FLAMMABILITY

Under the conditions of the flammability test apparatus, when the oxygen level is below a certain value, flame propagation is no longer possible. That is, the mixture is not flammable below such oxygen conditions. The problem was first investigated by Rhead in 1918[358]. Currently used data are primarily from the Bureau of Mines[50,359]; these and values from NFPA 69[360] are shown in Table 23. It can be seen that, with the exception of a few unusual or highly flammable fuels, the rest of the fuels show a remarkably consistent pattern. The minimum oxygen concentration below which flame propagation is impossible (at 1 atm and 298 K) is approximately 12 vol% if air is diluted with nitrogen. Very often, however, dilution occurs because the burning substance vitiates a closed atmosphere in which the burning is occurring. In such cases, it is reasonable to assume that CO_2 is the main diluent. Table 23 then indicates that for vitiated burning, flame propagation is no longer to be expected once the oxygen concentration drops below 14%.

Concentration is normally defined with the denominator comprising the total contents of the volume, so that oxygen concentration, for example, is defined as $= O_2/(N_2 + O_2 + \text{fuel})$. In some cases, however, it is more convenient to work with the oxygen concentration of the atmosphere to which the fuel is being introduced, rather than with the atmosphere that results when the fuel is actually mixed in. Such a definition, for example, was used by Rhead in his original study. If this definition is used, it should actually be called the *minimum oxygen index*, since oxygen index is defined as: $OI = O_2/(N_2 + O_2)$. In practice, the distinction is normally not made, since numerically the effect is smaller than the experimental data scatter.

If the LFL is known and the diluent is N_2, then the MOC can be predicted by the following relation:

Table 22 Heat capacities of some gases

Gas	C_p (J mol^{-1} K^{-1})
Ar	20.79
He	20.79
N_2	29.13
H_2O (g)	33.58
CO_2	37.11

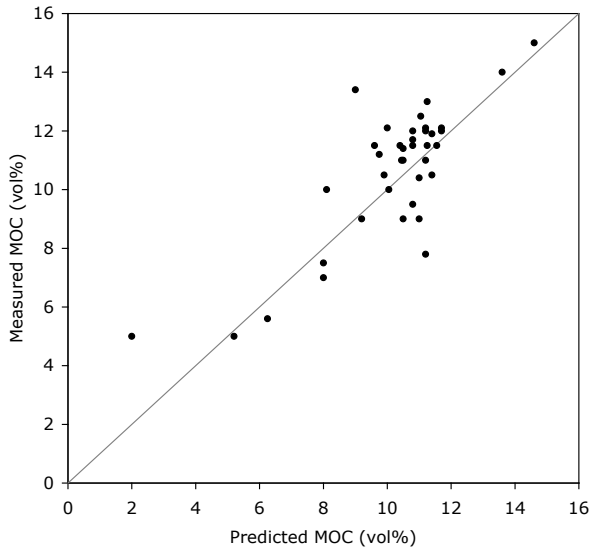

Figure 115 Prediction of MOC on the basis of measured LFL

$$MOC = LFL \times \gamma_o$$

where γ_o = stoichiometric oxygen/fuel mole ratio. The latter quantity is not tabulated in Chapter 15, but it can also be seen that the prediction can be made as:

$$MOC = LFL \times \frac{1}{4.77}\left(\frac{100}{C_{st}} - 1\right)$$

where C_{st} = stoichiometric fuel concentration (vol%). This latter relation is plotted in Figure 115 and it is seen that there is no systematic deviation, although there is a fair bit of scatter. The basis of this prediction can best be seen from an example. For *n*-hexane, LFL = 1.2% and C_{st} = 2.16%. Thus, at the LFL, the mixture composition is 1.2% fuel, (100 – 1.2)×0.21 = 20.7% O_2, and 78.1% N_2. Now, the MOC implicitly assumes that—to be a minimum—the percent of fuel is at optimal value to allow combustion at the minimum O_2 concentration. The optimum amount of fuel will be close to the stoichiometric amount, so it assumed that the oxygen/fuel mole ratio is exactly the stoichiometric one. For hexane, this ratio is 9.50. The minimum amount of fuel is 1.2%, therefore the minimum amount of oxygen is 1.2×9.50 = 11.4%. The experimentally-determined value is 11.9%, which is quite close. An entirely different prediction method—based on functional-group contributions has been proposed[361], but there is not enough validation data to assess its quality of prediction.

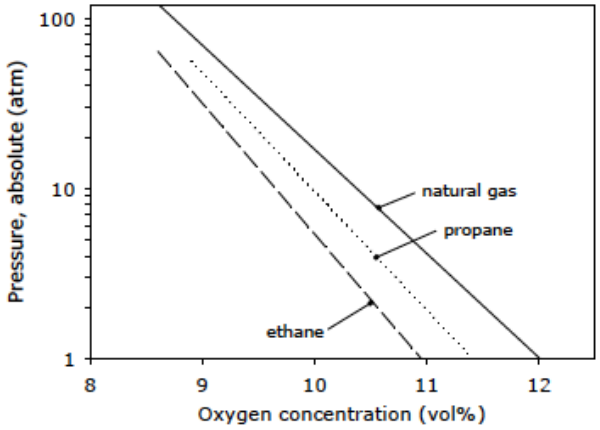

Figure 116 The effect of pressure on the minimum oxygen concentration for combustion[50]

Elevated pressure lowers the minimum oxygen concentration at which burning is sustained. Figure 116 illustrates this for several gases.

While flammability limits are not applicable to *non-premixed* conditions, e.g., diffusion flames, the concept of minimum oxygen concentration does apply. Not only that, but the numerical values are very close (Table 24). Since combustion, perforce, is less efficient for diffusion flames, it is not surprising that the minimum O_2 values are all about 1% higher than for the premixed case.

Unified theories of gas ignition

Yang made the observation that, in the simplest theoretical formulation, there will be no difference between autoignition and piloted ignition. If a volume of gas is below the AIT, a non-zero energy needs to be introduced in order to give ignition. If the volume is above the AIT, the ignition energy needed is zero. Using these concepts, he produced a mathematical ignition formalism[362]. The formalism, however, is too simplified to describe experimental results. Specifically, only single-step Arrhenius kinetics is used, while heat losses are represented as a radiant loss of the entire gas volume. More current theories of spark ignition, described earlier in this Chapter, clearly indicate that complex phenomena take place in the flame kernel, and that performing heat transfer analysis on the lumped gas volume will not suffice to give results of quantitative utility. Yang was able to demonstrate qualitative agreement in modeling the spark gap as a thermal volume. For large gap lengths, the heated volume was considered to be roughly cylindrical, and his theory correctly predicts the experimental fact that MIE increases linearly with increasing gap length[363]. Similarly, for short gap lengths, the MIE is independent of gap length, and Yang's theory, considering the thermal volume as a sphere, correctly predicts that MIE is independent of gap length.

A unified theory in a different context was later set out by Yang and Gray[365,366]. In the early days of combustion modeling, the simplest theory was that of Semenov, discussed earlier in this Chapter; it is called a 'thermal' theory. Later, the concept of chain-branching was introduced, which allowed more complex chemical reactions to be treated. Like Semenov's thermal theory, the unified theory focuses primarily on criteria for instability, rather than detailed tracking of reaction progress. The first achievement of the theory was to predict the P-T relation for ignition of hydrogen.

Ignition of non-premixed gases

By far, the most research on ignition of gases has been done for the premixed case. This is not surprising, since there is only one premixed possibility, but an infinity of non-premixed fuel/air arrangements possible. As the simplest geometry, Maksyutov et al.[367] studied the case where a hemisphere of fuel gas suddenly comes into contact with a hemisphere of oxidizer. This was found to be a relatively tractable problem, but its practical applicability would be rare.

It is sometimes taken that hazard will be small if an amount of fuel gas is introduced into a closed space which yields a computed concentration below the LFL. This is incorrect, if the gas happens to be introduced (as nearly always will happen) in a way that it is not uniformly premixed. Hirano[368] studied situations where (a) a methane layer was evenly created above a layer of air; and (b) a fuel gas was injected, but measures were not taken to premix. In both cases, ignitions were easy to achieve. For the latter case, the pressure rise upon ignition smoothly increased with mean fuel concentration, with no jump occurring as the concentration rose beyond the LFL. The pressure rise was sufficient for collapsing structural elements before the LFL was reached.

If a layer of denser-than-air fuel gas is deposited, unpremixed, at floor level, ignition and a layer-type burning, without explosion, is possible. A more likely outcome is that the initial burning will sufficiently stir up the layer that eventually an explosive behavior will be seen. Recently Tamanini[369] reported brief results of experiments where propane was leaked at floor level and most of the room was initially below the LFL.

Liebman et al.[370] studied the flammable regions of a tank being filled with liquid JP-4. For both top-filling and bottom-filling conditions, they found that initially four distinct layers formed, bottom to top: (1) liquid, (2) vapor above the UFL, (3) vapor within the flammable region, and (4) vapor below the LFL. With time, however, the regions moved up until some vanished at the top of the tank. With modest filling rates, the upward movement of the three gas layers occurred faster than the rise in liquid level. Eventually, except at extremely low temperatures, the entire vapor space came to be above the UFL. Similar results were obtained with gasoline filling, except that the fully fuel-rich layering occurred much earlier. Ignitions of atmospheres were generally violently explosive, unless the over-rich layer occupied the bulk of the vapor space. In those cases, 'mild' ignitions were observed.

Table 24 Minimum oxygen concentration for premixed versus diffusion flames[364]

Fuel	Min. O_2 conc. (vol%)	
	Premixed	Diffusion flames
propane C_3H_8	11.4	12.3
pentane C_5H_{12}	12.0	13.0
hexane C_6H_{14}	11.7	13.1
octane C_8H_{18}	11.9	13.1
decane $C_{10}H_{22}$	11.9	13.2
methanol CH_3OH	9.8	10.0
ethanol C_2H_5OH	10.7	11.9

The explosion of enclosed spaces such as tanks that have a composition nominally above the UFL, but where the atmosphere is not well-mixed, can occur as a two-stage process. An initial hot spot or spark ignites a portion of the volume which is readily flammable. This causes relief devices to operate or other means to vent. The venting then causes temperatures and pressures to drop, with atmospheric air being sucked in through openings. A bulk of the interior volume now becomes lower than the UFL and better mixed, so a much larger second explosion follows the first. This sequence has been observed on a number of ship explosions[371].

The flammability limits within *partly-mixed* mixtures have been reported to be slightly wider, under some conditions, than in well-mixed environments, but the effect numerically was quite small[372].

The topics of fuel gas/vapor distribution in rooms and other near-closed spaces from gaseous discharges and from liquid spills are further treated in Chapter 13.

Initiation of gaseous detonations

Most mixtures of fuel gases in oxygen can be detonated, and many fuel gas/air mixtures can also. Detonation can occur by two means: (1) direct detonation, which occurs when a powerful ignitor is used; (2) deflagration-to-detonation transition (DDT). The latter process is one of 'flame acceleration,' and the ignition source which caused the initial deflagration is not relevant towards determining if a transition to detonation will occur. Two mechanisms are identified[373] as causing a laminar deflagration to transition to a detonation: (a) Interaction of pressure waves with the flame. Pressure waves cause the initially-smooth flame front to become wrinkled, due to an interface instability mechanism. Since the heat release rate per unit flame area remains roughly constant, increasing the flame area causes an increase in HRR, and this interaction sets up a positive-feedback condition. Eventually, detonation occurs at a local hot spot in the highly turbulent flame. The onset of detonation from accelerating laminar flames was initially modeled by Oppenheim and associates[374]. (b) The onset of turbulence in the flow of the unburned ahead of the flame, which occurs when the Reynolds number gets sufficiently high. In the simplest case of a tube open at one end and closed at the other, if the mixture is ignited at the open end, a combustion wave will propagate steadily through the mixture and a transition to detonation will not occur. But in the converse situation of a mixture ignited at the closed end, the combustion wave will progressively accelerate as it moves through the mixture and a DDT may take place. Thus, a prerequisite for a DDT to develop is an attainment of a minimum velocity turbulence component.

A transition to detonation is found not to occur in short pipe, and a minimum pipe length is necessary. The minimum tube length ('run-up distance' or 'detonation induction distance') decreases with increasing pressure or decreasing pipe diameter and is also strongly dependent on the chemical nature of the fuel molecule. Ginsburgh and Bulkley[375] provided some data on needed run-up distances for ammonia, ethylene, hydrogen, methane, and propane and proposed that $\frac{(\text{run-up distance})W^{3/2}}{(\text{pipe diameter})}$ can be correlated as a decreasing function of the burning velocity, where W = molar mass. Their correlation was poor, however, and the effect of pressure was not successfully represented. Also, they did not study enough gases to determine whether correlating molar mass against burning velocity successfully captures the chemistry involved. The chemistry effect is significant, as shown by the data of Westbrook[376] in Table 25. Bartknecht[357] and Steen and Schampel[377] conducted more extensive tests and their results (Figure 117) suggest that, even if the approach of Ginsburgh and Bulkley has merit, it should be modified to include an additive constant in the run-up distance within the correlating variable. They also obtained data as a function of fuel concentration and found that the minimum run-up distance is required at stoichiometric fuel concentration. The results should only be viewed as indicative, since pressure, head-end volume, and other factors affect the actual numerical values. Additional data obtained by Chatrathi et al.[378] are also shown in Figure

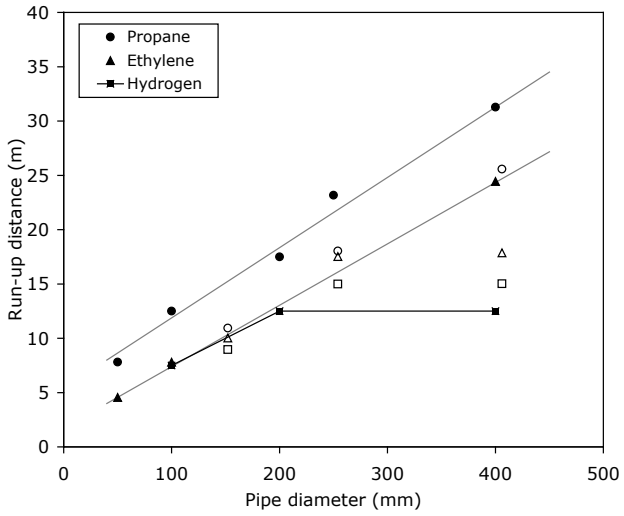

Figure 117 Effect of pipe diameter on run-up distance for detonation (dark symbols: German data; open symbols: Chatrathi)

Table 25 Relative run-up distances required for detonation to occur in circular tubes

Gas	Length (mm)
acetylene	0.1
ethylene	2
methanol	2
ethane	4
methane	20

Table 26 Cell sizes and minimum tube diameters necessary to detonate an unconfined vapor cloud

Fuel gas	Cell size (mm)	Min. tube diam. to detonate cloud (mm)
acetylene	10	150
hydrogen	15	200
ethylene	29	430
ethane	54 – 62	900
propylene	52	
propane	69	900
n-butane	50 – 62	900
methane	250 – 310	

117. Pure methane is extremely difficult to detonate, but small amounts of ethane and other hydrocarbons, as present in natural gas, make detonations in the latter notably easier. In one experimental study, it was found that 0.08 kg of tetryl sufficed to detonate an ethane/air mixture, but 22 kg was required for methane/air[379]. The above results should not be taken to mean that larger diameters are safer—in fact, detonations are precluded if the diameter becomes small enough. This is discussed below and a quantitative example for acetylene is given in Chapter 14.

For a pipeline detonation to be feasible, it is also necessary that the pipe not be too narrow. Fuel/air detonations have a cellular structure and this structure establishes a lower limit to the diameter of the pipe, which is very roughly equal to this cell size. Experimental determinations of cell size differ substantially, but some indicative values are shown in Table 26[380]. These results are all obtained at the most-readily detonable mixture, which is a composition usually close to the stoichiometric one. Methane is anomalous in that a tube diameter ca. 50 mm is sufficient, which is only about 1/6 the cell size[381]. For any gas, a much larger tube diameter is needed if the detonation is to emerge from the end of the tube and be capable of detonating an unconfined vapor cloud at that location. The data indicate that the diameter must be about 15× the cell size for a cloud detonation to be feasible.

Table 27 Minimum energy needed for detonation of various gases in oxygen and in air

Gas	In oxygen		In air	
	Fuel conc. (vol%)	MIE (J)	Fuel conc. (vol%)	MIE (J)
acetylene	40	3.83×10^{-4}	12.5	1.29×10^{2}
ethane	28.6	1.07	7.7	5.09×10^{6}
ethylene	33	7.2×10^{-2}	9.5	1.20×10^{5}
ethylene oxide	40	1.2×10^{-2}	12.3	7.62×10^{3}
hydrogen	60	1.58	29.6	4.16×10^{6}
methane	40	5.07×10	12.3	2.28×10^{8}
propane	22.2	5.77×10^{-1}	5.7	2.52×10^{6}
propylene	25	2.03×10^{-1}	6.6	7.55×10^{5}

Table 28 Constants for computing the relation between tube diameter and the minimum pressure needed for detonation

Fuel	Mixture	K	n
acetylene	8.8% C_2H_2 in air	1.15	0.915
	12.5% C_2H_2 in air	0.83	0.912
	$C_2H_2 + 4O_2$	0.049	0.884
	$2C_2H_2 + 5O_2$	0.022	0.882
	$C_2H_2 + O_2$	0.012	0.924
ethane	$C_2H_6 + 7O_2$	0.15	0.976
ethylene	$C_2H_4 + 3O_2$	0.081	0.918
hydrogen	$2H_2 + O_2$	0.23	0.928
methane	$CH_4 + 2O_2$	0.54	0.955
propane	$C_3H_8 + 5O_2$	0.13	0.933
propylene	$2C_3H_6 + 9O_2$	0.099	0.970

Lee[373] developed a semi-quantitative model for predicting the onset condition to transition to detonation. Based on this, he identifies a minimum turbulent flame speed of around 230 m s^{-1} as needed in air; in oxygen, only ca. 65 m s^{-1} is needed. Since laminar flame speeds in air are typically 0.5 m s^{-1}, this means that mechanisms must exist for increasing the speed about 460-fold for detonation to occur. In oxygen, however, typical laminar flame speeds are 10 m s^{-1}, thus an amplification of only 6-fold is needed. This explains why transitions to detonation are much more likely in oxygen atmospheres. The laminar flame speeds of acetylene and of hydrogen are much greater than those of other fuel gases; thus the hazards of detonation are also proportionately greater for these fuels.

Table 29 Some reported values of detonation limits (to be used as rough guide only, since values are highly dependent on experimental conditions)

Gas	Limits (vol%)	
	In O_2	In air
acetylene	3.5 – 92	4.2 – 50
butane	2.1 – 38	2.0 – 6.2
butanol	2.6 – >40	2.8 – 4.5
ammonia	25 – 76	
carbon monoxide	40 – 82	
cyclohexane	1.4 – 29	
ethane	3.6 – 46	2.87 – 12.2
ethanol		5.1 – 9.8
ethylene	4.1 – 60	3.3 – 14.7
ethylene oxide	2.6 – ?	2.8 – 4.5
hexane	1.6 – 36	1.6 – 5.6
hydrogen	15 – 90	18 – 59
MAPP		3.0 – 10.1
methane	1.9 – 15	6.3 – 13.5
methanol	9.5 – 65	
octane	1.6 – 17	1.5 – 2.9
propane	2.5 – 43	2.6 – 7.4
propylene	2.5 – 50	3.6 – 10.4
propylene oxide	3.3 – 40	
xylene	1.1 – 27	

Since flame speeds are increased by obstructions, passage of flame through a wire mesh or grid which is not fine enough to act as an effective flame arrester can lead to a detonation. The passage of flame through a grid increases its 'wrinkling,' and this acts to increase the flame speed.

Direct detonations of gas mixtures can be achieved by energetic sparks, in addition to condensed-phase explosives. A theory exists for predicting such detonations[373]. Spark energies several orders of magnitude greater than for igniting deflagrations are needed; however, values in the range of 0.1 J, sufficient for acetylene/air mixtures, are large enough that they would be uncommon for static electricity discharges.

MINIMUM ENERGY FOR DETONATION

In some industrial situations, the possibility of a detonation must be considered, thus it is of interest to have some measure of the energy needed to initiate one. Matsui and Lee[382] made a series of determinations using an indirect technique, whereby detonations were caused in a tube and then propagated (or not) into a large spherical vessel. The minimum energies were computed from a theoretical relationship based on the gas pressure and the minimum tube diameter needed for detonation. Table 27 shows the results obtained. The fuel concentrations given have been found to be the concentrations corresponding to the least energy needed. Note that 228 MJ are needed to detonate methane in air; even though the numbers should be understood only as relative indicators, nonetheless this suggests that it is very difficult to detonate methane in air (but not too hard in oxygen).

There is a relation[382] between the initial pressure and size of the tube that forms a minimum requirement for detonation,

$$P_i = Kd^{-n}$$

where P_i = minimum initial pressure needed for detonation (atm), and d = tube diameter (mm). Example values are shown in Table 28.

DETONATION LIMITS

It is sometimes of interest to know the lower and upper limits between which a detonation can occur. These have not been documented as extensively as have normal flammability limits, but several studies[112,336,382- 387] indicate that they are somewhat more narrow than flammability limits (Table 29). The values shown generally pertain to experiments in tubes; for unconfined detonations, the limits, especially the lower limit, become narrower. In addition, there are various other experimental details which can affect the results, and no measurement technique has been standardized. Almost any gas can be detonated, including such low-combustibility ones as carbon tetrachloride and tetrachloroethylene[388]; although detonation limits are not published on those.

Table 30 Effect of ignition energy on detonation limits of acetylene/oxygen mixtures

Ignition energy (J)	Detonation limits (vol%)
4.5	15 – 60
6.5	14 – 60
12	14 – 62
84	10 – 65
320	10 – 67

Detonation limits are affected by the ignition energy, but this makes results often difficult to apply to actual explosion incidents. BM data[389] illustrate this for acetylene (Table 30).

Tests for ignition properties of gases

AUTOIGNITION TEMPERATURE

EARLY METHODS

The most famous method for determining the autoignition temperature of gases was that developed by Mallard and Le Chatelier[49] in 1880. They used an evacuated, heated vessel into which a pre-measured quantity of a gas mixture (at ambient temperature) was suddenly admitted. This seemingly simple technique is actually complicated and non-ideal. There are several problems: (a) the volume is not at a uniform temperature, since a cold gas is admitted into a hot vessel; (b) there is an unaccounted-for 'physical' temperature rise which occurs because the vessel, originally at a low pressure, becomes pressurized; and (c) ignition delay times cannot be correctly determined, since the mixture takes some time to warm up. For a reversible, adiabatic process, thermodynamics would predict that the temperature rise from admitting a gas into an evacuated vessel would be:

$$T_f - T_o = T_o(\gamma - 1)$$

where $\gamma = C_p/C_v$, C_p = constant-pressure heat capacity, and C_v = constant-volume heat capacity. For an ideal gas, $C_p - C_v = R$, where R = universal gas constant. An ideal monatomic gas will have $\gamma = 5/3$, and a diatomic gas $\gamma = 1.4$, but fuel gas molecules normally have a much greater number of atoms and, for them, the effect is smaller. Fine et al.[391] explored the effect experimentally. A temperature rise (above the original vessel temperature) of 139 – 225ºC were found

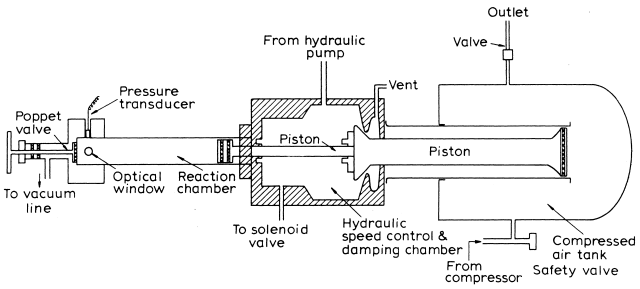

Figure 118 A rapid compression machine[390]

at the center of the test vessel when monatomic inert gases at 0.105 atm were introduced into a preheated, evacuated vessel.

Other early test methods included: (1) A sealed glass bulb containing the gas mixture is plunged into a constant-temperature bath, and ignition or lack thereof is observed. (2) The gas mixture in a tube is led through a rising-temperature bath. (3) Rapid compression machines (Figure 118), using a cylinder generally reminiscent of an automotive engine cylinder. This technique was highly favored in early 20th century testing, due to the similarity of conditions created there, compared to those in the automotive engine. For compression to be adiabatic, it must be very rapid. However, if the cylinder is compressed rapidly, it will overshoot the final temperature. Slowing down the cylinder helps reduce the overshoot, but introduces an unknown heat loss term. If an automotive engine is not the application of concern, then this technique has the additional disadvantage that elevated pressure is used rather than atmospheric. Consequently, AIT values will be inappropriately low (by as much as 300ºC), due to the inverse effect of pressure on AIT. Such data are not readily correctable to reflect 1 atm conditions. Recent studies with rapid compression machines have been reviewed by Griffiths[395].

HEATED TUBE TESTS

One of the few methods which allows a reliable determination of the induction period is a heated tube test. In this test, pure fuel and oxidizer gases are introduced into two separate, heated tubes[392]. The gases emerge into a cavity which is also at the same temperature as the preheat temperature of the supply tubes. Variants of this technique have been used in the UK[393,394] and in Russia[56]. Most of the studies with this arrangement are quite old and the reliability of the test apparatuses may be questionable, but the apparatus built by Jackson et al.[89] in 1954 was sophisticated, and a recent version was developed at the University of Leeds in 1996, which also includes provisions for atomization of liquid fuels[395]. While the scheme seems to be the one with the fewest drawbacks, nonetheless the results can be quite sensitive to apparatus details[84], so it is not necessarily evident that this geometry produces more 'fundamental' data.

TESTS PRIMARILY FOR LIQUIDS

The number of chemical substances which are gases at room temperature is vastly outnumbered by those which are liquids. Consequently, there has not been much interest in developing test methods solely for gases and most of the development efforts historically focused on liquids. These typically take the form of some heated apparatus into which drops of the liquid are dropped in and which rapidly vaporize at the elevated temperature. Such test methods are discussed in Chapter 6.

OTHER TEST METHODS

Griffiths et al.[396] developed a modern variant of the heated flask test used by Mallard and Le Chatelier. One new feature is a magnetic stirrer that is located in the flask. Some experimental results on methane with and without stirrer suggest that, at least for that gas, the effect of the stirrer on the value of AIT is small[41].

Sage and Weinberg[397] developed an innovative test where a flow-through vessel is used with two heaters, a main 'preheat' heater and a secondary 'supplement' heater. The gas mixture is preheated to a temperature below its AIT, then various temperatures of the supplement heater are used and the AIT is determined by extrapolation.

HEATED-SURFACE IGNITION

Smyth and Bryner[398] at NIST developed a hot-surface test method for the US Air Force. It was considered that in jet engine applications the flow velocities would be fast enough that a specially designed test method was needed which provided for short-duration exposures. Their test method comprises an electrically heated foil, which may be nickel, stainless steel, or titanium. The mixture is introduced as a jet impinging at 45º to the heated foil. The boundary-layer contact time is estimated at 90 ms. The results obtained with the test apparatus gave, with a few exceptions, highest T_{ig} values using the nickel foil and lowest values using the stainless steel foil. Similar to other research investigations, the dependence on the equivalence ratio was monotonically downward, with richest mixtures showing lowest T_{ig} values. Using the stainless steel foil and $\varphi = 1$, of the 15 hydrocarbons tested, all showed T_{ig} values within a narrow range of 720 – 840ºC except for acetylene, which gave 662ºC.

FLAMMABILITY LIMITS

BUREAU OF MINES FLAMMABILITY TUBE

The best known apparatus (Figure 119) for measuring the flammability limits of premixed gases is that developed by BM[242]. It consists of a 50 mm I.D. glass tube, 1.5 m long. The glass tube is closed off with a ground glass plate *b* and sealed in a pool of mercury *c*. It is evacuated with a vacuum pump through tube *j*. For testing vapors of combustible substances which are liquids at room temperature, the liquid is held in container *p*. Air (or oxygen, or diluents) is admitted through a drying tube *q*. Mixing is accomplished by repeatedly raising and lowering mercury reservoir *g*. The mixing time is generally 10 – 30 min. A test is then started by removing the mercury seal *c*, removing the plate *b*, and introducing a spark or a small flame at the open bottom of the glass tube. For spark ignition, platinum electrodes with a 6.3 mm spark gap and an AC power source of ca. 7.5 kV are used. For a mixture to be declared flammable, propagation has to occur at least halfway up the tube; if only a shorter propagation distance is found, this is deemed to

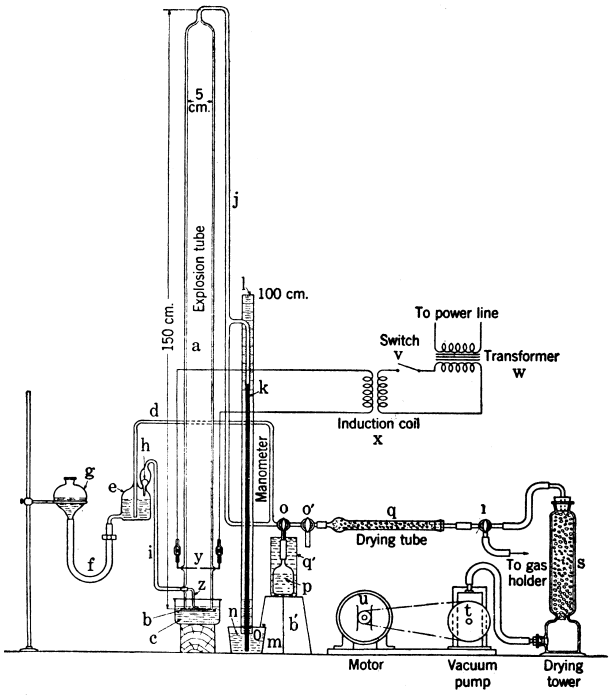

Figure 119 The standard Bureau of Mines apparatus for determining flammability limits of gases and vapors

occur due to localized heating from the igniter, and is not considered representative of the substance. A number of higher-molecular-mass compounds would be 'non-flammable' if tested in the standard apparatus, since at room temperature they do not vaporize sufficiently. The substances may propagate flame, however, if warmed up to a higher temperature. Thus, the Bureau of Mines evaluated the LFL of a number of such compounds at temperatures high enough (up to 203ºC) so that their flammability limits are attained. This was done using a similar apparatus, but with the propagation tube being located in an air oven[344].

There is an effect of the tube diameter on the results from the Bureau of Mines test. When the diameter was doubled, in a very limited series of tests it was found that the LFL limit stayed constant, but the UFL limit decreased[399]. During the 1970s, BM discontinued the use of the traditional apparatus and replaced it with the apparatus of ASTM E 681; however, very few data have been published from the later apparatus.

ASTM E 681

BM research showed that for some halogenated compounds the 50 mm tube apparatus may give 'non-flammable' results, but a special 100 mm version indicates that modest flammability does exist. The latter was

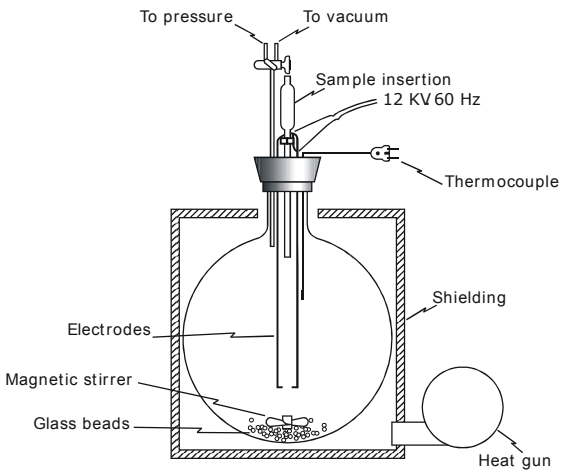

Figure 120 ASTM E 681 apparatus (5 L sphere)

not standardized and eventually, when Eastman Kodak developed the 5 liter sphere[400], BM also installed one in their laboratories. The Kodak apparatus became the ASTM E 681 test[401], which uses a 5 L glass sphere (Figure 120) to determine the flammability limits of substances in air at 1 atm or lower pressures and at temperatures below 150ºC. Pure-oxygen is not permitted to be used as the oxidizer in this test method. Samples may be introduced either as a gas, or a liquid which vaporizes within the test vessel. A magnetic stirrer is provided at the bottom of the vessel to aid mixing. Ignition is by electrodes which are 3.2 to 4.8 mm diameter and have a spark gap of 6.4 mm. The spark gap is located somewhat below the mid-height of the sphere. The test method also provides for a 12 L sphere, to be used for specimens which do not readily ignite in the 5 L apparatus. The test basically measures upward flame propagation, although the flame will also have a spherically-expanding aspect to it. Figure 121 compares results[402] obtained in the BM vertical propagation apparatus to those obtained in the ASTM E 681 sphere. With a few exceptions, the results are generally quite close. The same apparatus is called out in the ASTM E 1232 method[403], which is used to determine

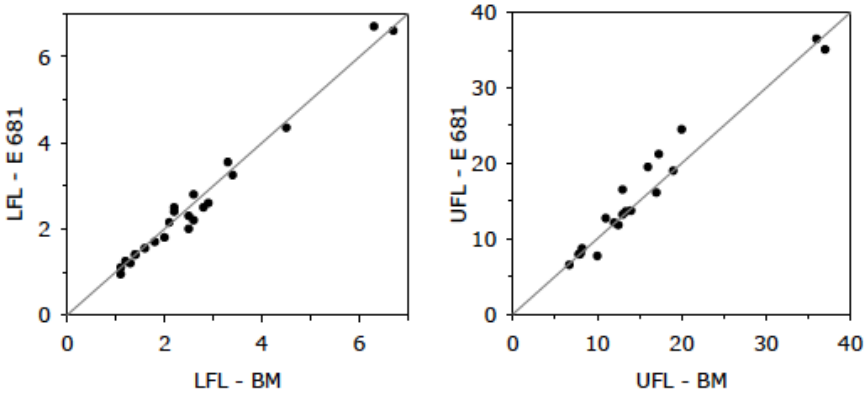

Figure 121 Comparison of LFL and UFL values obtained in BM flammability tube to values in the ASTM E 681 sphere

the lower temperature limit of flammability (LTL), as contrasted to determining the flammability limits at a preselected temperature. Few research studies have been published with the ASTM E 681 apparatus, although researchers at the University of Edinburgh[404] documented rather extensively the performance of a similar apparatus using a 6 L stainless steel sphere.

PROPOSED EN METHOD

In Europe, the original work at the Bureau of Mines was the inspiration for a German test, DIN 51649[405]. The test uses a vertical glass tube 300 mm long and 60 mm ID. Ignition is by means of spark electrodes at 60 mm above the bottom. For elevated temperatures, a hot-air jacket is used or the apparatus is placed in an oven. For gas mixtures, a steady flow rate is established within the tube, then flow is stopped prior to testing. For mixtures where a vapor is involved, a heated-tube vaporizer is used[406]. The method has become the basis for the proposed European standard EN 1839[407]. The latter expands the original concept by allowing the user the choice of either the tube apparatus or a sphere apparatus. The tube apparatus has been expanded somewhat to 80 mm diameter. The sphere apparatus similarly follows the ASTM E 681 scheme, with sizes of 5 L or greater being allowed. Ignition for the sphere apparatus is a fused-wire device, not the electric spark which is used in ASTM E 681. Curiously, there is no US standard test today which retains vertical tube type apparatus. A small amount of data cited in the EN standard indicate that the flammability limits are slightly broader when using the tube apparatus, but the data do not encompass any halogenated compounds.

ASTM E 918

If flammability limits at elevated pressures and temperatures are required, ASTM E 918[408] test allows determinations to be made at pressures up to 1.38 MPa and temperatures up to 200ºC. The vessel is a 1 L, 76 mm diameter, metal cylinder with spherical ends. Ignition is by means of a fuse wire which is located somewhat above the bottom of the vessel. Flame propagation is defined to have occurred when a pressure rise of more than 7% above initial pressure (absolute) occurs.

ASTM E 2079

The ASTM E 2079 method[409] describes a test where a spherical vessel is placed in a heating oven and is initially evacuated. The vessel may be as small as 4 L, with vessels up to 35 L reported to have been used. The test mixture is introduced and ignited by one of 5 optional igniters. The purpose of the test is solely to establish the MOC, so various concentrations of oxygen are supplied by trial-and-error until the minimum value is found. A 7% rise in the initial vessel pressure is used as the criterion of flame propagation, and visual observations are not made. The only paper that describes the test method is a study by CDC[305] describing the use of a 20 L vessel for making flammability limits measurements; no data on MOC measurements using this test method have yet been published in the literature. The physical hardware used by CDC is identical to the 20 L BM vessel described in Chapter 5 for testing dust clouds; the latter is standardized as ASTM E 1515.

UL TESTS

UL has used a 28 L steel cylindrical vessel for making LFL determinations at various temperatures. In this procedure, which apparently was only used for testing vapors and not gases, the vessel was first preheated to a desired temperature. Then the test liquid was injected with a syringe and a stirring fan activated inside the vessel. After a time of stirring, the fan was stopped, an electric spark was discharged through electrodes located near the bottom, and presence or absence of upward flame propagation observed.

RESEARCH TESTS

In the standard ASTM E 681 test method, the convection currents set up by the flame are a factor which influences the numeric value of the flammability limits reported. This reproduces the situation in accidental fires, but leads to complications and difficulties in modeling. More theory-friendly burner arrangements are possible, but Lewis and von Elbe[70] clearly warned: "It has been found possible to obtain limits considerably outside those obtained from practical testing by using flat-flame burners." A number of researchers worked with flat-flame, tubular-flame, and similar burners, although, following the *caveat* of Lewis and von Elbe, their results should not be considered as safety characteristics of the substances tested. Studies in this vein include those of C. K. Law et al.[410], Ishizuka[411], Liao et al.[412,413], and NIST[414].

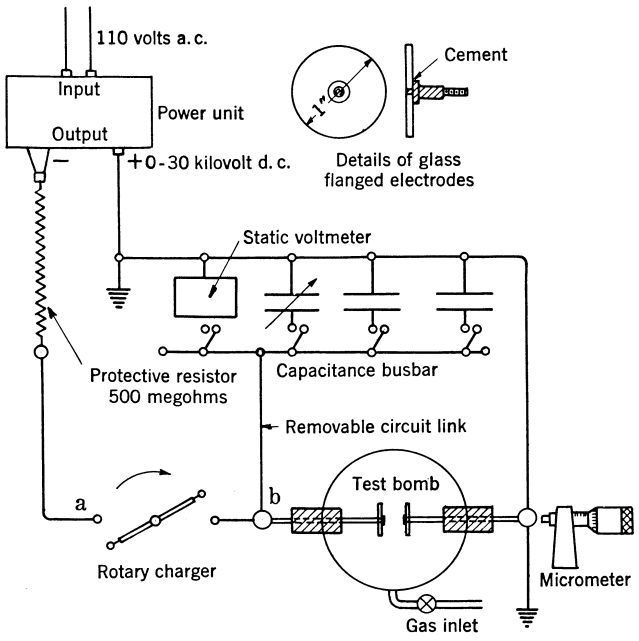

Figure 122 General arrangement of the Bureau of Mines MIE testing rig

MINIMUM IGNITION ENERGY

Apart from the ASTM test described below, several other tests of the 'break-flash' type are described in Chapter 12.

ASTM E 582 TEST

The ASTM version[415] is based on the Bureau of Mines procedures[181,416] (Figure 122) for determining the MIE and quenching distances of gases and vapors. The apparatus uses a 1 L stainless steel sphere, with capacitive discharge between flanged electrodes. The electrodes are 3.2 mm diameter and tipped with glass flanges which have a diameter of 5 – 10 times the spark gap distance. A high voltage power supply is used which can deliver 1 – 30 kV. The minimum voltage that can be used will, of course, depend on the breakdown voltage (Paschen's Law) for the particular gap distance and pressure selected. The capacitance is normally comprised solely of the stray capacitance and is in the range of 8 – 12 pF. To obtain a true MIE value requires that assurance be had that more than one spark does not occur. The Bureau of Mines recommends that the relaxation time of the flame kernel first be estimated as:

$$\tau = \frac{r^2 \rho C_p}{\lambda}$$

where r = half-width of spark gap (m), ρ = density of gas mixture (kg m^{-3}), C_p = heat capacity of gas mixture (J kg^{-1} K^{-1}), and λ = thermal conductivity (W m^{-1} K^{-1}). The RC value of the discharge circuit is then to be chosen so that it is greater than the value of τ computed above. This will normally require a resistor in the range of 10^9 to 10^{11} Ω. The ASTM standard, however, recommends that a fixed value for the series resistor of 10^{12} Ω (10^6 MΩ) be used. The test procedure involves first determining the quenching distance, then setting the spark gap to be slightly greater than the quenching distance and determining MIE. Both procedures have to be done by trial-and-error. The test apparatus may be used for temperatures up to 400ºC and pressures up to 3 atm. The BM report points out that for certain substances, larger spheres or spheres made of glass or metal are needed, but these have not been standardized by ASTM.

QUENCHING DISTANCE

There are no standard tests for measuring quenching distance. Experimentally, four different techniques have been used[107].

(1) Flowing the fuel/oxidizer mixture through a small burner tube, then quickly shutting off the flow. If the flame flashes back down into the tube, this means that the diameter is greater than d_T, the quenching diameter (mm). A smaller diameter tube is then tried and the process continued until the maximum diameter is found for which flashback does not occur. This diameter is d_T.

(2) Putting a stationary fuel/oxidizer mixture into a tube, then determining if propagation down the tube will or will not occur. Experimentally, this is commonly done in an all-glass apparatus. A portion of the apparatus is of a sizeable diameter and it contains a pair of spark electrodes. Attached to the large apparatus is a small-diameter, thin tube which is closed at the far end. The entire volume of the apparatus is filled with a mixture and the spark is ignited. The propagation or not of the mixture down the small tube is recorded. Since pressure has an effect on the results, the large cavity must be adequately vented to the atmosphere or to a plenum of controlled pressure. Practical details are illustrated by Potter et al.[417] A modified method uses a conically-shaped closed-end tube. In that method, propagation stops at a certain distance and knowing the inside diameter at that place the quenching diameter can be directly determined without need of a trial-and-error procedure using tubes of various sizes.

(3) Measuring the distance between flanged electrodes. In this technique, the standard Bureau of Mines flanged-electrode apparatus (e.g., the ASTM E 582 version) is used that is normally used to measure the MIE. As the electrode spacing is reduced, below a certain spacing a near-infinite rise occurs in the energy required for ignition. The spacing between the two electrodes is taken to be the parallel-plate quenching distance d_{II}. The results from this method are considered to be less precise than from the preceding two methods.

(4) Extrapolation from blowoff-flashback stability diagrams. This method[5] is somewhat convoluted and is of limited precision, so it would rarely be the tool of first choice.

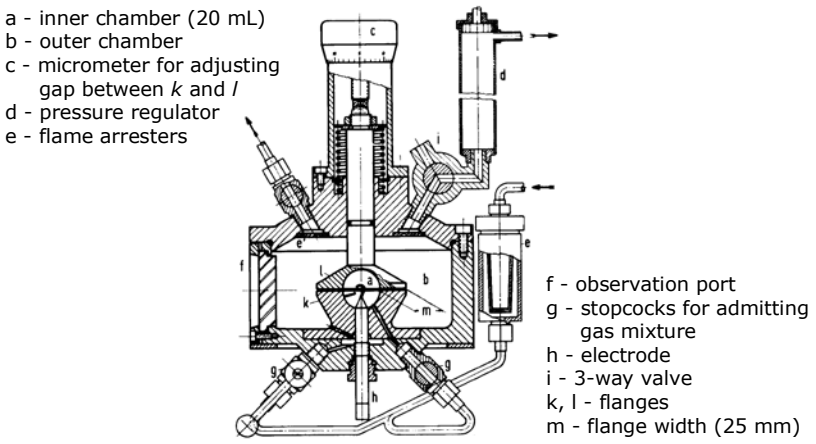

Figure 123 The 20 mL sphere developed by PTB and standardized by IEC

MESG

IEC/PTB AND HSE 20 mL SPHERES

Outside of the US, most MESG data have been obtained using a 20 mL sphere apparatus developed at the Physikalisch-Technische Bundesanstalt (PTB) in Germany[272]. Figure 123 shows the main features of the apparatus. The same gas mixture is admitted into the inner chamber (20 mL sphere) and into the outer explosion chamber (4.5 L). For an explosion to propagate from the inner chamber to the outer chamber, the gases must travel through a flange gap. The gap is adjustable, but the flange width is fixed at 25 mm. The apparatus has been standardized by IEC as IEC 60079-1A[418].

Much experimental MESG data have been published on the basis of testing with the 20 mL apparatus of the Health and Safety Executive laboratories[419]. The operating portions of the HSE apparatus are identical, but the equipment was redesigned so that it can be heated up to 130ºC, so that MESG values could more easily be determined for substances which have too low a vapor pressure at ambient temperature. Such substances are studied in the IEC/PTB apparatus by placing the test apparatus within an oven. Even though 20 mL is a small volume, HSE compared the results from the 20 mL apparatus to a large, 8 L apparatus[420] and found good agreement.

WESTERBERG APPARATUS (UL)

The apparatus in which testing of MESG values has been done in support of the National Electrical Code was developed by W. C. Westerberg at Underwriters Laboratories[421] and is described in UL's Technical Report No. 58[422]. The primary explosion chamber comprises a section of nominal 12-inch (0.3 m) pipe with a volume of 28.3 L. The secondary chamber into which the explosion does or does not propagate is 18 L. UL explored various breadths for the flange gap through which the gases escape, but adopted a 19 mm flange for their standard tests. The procedure involves running five tests and taking the worst results obtained:

(1) quiescent mixture in primary explosion chamber; ignition near flange;
(2) quiescent mixture in primary explosion chamber; ignition at opposite end of chamber from flange;
(3) turbulent mixture in primary explosion chamber, created with a small fan in the chamber; ignition near flange;
(4) turbulent mixture in primary explosion chamber; ignition at opposite end of chamber from flange;
(5) a pressure-piling configuration, wherein a 3.05 m long, closed-ended pipe (nominal 1.5 inch size) is connected onto the primary explosion chamber; no fan is used in this configuration.

Further readings

Bernard Lewis and Günther von Elbe, **Combustion, Flames and Explosions in Gases**, 3rd ed., Academic Press, Orlando FL (1987). This is the most famous, classical textbook on the combustion of gases. It includes a plethora of experimental observations no more recent author has attempted to encompass. The authors were associated for many years with the Bureau of Mines.

Guide to Fire Hazard Properties of Flammable Liquids, Gases, and Volatile Solids (NFPA 325), NFPA. This is the standard guide to autoignition temperatures. Note that the philosophy taken by the compilers has been exceptionally conservative: Instead of evaluating the data for accuracy and discarding dubious values, the authors have chosen to report the most conservative value found in the literature for a particular substance. Consequently, in many cases what is reported is an outlier, rather than a best estimate of the value.

Dag Bjerketvedt, Jan Roar Bakke, and Kees van Wingerden, Gas Explosion Handbook, *J. Hazardous Materials* **52**, 1-150 (1997). This study, prepared Christian Michelsen Research, is a technical, but highly readable, monograph on gas explosions.

Highlights and summary of practical guidance

Dusts can present three types of ignition hazards: (1) layers of dust can ignite if they pile up on hot surfaces; (2) dust clouds in the air can ignite and lead to a flash fire; (3) dust clouds in air can explode (Color Plate 1). The present chapter deals with the explosion hazard; the layer heating hazard is treating under Self-heating in Chapter 9. In some cases, stirring up and igniting dust may lead only to a flash fire, instead of an explosion. But, because an explosion is a more severe consequence than a flash fire, there has not been much research on flash fires.

Dust explosions are generally possible only in unoccupied spaces. This is because the dust concentrations needed for an explosion are high enough that the spaces would not be habitable. But in a habitable space, stirring up dust that has settled on various surfaces may produce an explosive concentration.

Much of the ignition and combustion behavior of dust clouds resembles that of fuel gas/air mixtures. Thus, ignitability of dust clouds is characterized by flammability limits, minimum ignition energy values, and AIT values. As with gases, the AIT value has been much used by regulatory bodies, but is generally not a reasonable descriptor of actual hazards, since ignition almost never occurs by uniformly raising the temperature of the dust cloud to an elevated value.

Because of the added complexity of the solid phase, dust clouds are significantly more difficult to study, and furthermore, have traditionally been less researched than have gas mixtures. Thus, guidance available is often sparse or contradictory. It must be noted, however, that in the last two decades or so there has been a substantial increase in research and currently dust cloud explosions are probably receiving every bit as much study as are gas explosions.

Safety specialists in dust explosions have mostly focused on small-scale test methods, yet the ability of these methods to predict real-scale reality has been at best uncertain, and at worst non-existent. This is hardly reliable, economical, or conservative. Hopefully future work will either lead to

well-validated small-scale methods or to other procedures which reliably—yet not over-conservatively—assess real-scale hazards. The most serious problem with present-day tests is poor uniformity of the dust concentration within the chamber. Since results are reported on the basis of the nominal concentration (mass of dust released, divided by volume of chamber), published LFL* values are often erroneously low, sometimes extremely so.

Dust particle diameter is a critical variable, yet tabulated data will hardly ever pertain to the size that is of specific interest. Thus, tabulated data (such as given in Chapter 15) must only be viewed as a rough guide, not as a quantitative indicator. Tests must be performed on the dust of interest to determine actual values, but even then great faith should not be placed in results from small-scale tests.

In some cases, the system of interest is a hybrid mixture (dust cloud + flammable gas). This is quite common in coal mines, where methane + coal dust is encountered. In hybrid mixtures, the presence of one component reduces the amount of the other component that can be present to maintain the atmosphere below its explosive limit. The LFL can often—but not always—be computed by a simple linear proportioning formula.

For flammable gas atmospheres, one of the main tools available for avoiding ignition is dilution. If sufficiently high ventilation rates can be assured in a system that the fuel concentration is well below the LFL, then ignition is avoided. This is generally not possible to do for dusts. Ventilation flow rates sufficiently high to avoid the LFL are often impractical. In addition, high ventilation velocities can serve to stir up dust layers and introduce new dust into the atmosphere. In some systems and machinery where effective dilution is not possible, inerting, for example, with nitrogen gas, must be utilized.

In 1977 Prof. Essenhigh[1] noted that: "Most research since the explosion hazard was recognized in 1785 by the Turin Academy of Sciences has been experimental." This is still largely the case, and while a number of theories have been put forth, little has emerged in terms of calculational equations suitable for practical assessment of dust cloud ignition hazards. As in many other fields of applied science, some practical problems (when sizable resources can be allocated!) are already being solved by advanced modeling schemes based on computational fluid dynamics. However, review of CFD methodologies is not within the scope of this handbook.

* In the dust explosion literature, it is more common to find the abbreviations LEL or MEC used; however, for consistency and generality, LFL is used here for dust clouds, just as well as for gases.

General principles

Dusts are solids; however, a suspension of dust in air (a *dust cloud*, or a *solid aerosol*) shares many more ignition characteristics with gases than it does with solids, as far as the ignition behavior is concerned. The particles comprising a dust cloud can have a wide variety of shapes. Many are roughly spherical, but platelets, needles, and other shapes are also found. Grain elevators and other agricultural product handling or processing facilities have proven particularly susceptible to dust explosions, since movement of the product tends to create dust and then to transport it. The dusts in grain handling facilities are typically particles of 17 to 120 μm diameter[2]. Also problematic have been the explosions in coal mines of mixtures of methane gas and coal dust. Other explosions tend to occur in chemical industry and in sundry manufacturing processes where dusts are generated. Curiously, the scientific world was not always convinced of the reality of dust explosions, and it was well into the 20th century before certain scientists stopped doubting that the phenomenon can occur. On the other hand, already in 1882, Marreco and Morrison[3] were conducting experiments by firing pistols into a 25 m long dust chamber containing coal dust. One of their findings was that a mixture of coal dust + methane ignites more readily than coal dust alone. Shortly thereafter, in 1885 Engler[4] documented that that a mixture of charcoal dust + methane can be explosible, even if the concentration of neither one alone would be high enough for ignitability. The term *hybrid explosions* is applied to such combinations.

It is a common rule of thumb that a dust cloud of explosive concentration is one in which the hand cannot be seen when the arm is stretched straight out in front of its owner[5]. Under normal conditions, few habitable spaces would have housekeeping so poor that this level of dustiness was present. But dust explosions tend to happen under abnormal circumstances, and high levels of dust can be introduced by a failure of machinery, events which stir up dust previously laying on horizontal surfaces, etc.

An important difference between gas and dust explosions concerns the physical nature of the fuel. For gases, only the chemical nature of the molecule has to be known. For dusts, however, physical properties such as diameter, shape, agglomeration, and sorption of moisture can play an important role. Thus, any theoretical treatment becomes more complicated and difficult. Also, aerodynamics plays a much more crucial role. Gas explosions can occur in quiescent atmospheres, but a dust explosion cannot, since air movement must exist in order to make the dust airborne. If dusts are fully settled in a layer, then ignition may be possible, but the combustion will resemble the combustion of normal solids, and not be an explosion. This problem is identical to the problem of self-heating of porous or granular materials and is treated in Chapter 9. The possibility must also sometimes be considered that quiescent burning of a dust layer

could get stirred up and lead to an explosion, although this chain of events has not been systematically studied.

Because of the possibility of lofting previously settled material, dust explosions often are a 2-stage event: (1) an initial ignition occurs and a certain amount of dust which was present in the air explodes; (2) the explosion makes airborne a large amount of dust which was previously settled out on various surfaces, this new fuel then explodes. The two stages are sometimes identified as *primary* and *secondary* explosions. In coal mining, a variant is encountered, where the primary explosion occurs due to a methane 'pocket.' The methane explosion then stirs up dust and the secondary explosion is a coal dust explosion. Experiments[6] have shown that dust explosions often tend to generate their own secondary explosion, although this question is poorly understood. Recently, Scherpa[7] conducted small-scale experiments on the dispersal of dust from settled layers into a dust cloud, but his technique involved an air blast and not an actual primary explosion. Apparently, the initial explosion acts to drive pyrolyze more fuel vapors from the dust cloud than can be burned locally, and this surplus amount is then available for burning later or at a different place. It is not always necessary to have a primary explosion in order to convert a dust layer into a dust cloud and to explode it. A case is reported where a smoldering layer of wood dust was found and a water stream applied to it for extinguishment[8]. Instead, the hose stream stirred up the dust and an explosion occurred. Dust explosions are normally deflagrations; detonations have been created in experimental studies[9-12] but have not been reported in practice.

Apparatuses developed for testing dusts necessarily differ from those for gas mixtures, because of their different characteristics as regards mixing. Gases are easy to mix uniformly and, once mixed, will not separate out. On the other hand, it is very difficult to create a uniformly mixed dust cloud and, once created, it does not remain in the same condition for long. Solid dispersions in air can be relatively stable if the particles are of very small size (< 0.1 μm), but this is much smaller than the dust clouds generated in typical processing or storage applications. These traits also make measurements on dust clouds less accurate than those on gases, since the basic starting point of an accurately-known concentration comes into question.

A specialized form of combustion is when a primary explosion stirs up a settled dust layer, but the ensuing secondary explosion has the character of propagating in a layer, rather than volumetrically. Explosions of this kind, where fuel is progressively driven into the air by entrainment, rather than being first lofted then burned, were studied by Srinath[13].

Chemistry of combustion

van der Wel[14] classified the chemistry of dust clouds into three types:

Type 1. The combustion reaction occurs on the surface (heterogeneous) and produces gas-phase combustion products. Example: graphite.
Type 2. The combustion reaction occurs on the surface; the products are solid or liquid. Example: most metals.
Type 3. The material pyrolyzes first, and the fuel actually combusting is in the gas phase. Example: most organic substances.
The main steps required to take place for ignition of Type 3 dust clouds are basically the same as for common solids (bulk material):

- the material is heated
- heat causes pyrolysis
- the pyrolysis process produces combustible gases
- the pyrolysis gases are liberated from the solid
- the pyrolysis gases mix in the atmosphere with oxygen
- ignition and explosion occur in the gas phase.

For organic materials, any effects of direct surface oxidation are considered to be small-to-nil, although in earlier years some researchers[15] argued the converse, that dusts ignite primarily by surface oxidation. The process of ignition of metals is discussed in detail in Chapter 8, although example data pertinent to ignition of metals dust clouds are also included throughout this Chapter.

A fourth type of ignition that can take place, not elaborated by van der Wel, involves solid-state decomposition or auto-oxidation, as for explosives and pyrotechnics. A few studies of explosions of dust clouds of propellants exist[19], but the problem is rarely encountered in practice, since most production processes for explosives are not accompanied by the generation of dense dust clouds.

The combustion of a dust cloud differs from combustion of gas mixtures due to the discrete nature of the particles, each one of which forms a local combustion zone. For an explosion to take place, the zones have to be close enough, so that what has been charmingly called[16] "the cooperative mechanism" can sustain flaming. In addition, a dust cloud is rarely created without turbulence, unlike flammable gas atmospheres. The consequence is that the flame thickness in a dust cloud explosion is on the order of centimeters, instead of the 1 mm or so found for flames of gases.

There is not much data on flame temperatures or laminar burning velocities for dust clouds, but limited results for cornstarch and lycopodium[6,17] showed stoichiometric flame temperatures of 1500 – 1600ºC and velocities of 0.13 – 0.59 m s^{-1}. The peak flame temperatures reported in another study[18] for cornstarch, coal, and toner powder were 1100 – 1400ºC. In detonations of various dusts, temperatures up to 2400 – 2600ºC were found. An adiabatic flame temperature of 1720ºC has been calculated for corn dust[13]. Some other researchers found higher laminar burning velocities[13], on the order of 0.5 – 1.5 m s^{-1}; it appears that results are highly dependent on the experimental arrangement used. Turbulent burning velocity, of course, depends on the nature of the

turbulence—experimental values in the range 5 – 1000 m s^{-1} have been reported[13]. The *duration* of flaming in a dust cloud explosion[18] is generally 0.2 – 0.5 s, as measured in test chambers of 2 – 20 m^3 volume.

Flammability limits

LOWER FLAMMABILITY LIMITS

Analogous to the lower flammability limit for gases, a minimum explosible concentration of dusts can be defined. Most explosible dusts have reported lower limits in the range of 20 to 200 g m^{-3}, but the realism of values at the low end of this scale has to be judged in the context of LFL measurements on gases. The lowest reported value is 3.3 g m^{-3}, for hydrogen. The only two organic gas molecules that show LFL values below 30 g m^{-3} are acetylene at 26.6 g m^{-3} and 1,2-propadiene at 27.8 g m^{-3}. These results (see Chapter 15) were obtained by the Bureau of Mines using their flame propagation tube apparatus (see Chapter 4). The ignition source is an electric spark in that apparatus. As Eckhoff pointed out[19], dust combustion can be less efficient than that of gases, but cannot be more efficient—so higher, not lower, LFL values must be expected for dust clouds. The LFL for a dust cloud could, in principle, be identical to that of a gas, if volatilization is rapid enough, such that all of the dust material is pre-volatilized and if the dust suspension were truly uniform.

In 1924 Trostel and Frevert[20] noted that "One of the weak points in any work done with dusts lies in the inability to create and maintain for much more than a second or so a fair homogeneous suspension of definite dust-air proportions." This problem has not been fully solved to date. In 1967, researchers at the Southwest Research Institute[21] reported that LFL values obtained with the Hartmann apparatus, the still-most-common apparatus for this purpose, are roughly a factor of 2× too low, since visible observations indicate that the dust fills only about half the chamber, yet calculations assume that the given mass of dust is dispersed evenly throughout the entire volume. They also noted that the concentration is uneven radially, being higher near the tube walls and lower near the center. Quite recently, Wolański made a study on anomalously-low reported LFL values and similarly concluded that they were due to improperly mixed dust suspensions[22,23]. It remains very difficult to achieve a uniform mixture of dust within a given volume of air. Most typically, there will be pockets of more dense mixtures, interspersed with less dense pockets. If the igniter is so located that pockets of more than average density can flow by it, then it is possible that what was recorded as ignitable was a local concentration that was significantly greater than the average concentration value that was computed. Wolański further pointed out that an LFL of 20 g m^{-3} would mean an adiabatic flame temperature of ca. 500 K at the lean limit; this is grossly unreasonable, since all true limit flame temperatures (see Chapter 3) are generally ca. 1500 K. The same conclusion was reached by Lesikar et al.[24] who reported on tests not of materials showing anomalously low LFL values, but rather, ones in the 'normal' range. Wheat dust shows LFL ≈ 65 g m^{-3} when tested in the standard way in the Hartmann apparatus. But using high-speed photography, they documented that only a portion of the chamber actually contains dust at the moment of explosion, and that the effective LFL value is 110 – 150 g m^{-3}, depending on the particle size distribution. Even more problematic was lignite dust. Standard values, as obtained from Bureau of Mines testing[25] are in the range 25 – 50 g m^{-3}, but a value of 290 g m^{-3} was found by Lesikar et al.

The issue of spatial non-uniformity is also quite real in actual explosions, since mixing will not be perfect in these either. But there does not seem to be any basis for claiming that a small-scale test showing poor uniformity is predictive of a full-scale situation where mixing is imperfect. Eckhoff[19] reviewed various physics details of the mixing process, but it became clear that little progress has been made in dealing with the consequences of poor uniformity on test results or on accidental explosions.

Makris and Lee[26] perhaps best summarized the unsatisfactory state of the art by pointing out that most of the apparatuses used for determining LFL values produce values which have little relation to reality, with the main reasons for this being:

(1) some apparatuses, e.g., the Hartmann apparatus, are so small as to be below the quenching diameter for some dust types;
(2) most apparatuses produce a highly non-uniform dust concentration, and it is not clear that the average concentration has any physical meaningfulness;
(3) since flammability limits innately refer to the potential for flame to propagate through a large, open space, the realism of testing in small, closed volumes (e.g., 20 L spheres) is questionable;
(4) often excessively large ignition sources are used in the laboratory-scale apparatuses, unrealistically enlarging the flammability limits;
(5) the criteria adopted for the test influence the outcome, yet have no fundamental basis that could be related to real-scale performance;
(6) while attempts have been made to provide real-scale validations, the multiple apparatus-dependent features interact in such a way that it is not reasonable to conclude anything positive, in the absence of a large number of validation data points.

As an example of the apparatus-dependent problem, they observed that reported LFL values for cornstarch range from 8 to 380 g m^{-3}. They especially cautioned that a sizable pressure rise recorded in a fixed-volume chamber (the normal criterion applied in determining LFL values in such experiments) does *not* imply that the same mixture would generate an indefinitely propagating flame in a large environment. Instead, it simply means that a fixed quantity of dust ignited and burned enough to raise the pressure to the

criterion value. At the end of their study, the authors concluded that several apparatuses—the Nordtest 15 L apparatus, an experimental 5 m^3 sphere, and their own 180 L cylinder—gave values which were nearly identical (70 – 80 g m^{-3}) and appeared to be the optimum experimental value determined by pressure-rise methods. The extreme outlier (8 g m^{-3}) was obtained in the 20 L Siwek sphere. An entirely different set of results was obtained, however, from experiments done in tubes (similar to the Hartmann apparatus, but larger in scale) where actual flame front propagation was monitored, with the criterion being that the flame propagate at least ¾ of the tube length. Here, the authors found that in large-diameter tubes, LFL = 200 g m^{-3} if the tube is closed (constant volume). For open tubes (constant pressure), LFL = 400 g m^{-3} was measured. Finally, they found that certain coal dusts would not propagate flame at any concentration in their 180 mm diameter tube, which they attributed to the fact that the quenching diameter for this dust was ca. 190 mm. Their conclusions from this experimental work was that "All flammability limits of dust-air mixtures determined in closed-bomb experiments have no fundamental significance at all and are thus meaningless." Instead, they concluded that an open tube apparatus must be used, but that its diameter must exceed the quenching diameter of the dust. Additional data in related studies were reported by Jarosiński et al.[27,28]

A secondary dust explosion will be ignited by an extremely powerful ignition source—an ongoing explosion. Thus, to characterize the intensity of explosions it is prudent to assume that the secondary explosion is the one which does the major damage and therefore, to conduct tests using a very powerful ignition source. In view of this, within the dust explosion testing community over the last several decades, the concept of using pyrotechnic igniters has been developed. These igniters are appropriate for testing the maximum pressures developed in explosions, but when applied to determining of LFL values, three problems can be seen: (1) A highly energetic igniter is logically applicable only to situations where the primary explosion is a gas explosion. Yet, igniters of this kind have been applied to testing of all sorts of dusts even in situations where a primary gas explosion is unlikely or impossible. (2) When highly energetic ignition sources are employed, a non-parallelism is created in regards to the testing of gases, where such schemes are not used: dust clouds are effectively 'proven' to be more readily ignitable than gases. (3) The ignition flame from these devices is highly directional and non-spherical, making analysis or comparison to other igniters difficult.

To examine the effect on gases when highly energetic ignition sources were used, Hertzberg et al.[29] conducted comparative tests on methane using a conventional spark igniter and a series of pyrotechnic igniters. When tested in a 20 L chamber, methane showed LFL = 4.9 vol% (32.1 g m^{-3}) using a spark igniter and using pyrotechnic igniters up to 1000 J nominal rating. For a 2500 J pyrotechnic igniter, however, they found that the recorded LFL dropped to 4.4 vol% (32.4 g m^{-3}). When a larger 120 L chamber was used, then the LFL value associated with the 2500 J igniter rose back to 4.9% and only when going to a 5000 J igniter did it drop to 4.7% (30.8 g m^{-3}). A similar decrease in reported LFL with increasing igniter energy was found for dust clouds (Figure 1). Note, however, that the dust cloud data in Figure 1 are not given for ignition sources smaller than 500 J. Yet, typical ignition sources for dust clouds are mechanical sparks, electrostatic discharges, and other low-energy sources (dust cloud ignition statistics are discussed in Chapter 14).

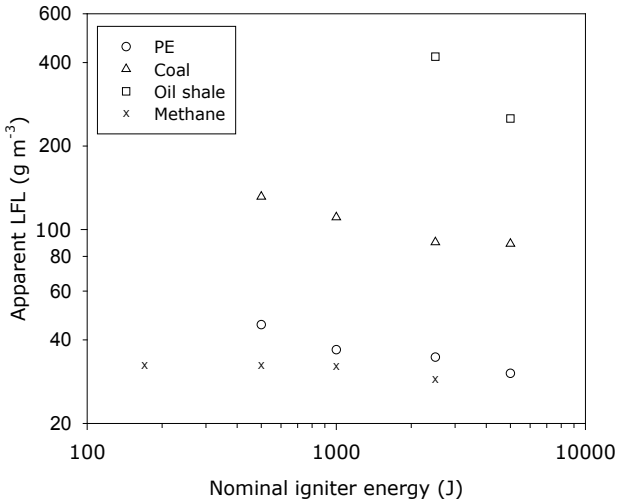

Figure 1 Effect of igniter energy on LFL values, as measured in the 20 L chamber used by the Bureau of Mines

Cashdollar et al.[30] conducted a series of experiments where they characterized coal and other dusts by their volatilizable mass fraction. It is a bit hard to view this mass fraction (termed 'volatility' by the authors) as being independent of the test conditions, but they were able to pin down the ends of the scale by using the definition that volatility of graphite dust ≡ 0, and volatility of polyethylene dust (which melts and gasifies before burning) = 100%. For other substances they used a laser pyrolysis method to determine the fraction that is volatilizable, and produced a relation between volatility (mass fraction volatilizable) and the measured LFL (Figure 2).

Their results show a straight line relation when 1/LFL is plotted against volatilizable fraction. The rightmost point on the graph is polyethylene (PE) with no graphite, and the authors found LFL = 33 g m^{-3} for the PE dust. Cashdollar et al. indicate a line which almost, but not quite, passes through the origin. If this small offset is ignored, then their results can be represented as:

$$LFL = \frac{3300}{VF}$$

where VF = volatilizable fraction (%). Conceptually, this is undoubtedly correct, although the numerical values ob-

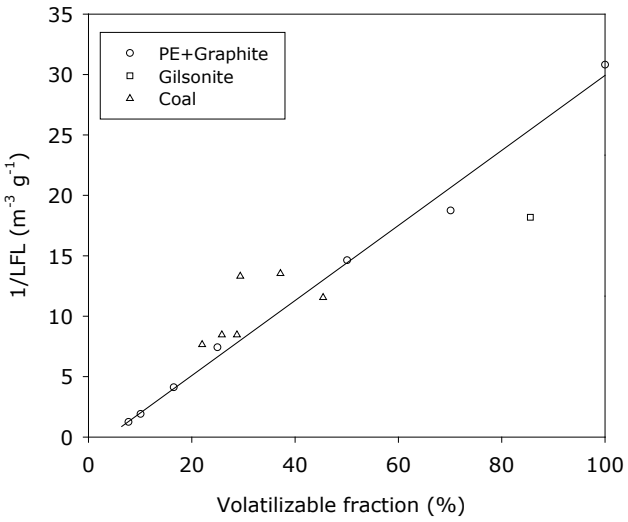

Figure 2 Effect of volatilizable fraction on LFL of dusts
(Copyright The Combustion Institute, used by permission)

tained in their experiments can be considered too low. These results are tantamount to concluding that the PE dust burns as a gas with LFL = 33 g m^{-3}. Table 1 in Chapter 15 shows that only 6 organic substances could be found in the literature with LFL values ≤ 33 g m^{-3}, and it appears questionable that the pyrolysis products for PE comprise only those six. Instead, as discussed later in this Chapter under Test Methods, the questionably-low values can be attributed to the use of a 2500 J pyrotechnic igniter in the 20 L Bureau of Mines test apparatus. The volatilizable fraction concept is fascinating and might possibly correlate the LFL of a wide variety of nonmetallic dusts. But at the moment only results for the three dusts in Figure 2 are available, as measured on a common basis.

The prediction scheme of Cashdollar et al. implies that all plastics which volatilize 100% without leaving a char have an identical LFL value. This, of course, is not true. Dividing the dust matter into volatiles and non-volatiles is the simplest subdivision. But as far as the volatiles are concerned, the heat of combustion might be expected to come into play. On this basis, Wolański[22] proposed that the LFL (g m^{-3}) can be approximated by:

$$LFL = 3634\ \Delta h_c^{-1.21}$$

where Δh_c = gross heat of combustion (MJ kg^{-1}) of the dust. In a practical scheme, the heat of combustion should actually pertain only to the volatile matter, setting as zero the contribution of the portion going into char. This next step of development has not yet been explored. Agricultural dusts normally have Δh_c < 24 MJ kg^{-1}, thus by this approximate formula they should show LFL > 78 g m^{-3}. According to extensive measurements that Wolański made, he finds that the minimum experimental LFL for agricultural dusts, when done with great care to obtain uniform mixtures, is 65 g m^{-3}. As mentioned above, he points out that many LFL values reported in the literature are systematically too low, due to insufficiently adequate uniformity of the tested mixture. The cornstarch studies of Makris, Lee, and Jarosiński, discussed above, must also be considered. They indicate that a realistic LFL for cornstarch is in the range 200 – 400 g m^{-3}, yet since cornstarch is nearly 100% volatilizing, LFL ≈ 33 kg m^{-3} would be obtained according to the scheme of Cashdollar et al. The heat of combustion of cornstarch is around 17.6 MJ kg^{-1}, so use of the Wolański relation would raise this to 113 g m^{-3}, which is much more reasonable, although still low.

Shevchuk et al.[31] proposed a simplified theory whereby:

$$LFL = \frac{C\rho\left(T_{ig} - T_o\right)}{0.5\Delta h_c - C_s\left(T_{ig} - T_o\right)}$$

where T_{ig} = autoignition temperature of dust (K), C_s = heat capacity (J kg^{-1} K^{-1}) of dust, and C and ρ are the room-temperature heat capacity and density, respectively, of air. Reasonable prediction of experimental results was claimed for an assortment of metal dusts; other dust types were not explored. In view of both theoretical and experimental problems in determining T_{ig}, however, it is not clear how robust such a method can be; in any case, no other workers have attempted a validation.

A general flammability diagram can be prepared for dust clouds using concentration vs. temperature axes, which establishes three basic regions of non-flammable atmospheres, atmospheres that ignite with the use of a pilot, and atmospheres which autoignite. Such a diagram is shown for coal dust in Figure 3[32].

Instead of expressing the LFL as a concentration, it is also possible to express it as an equivalence ratio. For example, the LFL for 5 µm PMMA dusts is 100 g m^{-3}. Stoichiometric combustion of PMMA in air is:

$$C_5H_8O_2 + 6\left(O_2 + 3.76N_2\right) \rightarrow 5\,CO_2 + 4H_2O + 22.56N_2$$

The molar mass of PMMA is 100.06. Thus, at φ = 1.0,

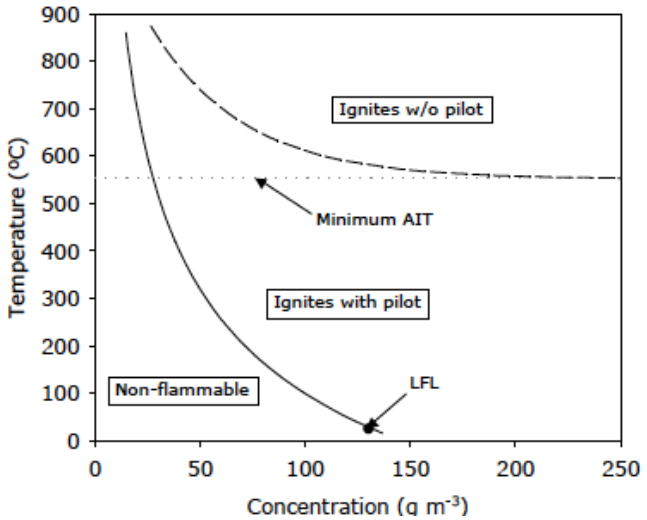

Figure 3 Regions of flammability for coal dust
(Bureau of Mines)

100.06 g of PMMA react with 28.56 mol of air. Assuming that ambient temperature is 20ºC, then 1 mol of an ideal gas = 0.024055 m^3, and 28.56 mol of air takes up 0.687 m^3. Therefore, the stoichiometric PMMA concentration is 100.06/0.687 = 146 g m^{-3}. At the LFL concentration of 100 g m^{-3}, the equivalence ratio = 100/146 = 0.69. This is not surprising. What is interesting is to consider the equivalence ratio for 50 μm particles, which have a reported LFL of 180 g m^{-3}. For such particles, the LFL corresponds to φ = 180/146 = 1.23, in other words, for the *lower* flammability limit to be reached, fuel-rich conditions must be attained! The explanation, of course, has to do with the fact that, for large particles, the fuel is not readily available—it must first be pyrolyzed and, thus, only a small fraction of the fuel can participate in the early stages of combustion.

In summary, if LFL values of dust clouds were to be obtained that have quantitative validity, rather than solely being an apparatus-dependent rank ordering, it would be necessary to follow Wolański's requirements[23]:

- the dust should be uniformly dispersed;
- ignition energy should be sufficient to ignite the mixture, but not so high as to enhance combustion of lean mixtures;
- flame propagation should be observed far enough away from the ignition so that the influence of the ignition source is negligible;
- if an alternate criterion is used to determine the LFL, it should be well correlated to the flame propagation criterion given above.

Unfortunately, none of the major data tabulations that are available conform to these requirements, although a few individual studies exist that do. It is especially noteworthy that there exist no validation experiments which would endeavor to quantify LFL values under conditions approximating those in real-scale explosions. Thus, while numerous combustion science considerations suggest that LFL values for dust clouds have to be appreciably higher than for gas explosions, a quantitative means of 'adjusting' the tabulations derived from conventional small-scale tests is not available. For agricultural dusts, values below 65 g m^{-3} can be considered to be erroneous. For any organic dust, values below 50 g m^{-3} must be considered spurious[22].

UPPER FLAMMABILITY LIMIT

Experimentally, an upper flammability limit (UFL) can be found for dusts, and it is generally around 2 – 3 kg m^{-3}, but as high as 13 kg m^{-3} for some substances. Very few studies exist in the literature where UFL values have been determined; Eckhoff[19] made a survey of a number of these studies. The UFL values are highly dependent on the ignition energy used, so even in a single apparatus, many different UFL values can be assigned[33]. At these enormous concentrations, it becomes very difficult to get any kind of uniformity of dispersion, so experimental uncertainties are large. In practice, huge concentrations can be created in processing and conveying machinery, but will not occur in habitable atmospheres, since there would be zero visibility if one were to enter a space with concentration above the UFL. Even in processing machinery, there is little assurance that a concentration reliably above the UFL could be created. Thus, since opportunities generally do not exist to operate a process above the UFL, there has been little impetus to quantify UFL values.

The chemical process occurring at the UFL is not analogous to gases. Apart from unique issues associated with metal dusts, dusts must first pyrolyze, or gasify, before they can combust. In a gaseous mixture of fuel/oxidizer, all of the material is already in gas phase and can react. The UFL in gases, thus, arises because the heat sink effect of a large excess of fuel molecules prevents high temperatures from being reached at which appropriate reactions could take place. In a dust cloud, however, the combustion takes place in a different phase than the one which comprises the fuel 'reservoir.' A stoichiometric flame sheet can propagate in the gas phase, where it has only a secondary thermal contact with the mass of yet-unpyrolyzed fuel. If expressed as an equivalence ratio, the UFL of dust clouds may be $\varphi \approx 30$, which is, of course, enormously higher than for gases ($\varphi \approx 2$ to 5, except for unstable gases).

With the above considerations in mind, for the general case, one of two mechanisms can limit the flame propagation in dust clouds: (1) diffusion and reaction in the gas phase; or (2) pyrolysis of the solid particle. The latter limit can come about due to either very large concentrations of particles, or else particles of very large diameter.

AIT, quenching distance and MESG

The autoignition temperature of dust clouds is measured in a furnace of one kind or another, and the value reported is the minimum temperature needed for ignition. In terms of fundamental interpretation of the results, difficulties arise because of the ill-defined environment for the test substance. The test dust is injected by means of a cold-air stream into the heated cavity. This makes it impossible to assume a single, fixed temperature for the volume. Since the walls are, perforce, at a higher temperature than the dust volume, hot-surface ignition aspects can come into play. The AIT concept would suggest that ignition is to be expected if the dust cloud experiences any temperature higher than the AIT. But a Bureau of Mines study[34] showed that one type of dust tested, polyethylene, gave an anomalous behavior—not only was there a minimum temperature below which ignition did not occur, but also a maximum temperature above which ignition was impossible. The reason for this is unclear, and six other materials tested did not exhibit such a non-ignition regime.

Same as for gases, dust clouds show a minimum distance below which propagation of flame cannot occur. The quenching distance for dust clouds, however, has not been extensively studied. Jarosiński et al.[27] designed a special

tube apparatus containing a series of quenching plates in the center. A dust cloud is generated in both halves of the tube, ignited in the bottom half, and propagates or not into the top half. Results for cornstarch are shown in Figure 4. The authors also found a minimum quenching distance of 10 mm for aluminum flakes and atomized aluminum, and 25 mm for coal dust of less than 5 µm. A very large value of 190 mm was found for polydisperse coal dust passing through a 200 mesh sieve. The coal tested was one of low volatility, and this accounts for the high values of quenching distance. Cornstarch, on the other hand, was found to be nearly 100% volatilizing, thus quenching distances, much as LFL values, can at least qualitatively be seen to depend on the fuel volatility.

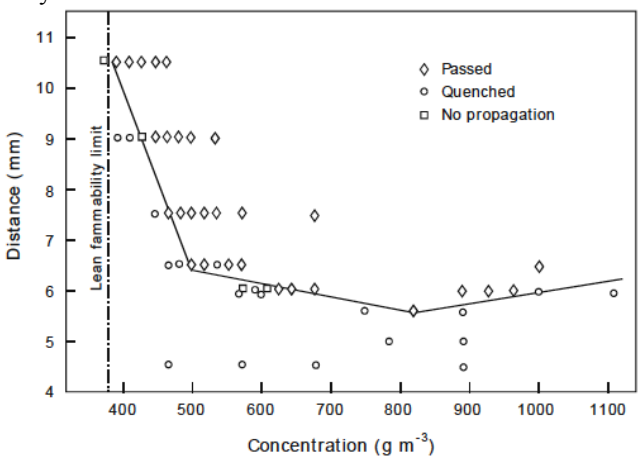

Figure 4 Quenching distance for 15 µm cornstarch dust
(Copyright The Combustion Institute, used by permission)

In design of explosionproof equipment the related concept of MESG (maximum experimental safe gap) is used, and the principles have been described in Chapter 4. MESG values can also be obtained for dust clouds, although the data are sparse. Jarosiński et al.[28] obtained a value of 1.5 mm for cornstarch at 600 g m^{-3}. Figure 4 shows that the quenching distance for the dust was 6 mm. Schuber[35] provided MESG data for a number of dust types. Using a flange breadth of 15 mm, he found typical values of 1 – 3 mm, but for two dusts, however, he found very low values. Lycopodium showed 0.75 mm, while a mixture of 80% sulfur and 20% lignum sulfate showed only 0.20 mm. There was generally a smoothly-increasing dependence of MESG value on the flange breadth, up to breadths of about 35 mm, beyond which point plateau values were reached. The lowest reported MESG value for a gas is 0.29 mm for hydrogen. The tabulated standard MESG values for gases were obtained in the IEC/PTB apparatus using a 25 mm flange breadth, so the 0.20 mm measurement would rise somewhat if referenced to the same flange breadth. Nonetheless, the reason why a dust cloud should show an MESG value essentially identical to the hydrogen mm is unclear. Schuber also provided a correlation for MESG (mm) as:

$$MESG = \left(MIE \times \frac{T_{ig} + 273}{273} \right)^{0.157}$$

where MIE is measured in mJ and T_{ig} is the AIT in ºC. The results pertain to a flange width of 25 mm and AIT values as measured in the BAM oven. The MESG values are typically several-fold smaller than the quenching distances.

Theory of ignition of dust clouds

In Chapter 4 it was pointed out that numerous theories for predicting the LFL of gases have been proposed, but that they are either seriously inaccurate, or unvalidated, or computationally very difficult. Thus, so far it has not been found viable to predict the LFL of gases from theory. For dust clouds, there are many further complications. Primary of these are: (1) the need to account for the volatilization of the solid; (2) a strong coupling of fluid dynamics—unlike for gases, the problem cannot be studied in a quiescent state; and (3) interactions between particles, especially the dominant role of heating by radiation[36]. Despite these daunting complexities, some progress has been made.

Several workers have put forth ambitious mathematical theories which try to cover comprehensively the phenomena involved in dust cloud combustion. Klemens and Wojcicki[37] offered such a comprehensive theory, but even with numerous simplifications, few conclusions could be drawn from the numerically computed results. Smirnov and coworkers[38] developed a numerical model that includes the effects of turbulence. The model was detailed enough so that a number of features, e.g., slow ignition, could be examined.

For predicting experimental trends through graphs or closed-form equations, simpler theories appear to hold more promise. Such theories generally postulate a limiting factor to the HRR, and this factor can be either (a) reaction kinetics or (b) external heat transfer. A theory based on reaction-kinetics limiting factor was proposed by van der Wel[14], who suggested that the autoignition temperature of dust clouds could be modeled in an analogy to the Semenov model for the AIT of gases (Chapter 4). In the Semenov theory, for a volume of gas, the HRR expression is:

$$\dot{q} = QAVc^n e^{-E/RT}$$

For dust clouds, van der Wel suggested that the HRR be considered proportional to the total surface area of particulate, and to be driven by the oxygen concentration. Thus,

$$\dot{q} = QAsVc_{O_2} e^{-E/RT}$$

where c_{O_2} = oxygen concentration (kg m^{-3}), V = volume (m^3), and s = surface area of particulates per volume (m^2/m^3). The latter can be evaluated as:

$$s = \frac{6c_s}{d_p \rho_s}$$

where c_s = dust concentration (kg m^{-3}), d_p = particle diameter (m), and ρ_s = particle density (kg m^{-3}). An expression for the AIT, T_{ig}, is then obtained from the implicit equation:

$$eQAsVc_{O_2}e^{-E/RT_{ig}} = hS_v\frac{RT_{ig}^2}{E}$$

where S_v = surface area of vessel (m^2).

A simple theoretical equation as the above lacks realism in a number of areas, as van der Wel points out:

- The theory assumes that as long a waiting time as needed is available for an explosion to develop. In practice, the explosion has to occur within a very short time, or the dust cloud settles out.
- The heat of pyrolysis is not taken into account.
- It is not possible to create a truly uniform-temperature environment in actual test apparatuses.
- Solid, unvolatilized particulates act as localized heat sinks.

Zielinski[39] was the first to suggest that better predictions of experimental results might be obtained if it were postulated that heat transfer, not chemical reaction, limits the HRR. Part of his reasoning was that chemical-reaction theories are likely to be systematically wrong numerically, since the numerical results from these theories are dominated by the particle temperature, yet this temperature is very hard to measure accurately and is usually overestimated. This line of thinking was subsequently extended by Hertzberg et al.[40] and Litton et al.[41] at BM. Litton proposed that a tractable theory could be formulated by considering the problem to be dominated by radiation. A propagating fire cannot be sustained unless a mass concentration of volatiles greater or equal to that of the LFL is produced. Energy is radiated from the ignition source and can be expressed as a source radiance I_o (W m^{-2}). The Beer-Lambert Law is assumed to be valid for attenuation of radiation by small particles:

$$I_a / I_o = 1 - e^{-\sigma c_s D}$$

where I_a = absorbed heat flux (W m^{-2}), σ = specific absorption area (m^2 kg^{-1}), c_s = mass concentration of dust (kg m^{-3}), and D = path length (m). It is assumed that the absorbed energy, E_a (J), is related to the mass of volatiles released M_v (kg) by an effective heat of vaporization L_v (J kg^{-1}):

$$E_a = M_v L_v$$

Using the Beer-Lambert Law, the absorbed energy can be expressed as the absorbed heat flux, times the area of the absorbing particles, times the time. The area of the absorbing particles is $\sigma c_s V$, where V = volume (m^3), thus:

$$E_a = \left(1 - e^{-\sigma c_s D}\right) I_o t_{ig} \sigma c_s V$$

where t_{ig} is an ignition time (s). Ignition will be propagated only if the available E_a is $\geq$ the required E_a, thus:

$$\left(1 - e^{-\sigma c_s D}\right) I_o t_{ig} \sigma c_s V \geq M_v L_v$$

Dividing by the volume gives:

$$\left(1 - e^{-\sigma c_s D}\right) I_o t_{ig} \sigma c_s \geq \frac{M_v L_v}{V}$$

If the volatilizable fraction of the dust is f_v (--), then $c_s = \frac{M_v}{f_v V}$, and substituting:

$$\left(1 - e^{-\sigma c_s D}\right) I_o t_{ig} \geq f_v L_v$$

Litton also noted that experimentally for coal dust it i s found that $L_v = 8.0 / f_v$, while I_o and t_{ig} are fixed properties of the ignition source. Thus, ignition (propagation) is possible if:

$$\left(1 - e^{-\sigma C D}\right)\sigma \geq \frac{8.0}{I_o t_{ig}}$$

where D = characteristic length (m) of the dust cloud; for example, for the BM 20 L test chamber it is 0.168 m. The specific absorption area σ depend both on the particle diameter and on the volatile fraction. Since the typical wavelength of radiation will be around 1 μm and explosible dusts are normally larger in size, it can be noted that for particle sizes >> the wavelength, $\sigma \propto \frac{1}{d_{32}}$ where d_{32} is the Sauter mean diameter (μm), or the diameter of a particle having the same volume/surface ratio as the entire cloud. The volatilizable fraction comes in because only the non-volatilizable portion of the particle is effective in absorbing radiation, thus σ will be proportional more or less to $(1 - f_v)$. Litton computed[42] that $\sigma = \frac{600}{d_{32}}$ m^2 kg^{-1} for HVB coal dust, and similarly $\sigma = \frac{672}{d_{32}}$ m^2 kg^{-1} for LVB coal dust. Since increasing particle diameters lead to decreasing σ values, the theory predicts that higher concentrations will be needed to achieve flammability as the particle size increases. This is borne out in the rising portion of the curves in Figure 18, although the theory does not describe the plateau region at small diameters.

Hertzberg et al.[43] suggested that examining the detailed behavior of a single particle could form the basis for understanding the greater complexity of dust clouds. Thus, they conducted an extensive series of tests on dusts of metals and some non-metallic elements; their data are summarized in Chapter 14. From these experimental studies, the authors proceeded to evolve some rudiments of a theory. Much as for gases, an adiabatic flame temperature, T_{ad}, corresponding to stoichiometric fuel concentration can be computed. Also in analogy to a gaseous fuel, an adiabatic limit temperature T_{LFL} can be defined as the adiabatic flame temperature corresponding to the fuel/air ratio found at the LFL. Finally, Hertzberg et al. consider that the propensity for the fuel to volatilize can roughly be represented by T_v, which is the temperature at which the amount of fuel vaporized is between 0.01 and 0.1 of the stoichiometric amount. In their model, the 'driving force' for the combustion of the fuel is then expressed as $(T_{ad} - T_{LFL})/T_v$. This group of variables should then be able to predict the LFL. The results of this

computation is shown in Figure 5. The authors point out that this is only a rough correlation, since it assumes that the solid and the surrounding gas are at the same temperature, which is not true. It is also not clear that this relation would be useful for predictive purposes, since T_{LFL} can only be determined once the LFL is known and there does not seem to be a useful recipe for computing T_v.

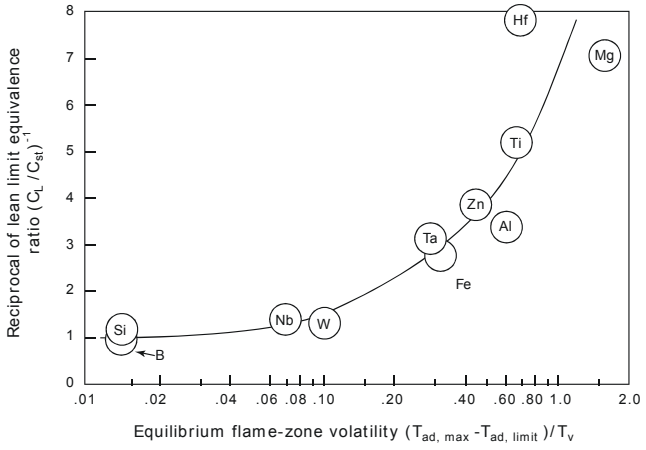

Figure 5 Prediction of the LFL of dusts on the basis of a volatility parameter
(Copyright The Combustion Institute, used by permission)

Yuasa and Takeno[44] conducted detailed studies of the early time history of a dust cloud explosion and concluded that a minimum kernel diameter exists, much as it does for gases. The events forming a kernel in dust cloud are more complicated, and the authors did not derive a quantitative theory. They did observe that the minimum kernel size was highly dependent on the size of the particles. For magnesium/aluminum alloy particles, the kernel was 1 – 3 mm for 18.5 μm particles and 5 – 11 mm for 63.5 μm particles.

Nomura and coworkers[45] proposed a simplified flame-sheet theory intended to predict the LFL, the UFL, and the MOC of a dust cloud. The validity of such a scheme is dubious, since dust clouds have all of the combustion complexities of gas mixtures, plus complications of their own—yet no simple theory has succeeded in accurately predicting the LFL values for gas mixtures.

Ballal[46] developed a theory for the minimum ignition energy (MIE) and quenching distance of dust clouds. Closed-form, but quite complex expressions were provided, based on an extension of Spalding's vaporization model[47]. Thus, the primary variable driving the system is viewed as the 'Spalding B-number,' which is a parameter that combines a number of thermochemical constants. Unfortunately, most of these constants will be unavailable except in the case of simple, pure compounds. An interesting aspect of Ballal's theory is that it unifies the treatment of dust clouds and liquid aerosols. The validation of his theory is uncertain. Ballal did not publish any of his raw data, and no other researchers have undertaken to attempt a validation.

Mittal and Guha[48] constructed a theory for predicting the AIT of polyethylene dust. The dust was assumed to pyrolyze primarily to butylene gas and their mechanism contains a number of empirical relations for this process. It is not readily evident how the theory might be generalized to dusts not already tested. Eckhoff[19] reviewed a variety of other dust cloud ignition theories.

Theoretical expressions for quenching distance are normally not sought with dust clouds, since inter-particle distances are large enough that the concept of a homogeneous mixture cannot be applied[14].

Hybrid gas/dust-cloud ignitions

Atmospheres containing a mixture of ignitable gases and dusts are common in some fields, for example, coal mines commonly contain a mixture of methane and coal dust. In other industries, dust clouds which also contain vapors of organic solvents are found. In Chapter 4, Le Chatelier's Law was presented, and it is a simple linear relation which states that the contribution of a substance to a mixture's property is directly proportional to its abundance. The Law is applicable to predicting the LFL of mixtures whenever the values of T_{ad} at the LFL condition are similar for the substances involved. As it turns out, the limit temperature of ca. 1500 K is found not only for most hydrocarbons, but also for many dusts. Perhaps of most practical import, it does hold for mixtures of coal dust and natural gas or methane. Figure 6 illustrates the linear relationship found in large-scale tests at the Bureau of Mines[49]. Similar relationships are also found in laboratory-scale tests[78,80], as shown in Figure 7. (It must be noted, however, that a German study[50] did not find a linear relation for coal dust/methane mixtures, but rather one with a complex S-shape.)

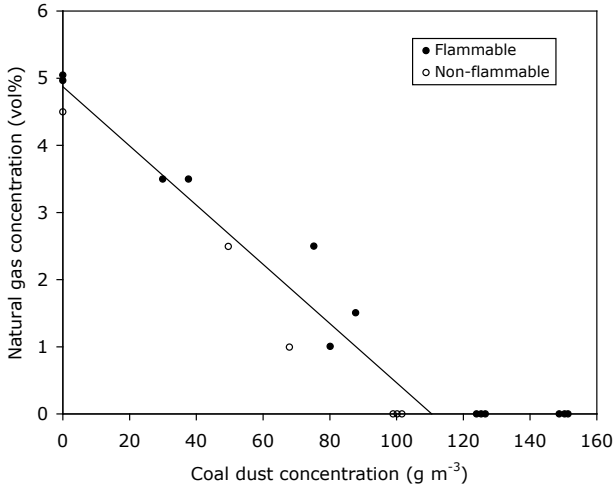

Figure 6 Flammability limits for natural gas/coal dust mixtures tested in a large-scale mine test by the Bureau of Mines

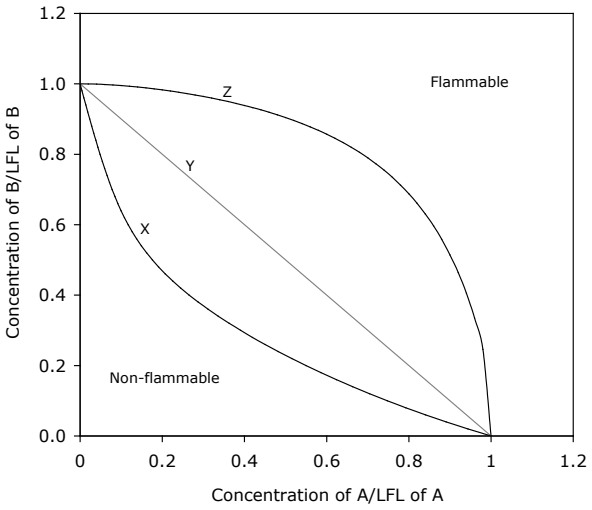

Figure 7 The LFL of mixtures. Line Y (linear) is found to be obeyed by many mixtures. Curve X (synergism) represents the combination A = PVC dust, B = methane. Curve Z (antagonism) represents the combination A = cornstarch dust, B = hydrogen.

Hybrid mixtures can also show much lower MIE values than expected for the dust alone. Pellmont[51] examined a series of dust/propane mixtures (Figure 8). Dusts which already showed low MIE values were little affected, but dusts needing high energy levels for ignition exhibited dramatic drops. Also shown in Figure 8 are the results for propane/air mixtures without dust, using the same turbulent conditions as used in testing for the hybrid mixtures. A number of other studies on this topic were reviewed by Eckhoff[19].

Britton noted that the results such as shown in Figure 8 fall along straight lines on a semi-log plot. This can be expressed in equation form as[52]:

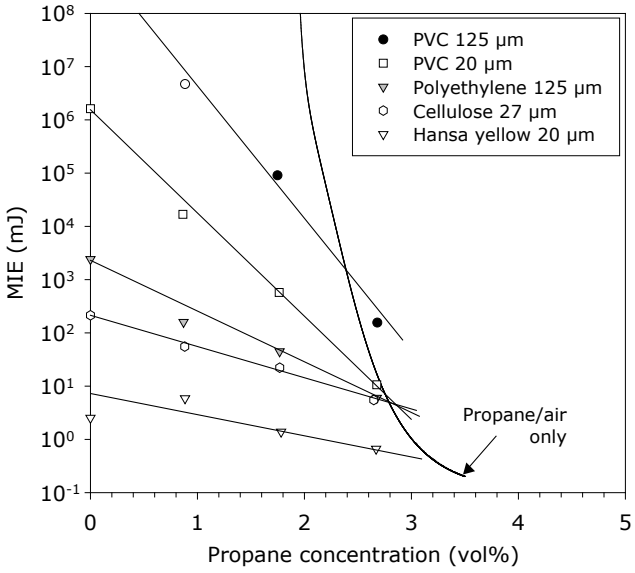

Figure 8 Hybrid dust/propane mixtures studied by Pellmont

$$MIE_h = \exp\left[\ln MIE_d - \frac{c}{c_o}\ln\frac{MIE_d}{MIE_g}\right]$$

where MIE_h = MIE of hybrid mixture; MIE_g = MIE of gas alone, obtained at a gas concentration of c_o; MIE_d = MIE of dust cloud alone; and c = concentration of gas in hybrid mixture (vol%).

Ignition sources for dust clouds

Common ignition sources for dust clouds include:

- *Open flames.* Combustion equipment using flames or pilot lights should not be used where ignition of dust suspensions is possible.
- *Hot surfaces.* These can be of various types and if a minimum ignition temperature is exceeded, an ignition can result.
- *Hot particles.* A dust cloud can be ignited from burning embers, including those generated by welding or cutting operations.
- *Friction, grinding sparks, or impact sparks.* Overheated bearings or jammed machinery can cause friction heating. Grinding sparks can ignite certain dust clouds under certain conditions. Impact sparks can result from tramp metal. The latter consists of inadvertent metal being included in processes where metal is not intended to be processed. A study has shown[53] that brief impacts of steel hand tools against steel or against concrete surfaces are not able to ignite dust clouds, however.
- *Sparks from electric devices, including electrostatic discharge.* The sensitivity of dusts to electrostatic discharges is dependent on the volume resistivity of the dust suspension. For the six electrostatic discharge types (see Chapter 11), the possibility for causing dust cloud ignitions is: (1) Corona discharge—too feeble to ignite. (2) Brush discharge—can ignite dust/flammable gas mixtures, but not pure dust clouds. (3) Powder heap discharge—can ignite most combustible dusts. (4) Spark ignition—can ignite any combustible dust, if appropriate MIE. (5) Propagating brush discharge—can ignite any combustible dust. (6) Lightning-like discharge—hypothetical; could conceivably ignite giant piles.

Statistics on ignition sources for grain dust explosions are given in Chapter 14.

Dust explosions are normally deflagrations. Limited research suggests that to achieve a d ust detonation would require a detonating initiator. With the possible exception of terrorist attack, such an event is unlikely. Unlike for gases, where unconfined vapor cloud explosions are possible, dust cloud explosions are normally considered impossible in open air. But Baker and Tang[54] consider that this possibility does exist if a detonating initiator were used, although there is no specific research on topic. A detonation would

also be possible if the cloud comprised a powdered explosive.

MECHANICAL SPARKS

The possibility of sparks created by tramp metal to act as an ignition source for dust explosions was already being studied as early as 1888[3]. More recently, Morse conducted experiments where she dropped broken files a distance of 26 m into a dust cloud explosion chamber[56]. No explosions were obtained, although in 215 trials there were several instances of "possible flame" reported. Experiments have shown that both sparks generated from grinding and those due to impacts can only ignite dust clouds having MIE values below about 13 mJ[53]. For this to happen, an especially susceptible metal, such as titanium, must be involved. Sparks from steel against steel, or steel against concrete, will not ignite dust clouds. It is also understood that a cluster of sparks is required to ignite a dust cloud, and that ignition could not occur if only a single spark was presented. The latest view[70] is that ignition from mechanical sparks is possible only if:

(1) the dust cloud has an MIE < 10 mJ; *and*
(2) the autoignition temperature of the dust cloud is < 500ºC.

In this context, the values of MIE refer to the use of an inductive circuit, while AIT measurements are taken in the BAM furnace.

ELECTRIC SPARKS

Any dusts that are capable of being charged to a high electric potential by friction or flow effects could possibly be self-ignited by electrostatic discharge. Many years ago, this question was of much interest[55], but little systematic guidance has been produced. The incendivity to grain dust clouds (only described as < 74 μm) of electric sparks from motor commutators was examined by Morse[56]. Using small electric motors rated at 1.7 A or less, she found that light, 'normal' sparking at the commutator was not incendive, but when the condition of the brushes was made poor by artificial roughening, incendive sparks were obtained.

HOT SURFACES

Dust clouds are ignitable by hot surfaces, but either very large areas or very high temperatures are needed. Not much data exists on this subject, with results from Zeeuwen[57] and Eckhoff[19] being shown in Figure 9. Similar trends are seen, but values differ substantially (note that wheat flour was tested by both authors). The differences are presumably due to experimental conditions, but details that might explain this have not been published.

Gibson and Schofield[58] compared data for a large number of dusts tested for the AIT by the Godbert-Greenwald furnace, and for the hot-surface ignition temperature by a British test (the 'No. 1 Wheeler test') which uses a 0.27 mm coiled wire as the hot surface. The largest cluster of AIT results was at 500 – 800ºC, but was at 900 – 1200ºC for the hot-wire test. In addition, around 45% of the total was found non-ignitable (over 1300ºC) by the hot-wire test, while only 8% were non-ignitable (over 1000ºC) in the Godbert-Greenwald furnace. These results imply that, roughly speaking, temperatures of a 0.27 mm hot wire must be about 400ºC greater than the AIT of the dust cloud for an ignition to be expected.

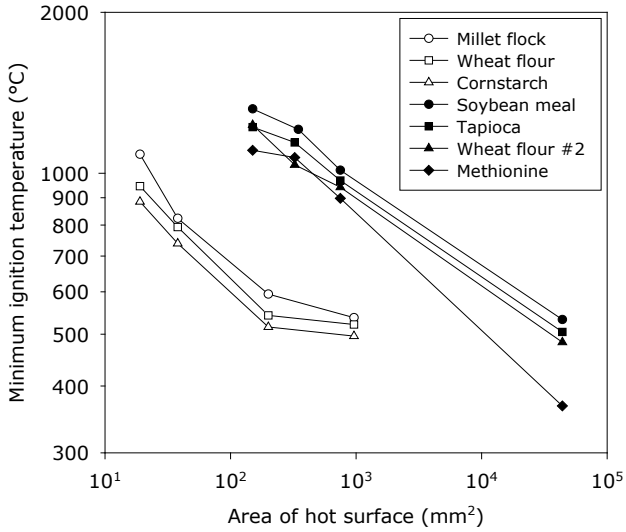

Figure 9 Relation between area of hot surface and minimum temperature needed for ignition (solid symbols: Zeeuwen; hollow symbols: Eckhoff)

Gibson and Rogers[59] found that there is a small effect of the bulk temperature of the dust cloud on the minimum hot surface temperature for ignition. Using a heated coil in a modified Godbert-Greenwald furnace, they found that the coil temperature needed for ignition of lycopodium dust* dropped from 920ºC to 890ºC as the dust cloud was preheated from ambient to 100ºC. Similarly, for hydroxy propyl methyl cellulose, the temperature dropped from 950ºC to 860ºC.

GLOWING NESTS

Most of the ignition mechanisms for dust cloud explosions are the common ones that have been studied extensively in connection with various other forms of substances. A type of ignition which is largely unique to dust clouds is the glowing nest. Various ignition sources may ignite an organic material while it is in the form of a layer or in storage, i.e., not in an air suspension. If the material is then conveyed by conveyors, pneumatic tubes, etc., the glowing nest may come to a region where an explosible dust concentration exists. The question then arises whether the glowing

* Lycopodium spores come from the club moss family and are roughly spherical and about 25 – 35 μm diameter; they are commonly used as a standard substance in dust explosion studies. Originally, they were used as flash powder in early photography.

nest has the capability of igniting the dust cloud. Eckhoff[19] surveyed a number of studies on the topic. While universally applicable guidance did not emerge, some salient conclusions were:

- Nests of 700ºC falling through dust clouds were non-incendive during flight, but caused some ignitions when landing at the bottom. Nest weights of at least 15 g were required for those ignitions to occur.
- Nests having a temperature ≥ 900ºC and a surface area ≥ 75 cm^2 were able to ignite dust clouds that had AIT values of ≤ 600ºC, as tested in the BAM oven.
- If nests disintegrate in free-fall, they may be able to create a fireball which then ignites the dust cloud. But nests of this type cannot be conveyed for any significant distance, because they would already disintegrate in transport.

OTHERS

Singer[60] reported on a study where laminar jets of hot nitrogen gas were used as an ignition source for coal dust + methane mixtures. Temperatures of 1100 – 1220ºC were needed, depending on the relative concentrations of dust and methane. HSE studied the ability of a flame-jet originating in one vessel to ignite a dust cloud present in an interconnected vessel[61]. Larger-diameter pipes were found more likely to lead to ignition, as did the presence of baffles, the latter because they cause flame acceleration. General guidelines, however, were not evolved. Studies have been reported where lasers were used to ignite dust clouds[14]. Taniguchi et al.[62] used a laser to ignite dust clouds of low-volatile bituminous coal in a pure oxygen atmosphere and found that 0.2 J was required to ignite clouds of 63 μm particles, but only 0.1 J for 22 μm particles.

Clouds of powdered fibers (flock)

In textile mills and other industries, airborne small fibers can be generated. These will be the thickness of a single fiber and maybe on the order of 1 mm in length. The ignitability characteristics of flock have some differences from clouds of particles having more compact shapes. Bartknecht[80] studied the problem and evolved a conservative estimate of the LFL (g m^{-3}) for flock. His graph can be simply represented as:

$$LFL \geq \left(3.7 + 16.75\,M^2\right)^2$$

where M is the mass per particle (μg). Similarly, the results for MIE (J) can be approximated as:

$$MIE \approx 0.0082\,e^{20.8\,M}$$

Analysis and application of data

VARIABLES AFFECTING THE AIT

DUST CONCENTRATION

The AIT varies inversely with dust concentrations at lean concentrations (< 100 g m^{-3}) and is nearly independent of the concentration at high concentrations. Figure 10 provides several examples[63].

VOLATILE CONTENT

Substances which liberate significant volatiles ignite at a lower temperature than ones which do not[63], but this tendency is hard to capture in a simple test. Total volatile content, as opposed to details on when and how they are evolved, is relatively easy to measure, so efforts have been made to see if it is useful for prediction purposes. Nagy and Verakis[68] explored whether it could be correlated to the AIT. Some trend for lower AIT values with increasing volatile content was found, but the data scatter was huge. For example, for volatile contents of 30 – 40%, AIT values

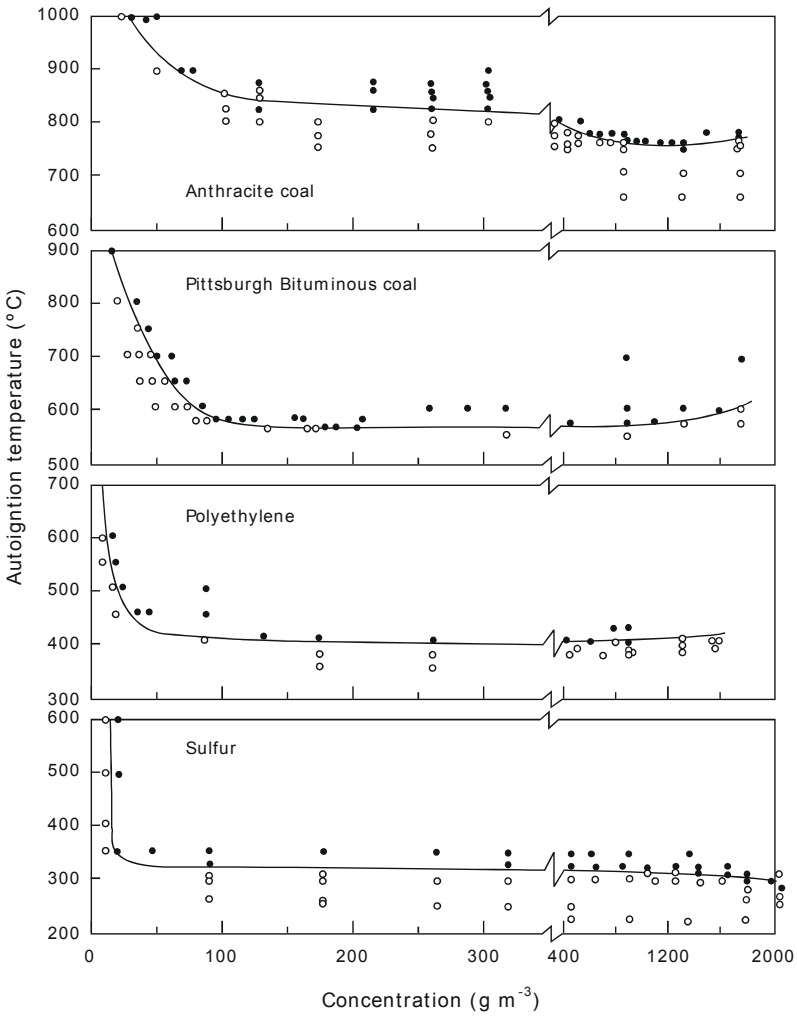

Figure 10 Effect of dust concentration on the AIT

ranged from 350 to 800ºC. Many years earlier, Wheeler[64] conducted a similar study and concluded that no correlation exists.

PARTICLE DIAMETER

Similar to its effect on the LFL, particle diameter does not affect the AIT for small particles, but large particles, beyond a certain size, show an increase of AIT with size (Figure 11)[63,65]. Nomura and Calcott[66] developed a theoretical model which predicts the rise in AIT with increasing particle diameter. Their theory also predicts that there is a minimum AIT value and that the AIT begins to rise again as the diameter becomes small; this is generally not observed in experiments. According to their theory, the rise in AIT for large-diameter particles is due to residence time effects—if residence times could be made very long in the test furnace then large particles would show a decrease, not an increase, in AIT. This is a bit academic, however, since dust clouds, especially of large particles, cannot be kept in suspension for long time periods.

A small amount of available data[16] indicates that the effect is opposite for dusts of metals, at least in dilute atmospheres (Figure 12). Mitsui and Tanaka[67] used a Semenov-type theory to explain this difference in trends, which they consider to be due to radiant emissivity effects, emissivity being low for metals and high for organics. The heat release term is proportional to the number of particles × the surface area of each particle. But for a fixed concentration, the number of particles $\propto 1/d^3$, while the surface area is $\propto d^2$. Thus, the heat release rate is $\propto 1/d$. But the heat losses scale differently. The convective heat losses are assumed to be equal to the number of particles, which for a fixed dust mass is $\propto \frac{1}{d^3}$, times the loss of each one $\propto d^2 \times \frac{1}{d}$, giving an overall dependence as $\propto \frac{1}{d^2}$. Radiation losses, on the other hand, are taken as being due to the entire cloud, not due to individual particles, thus, radiation scales according to the size of the cloud and has a $\propto d^0$ dependence with respect to particle diameter. The net result is that clouds having a high convection/radiation loss ratio show an AIT which decreases with increasing diameter, while the converse holds if the loss ratio is low. The authors obtained good predictive results and were able to correctly account for the difference in diameter-dependence between organics and metals, but caution that many of the needed constants are unavailable and estimates must be made.

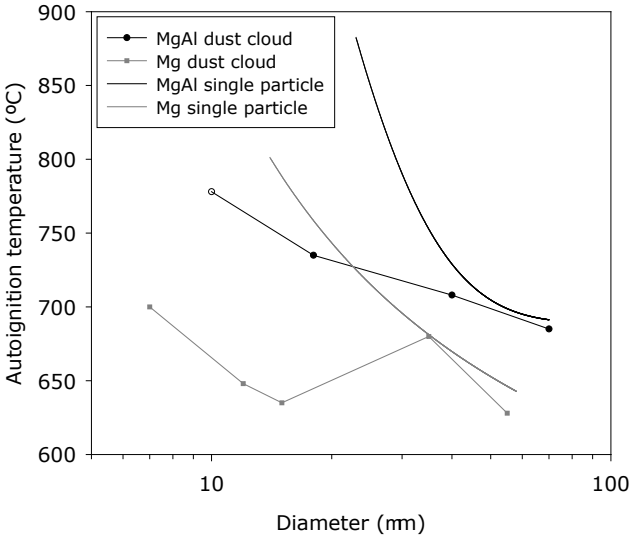

Figure 12 Effect of particle diameter on the AIT for two metal dusts (dust cloud concentration = 80 g m^{-3})

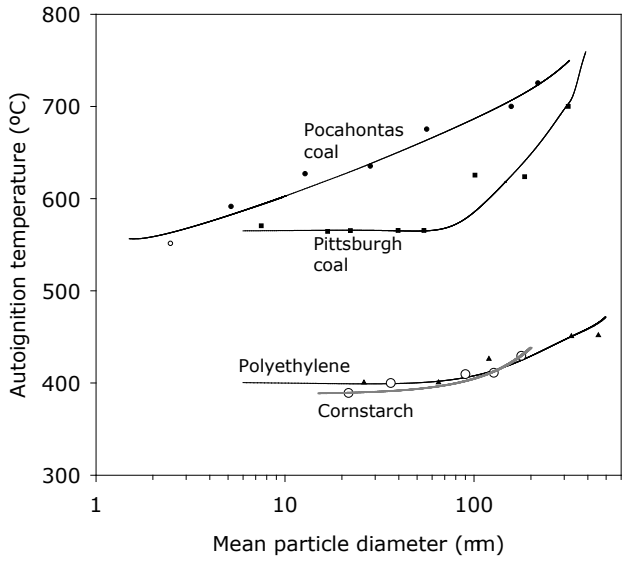

Figure 11 Effect of particle diameter on the AIT for some organic substances

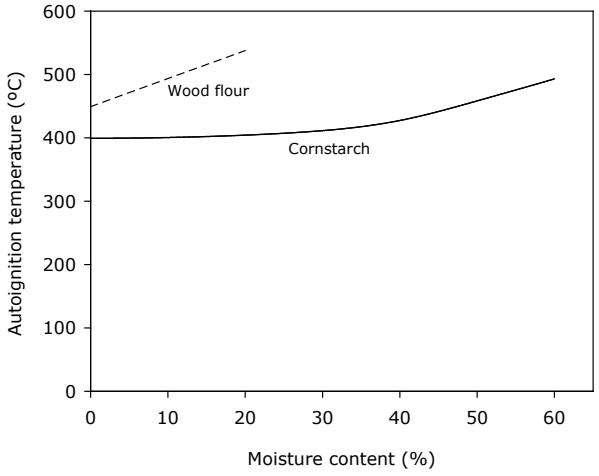

Figure 13 Effect of moisture on AIT

MOISTURE

Not surprisingly, if moisture is added to an organic dust, the AIT is raised. Some Bureau of Mines data[68] on this point are shown in Figure 13. Very little other data is available on the moisture effect, so a quantification of the effect is not possible.

OXYGEN CONCENTRATION

Nagy and Verakis[68] provided a limited amount of Bureau of Mines data on the effect of lowering the oxygen concentration. Figure 14 shows that lowering the oxygen concentration raises the AIT. Ignitions were possible down to as low as 5% oxygen concentration, in the case of cornstarch.

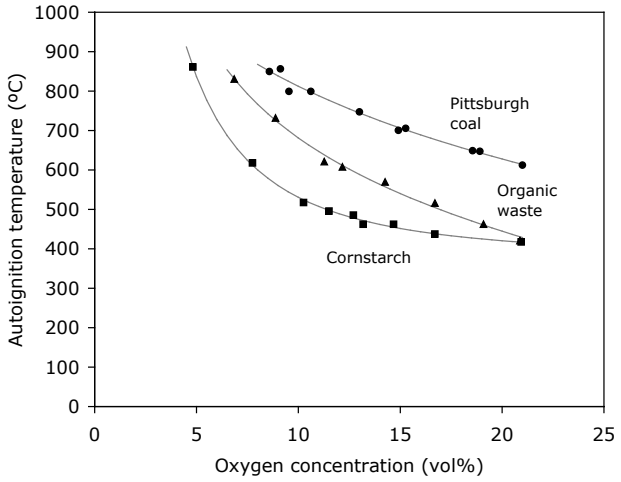

Figure 14 Effect of oxygen concentration on AIT

RESIDENCE TIME

When the AIT of gases is being determined, the test substance is mechanically stable and a long induction time is not problematic. For dusts, however, the suspension is inherently unstable and a long waiting time is not feasible. In an early study made before the design for the Godbert-Greenwald furnace was finalized, Wheeler[64] obtained the data shown in Figure 15. The residence times were extremely long and presumably the uniformity was poor, but the results are indicative nonetheless. More recent results of Griesche and Brandt[69] from the Godbert-Greenwald furnace are shown in Figure 16. When AIT values are determined in the BAM furnace, an anomaly in the test procedure prevents a similar comparison. Since the BAM furnace is horizontal, the dust settles out on the bottom, instead of leaving the apparatus as in the Godbert-Greenwald furnace. The dust can then ignite as a dust layer, rather than a dust cloud, which the BAM test protocol considers as an equally-valid determination of the AIT.

Siwek and Cesana[70] made a comparison of results obtained in the BAM furnace to those in the Godbert-Greenwald furnace. Figure 17 shows that sometimes the results for the

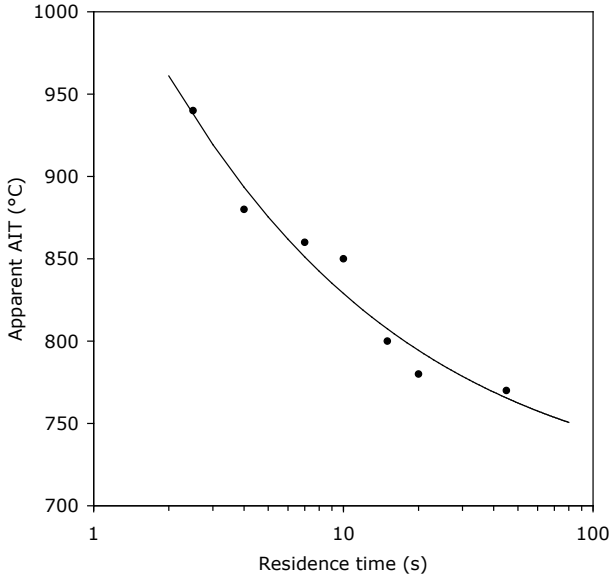

Figure 15 Effect of residence time in an early version of the G-G furnace, as determined for a coal dust by Wheeler

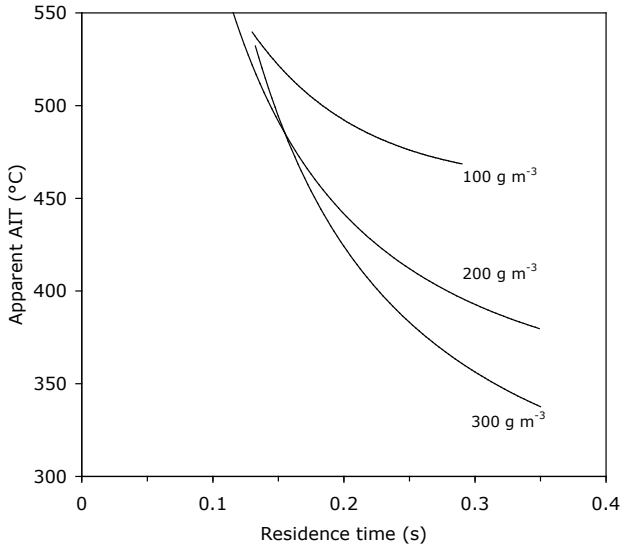

Figure 16 Effect of residence time in the G-G furnace as determined by Griesche and Brandt

two furnaces are close; rarely are the BAM results higher, but commonly they are lower than for the Godbert-Greenwald furnace. Some of the difference may be attributable to local heating effects. Some of the particles going through the BAM furnace are likely to impinge on the reflector and receive hot-surface heating there; a comparable effect does not exist in the G-G furnace.

TURBULENCE

For wheat and oats, experiments[6] showed that at a high dust concentration (800 g m^{-3}) turbulence does not affect the

AIT. But at a lower concentration of 300 g m^{-3}, the AIT was found to rise linearly with the intensity of turbulence, increasing by about 200ºC as the intensity went from 0 to 30%.

TEST APPARATUS VOLUME

Theory and experiments on gases show that if the system volume is increased, the AIT can be expected to decrease. This raises the question if dust clouds tested in small-size experimental rigs can reasonably be used to characterize explosibility in larger spaces. No data are known for dust clouds on this important issue.

VARIABLES AFFECTING THE FLAMMABILITY LIMITS

PROBABILITY LEVEL USED FOR THE DEFINITION OF THE LFL

To be able to develop reproducible values for the LFL, the probability level at which ignition is deemed to have taken place needs to be defined. This is not a major concern for gases, since the range of energy values spanned by going from slightly above 0 to slightly below 1.0 probability is not large. The same is not true for dusts, however. For polyethylene dust, for example[71], at P = 0.04, the concentration is 50 g m^{-3}, but when the concentration has increased to 300 g m^{-3}, P is still only ca. 0.5. Rare events are unlikely to be encountered, of course, if few trials are made. Thus, in German and Swiss studies[80] it has generally been a convention to run 20 trials.

PARTICLE DIAMETER

For organic dusts, the matter which is ignited and burns are the volatiles, not the original solid. Thus, increasing the diameter while keeping the mass loading fixed decreases the amount of fuel that is potentially available in the gas phase. When the particles are of large enough size, the atmosphere will be non-explosive at any loading that can be actually generated. Figure 18 shows how increasing particle size increases the LFL. The data are from Hanai et al.[72] and the Bureau of Mines[32,65]. The curves are flat for particles below a certain size; for very large particles, the curves become very steep. When very strong ignition sources, e.g., 10 kJ pyrotechnic igniters[78], are used, however, particle diameter does not affect the LFL for particles smaller than about 40 – 120 µm (the value depends on the substance). Note that in the graph the near-vertical portion of the curve scales according to the volatile fraction of the fuel. Low-volatile bituminous coal (LVB) is to the left of high-volatile bituminous coal (HVB). Even though PMMA and polyethylene are both thermoplastics, Hertzberg and Zlochower[73] found that a much higher fraction of PE is volatilized in a dust cloud than of PMMA. Xu et al.[75] consider that the reason most of the curves show a flat portion followed by a rising curve is because the particle size at the 'knee' represents the maximum size that can be fully volatilized within the available thickness of the flame zone.

Explosions do not occur with very large particles. Not a great deal of studies have been done on this point, but it appears that for most substances the largest explosible diameter is found at around 300 – 500 µm, given any practical igniter energy[74,75]. NFPA[76] considers that, by definition, dusts are not explosible if they are of size greater than 420 µm. In the case of halogenated substances, e.g., PVC dust, the combustion process is hindered by the halogen atoms; thus, UFL values of around 150 µm are found for these substances[19].

In research, it is customary to study dusts which have been sieved in order to be relatively monodisperse. In actual processing operations where dusts are involved, this may not be the case; in fact, the dust cloud may have a very wide distribution of particle sizes (polydisperse). Polydisperse systems are greatly more difficult to study since now at least one other parameter apart from diameter must be considered—some measure of spread of diameters. If the distribution does not lend itself to a mathematical function

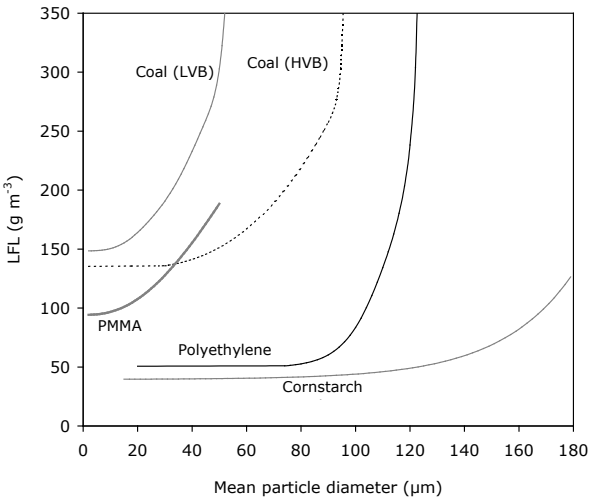

Figure 18 Effect of particle diameter on the LFL

needing only 2 variables, then even more cumbersome numerical treatments would have to be considered.

TEMPERATURE

Similarly as for gases, when the temperature increases,3 the LFL decreases. Data from Glarner[77] and Wiemann[79] illustrate this in Figure 19.

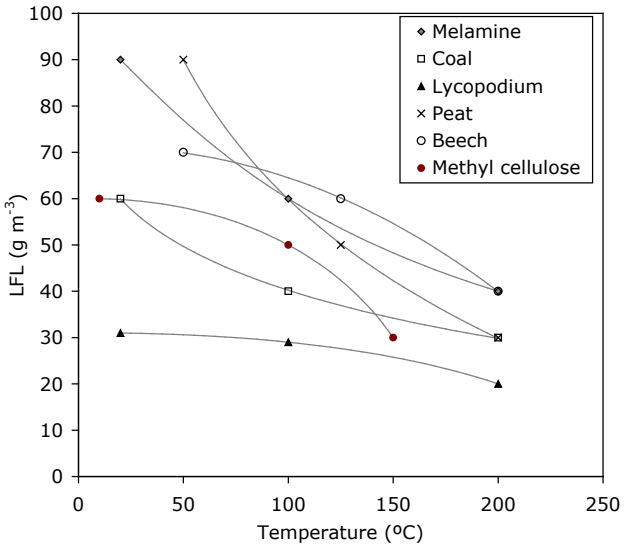

Figure 19 Effect of temperature on the LFL

BM[78] suggests that a prediction can be made by assuming that the temperature dependence is linear:

$$\frac{LFL_{T_2}}{LFL_{T_1}} = \left[1 - \beta\left(T_2 - T_1\right)\right]\frac{T_1}{T_2}$$

where LFL_T denotes the LFL (g m^{-3}) at a temperature T (K), and β = constant ≈ (6 to 7)×10^{-4} K^{-1}. Normally, standard test results will be available at T_1 = 293 or 295 K. The experimental data of Wiemann suggest that the relation holds only in a very rough sense and that, furthermore, the value of β is hardly a constant, with values needed to fit the data ranging from about 1×10^{-4} to 35×10^{-4}. The prediction results for two substances—melamine dust (measured by Glarner) and lycopodium dust (measured by BM[102])—are shown in Figure 20. For lycopodium dust, using the value β = 6.4×10^{-4} K^{-1} recommended by BM gives a rather poor fit, especially in the 100 – 400ºC region. For melamine dust, a value β = 17×10^{-4} was required, which is quite outside the range of β values recommended by BM and would have not been possible to anticipate without running the actual tests.

PRESSURE

Increasing pressure raises the LFL for dusts. For a few example dusts, this effect was shown to be linear. Figure 21 shows coal data from Wiemann[79], with the other data being from the Bureau of Mines[78]. Note that the gas data here are reported in the same mass units as for the dusts. Generally,

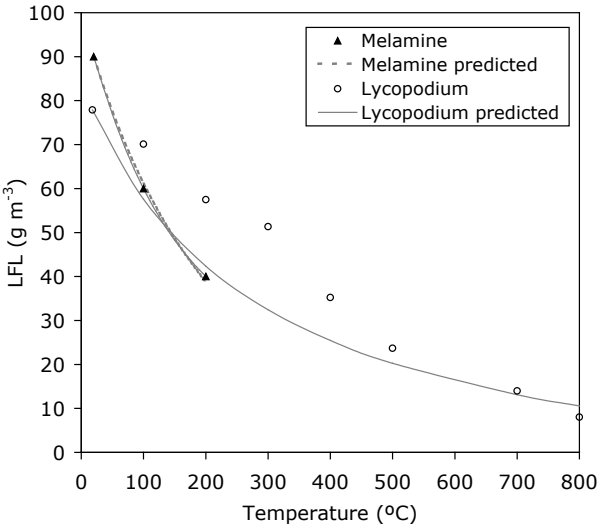

Figure 20 Prediction of the temperature dependence of the LFL of melamine, as compared to measured values

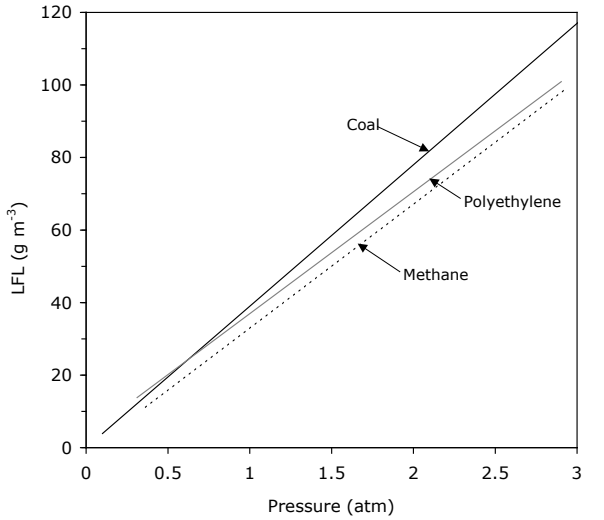

Figure 21 Effect of pressure on the LFL

LFL data for gases are reported in volume units and, in those units, the effect is much smaller.

MOISTURE

Moisture can affect many aspects of dust clouds and their ignitability. For organic, hygroscopic materials, high moisture promotes clumping. If the effective particle size becomes large due to moisture-induced agglomeration, then (a) it might become unlikely that a significant amount of dust will become airborne; and (b) ignition will be more difficult for the product that is airborne. Bartknecht[80] considers that, for many materials, it is unlikely that dusts having more than 10% moisture content will get lofted and dispersed sufficiently in order to become explosible. Simi-

larly, Eckhoff[81] concluded that agricultural dusts having more than 15% moisture, by mass, are unlikely to be ignitable. As a preventive strategy, however, introducing high levels of moisture will rarely be acceptable, since moisture may interfere with the primary function of the product being handled or produced. While increasing the moisture content always increases the minimum ignitable concentration of the dust, the dependence does not follow a universal law. Bureau of Mines results for cornstarch[65] and Pittsburgh coal[68] are shown in Figure 22, as are those of Monakhov[82] for 5-nitrofurfural diacetate. Studies on charcoal dust[83] indicate that moisture has a sizable effect on LFL for dusts with low volatile content, but the effect becomes smaller as the volatile content increases.

Mok et al.[84] studied the effect of RH on the LFL for dusts of a polymer resin, methacrylate-butadiene-styrene. They found no effect below 60% RH, but from 60% to 80% there was a very steep, linear increase, whereby the LFL went from 50 g m^{-3} to 150 g m^{-3}.

OXYGEN CONCENTRATION

Over the range tested by BM[85], increasing oxygen concentrations progressively decreased the LFL (Figure 23). This is in sharp contrast to the behavior for gases (methane is illustrated in Figure 23), where there is no difference between LFL measured at 21% versus at 100% oxygen. The authors hypothesized that the dust behavior is seen because increased oxygen concentrations promote volatilization of the dust. The combined effects[32] of particle diameter and oxygen concentration are illustrated in Figure 24.

IGNITER ENERGY SUPPLIED

Similar to the situation for gases, as greater amounts of spark energy are supplied, the apparent LFL of a dust cloud decreases. This issue was already known in 1924[20], and the problem has been discussed at the start of this Chapter. Additional studies on this topic were conducted by the Bureau of Mines using their smaller 7.8 L dust explosion cylinder. These results[85] are shown in Figure 25. The effect for methane gas is rather small. But for the dusts it is evident that increasing the igniter energy beyond about 10 J causes a sizable drop in the apparent LFL value.

Matsuda and Itagaki[86] explored the effect of igniter energy using a 1 m^3 sphere and a Japanese 30 L sphere on the flammability limits of activated carbon dusts using samples with a broad particle distribution of 1 – 400 μm. Their results (Figure 26) showed that in the 30 L sphere there is a substantial effect, down to the lowest igniter energy exam-

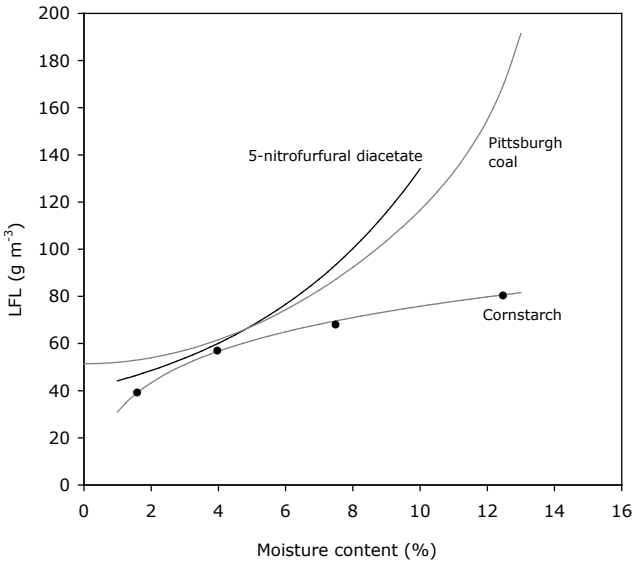

Figure 22 Effect of moisture content on the LFL

(Copyright The Combustion Institute, used by permission)

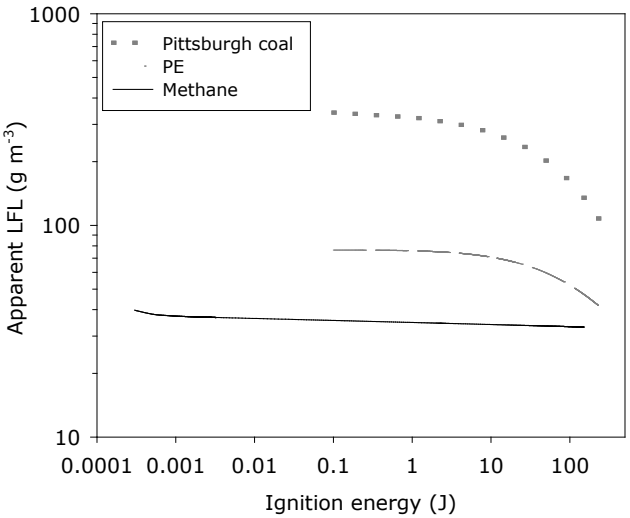

Figure 25 Relation between ignition energy and LFL for several dust types, as measured in the 7.8 L cylinder used by the Bureau of Mines

ined (0.9 kJ). Furthermore, if it is considered that 'overdriving' a test chamber is evidenced by a non-vertical curve on a concentration/energy plot, there was range of igniter energies that could be identified as 'non-overdriving' the chamber. The effect of igniter energy in the 1 m^3 chamber was much less significant. Observe also that the LFL, as determined in the larger chamber, was about 2× that found in the 30 L chamber. This suggests that LFL values measured in chambers of less than 1 m^3 size may quite generally have a large error due to the smallness of the test volume.

Their results obtained in the 1 m^3 chamber also illustrate that if the igniter energy is too small, no ignition at all will be observed. The minimum energy required for the activated carbon dust (ca. 1.8 kJ) is, of course, huge, and such dusts could not be ignited from limited-energy sources such as normal static electricity discharges. There is clearly a volume effect for the minimum igniter energy, with < 0.9 kJ sufficing in the 30 L chamber. But if one assumes that a location with a potentially ignitable dust cloud will generally be greater than 1 m^3 in size, the ignition energy required to cause an explosion in a real-scale application will presumably be > 1.8 kJ. Gibson et al.[87] presented data showing that large chemical igniters, while totally atypical of spark discharges, do rank materials more or less similarly as do open-flame ignition sources.

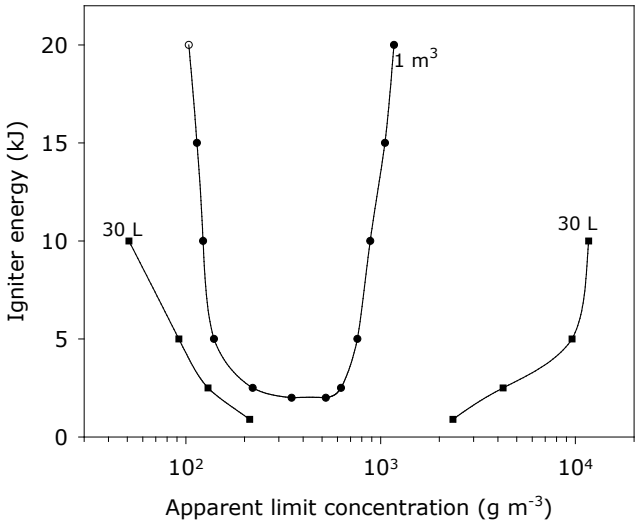

Figure 26 Effect of igniter energy on the apparent flammability limits for polydisperse activated carbon dust in test chambers of two sizes

The combined effects on the flammability limits of temperature and igniter energy are illustrated in Figure 28 and Figure 27[101]. The lines identified as 'lean flammability limit' were determined using a pyrotechnic igniter of 2500 or 5000 J. For coal dust, the LFL determined using the pyrotechnic igniter is about 3 times lower than when determined using a 1.36 J (effective) spark. In the case of polyethylene dust, the highly anomalous curves are a consequence of the melting of polyethylene at around 115 C.

Glowing-wire ignition sources have been used by some European investigators as an alternate ignition source for the Hartmann apparatus, but without published data comparing the results against the standard spark source. The only study on the topic appears to be a 1924 paper[20], which gave data on a handful of dust types showing that LFL values were lower by about a factor of 2 when tested with a 1200ºC platinum glow wire, compared to values obtained by an inductive spark. For gases, glowing-metal ignition sources are much *less* effective than sparks, so it is surprising that the opposite should be true for dusts. There is, however, some limited modern corroboration on this point, as indicated under the presentation of the Hartmann Apparatus test, below.

VARIABLES AFFECTING THE MIE

DUST CONCENTRATION

Studies with gases (Chapter 4) show a concentration dependence that is roughly parabolic: somewhere in the vicinity of stoichiometric conditions there is a minimum value, with needed ignition energy rising smoothly to either side of that minimum. For dust clouds, the minimum value occurs at a concentration substantially greater than the stoichiometric one. To compute the stoichiometric concentration, all of the fuel present is taken into account. In the case of a dust explosion, the pyrolysis is neither complete nor instantaneous, thus, in effect, a sizeable fuel fraction cannot contribute to the early development of the explosion and only becomes combusted later. Some experimental results of Bartknecht[80] on three plastics, of Matsuda and Naito[97] on cork dust, and of Maranda et al.[88] on aluminum dust are shown in Figure 29. The aluminum dust was in the form of flakes with two different mass-mean diameters, 11 μm and 68 μm. The behavior of the polyester and the cork dust is probably the most representative of a wider variety of substances—same as with gases, increased difficulty of ignition becomes evident as the LFL is approached.

PARTICLE DIAMETER

For particle diameters greater than a certain value, particle diameter influences the MIE. Some examples are given in Figure 30. The data for cornstarch, ethyl cellulose, and sugar were taken in a conventional Hartmann apparatus[65,89,90], while the data for methyl cellulose[19], polyethylene and aluminum[80] used the European spark ignition procedures (see below). Theories have been proposed by Kalkert and Schecker[91] and Ballal[46] to explain the dependence on diameter, and they predict that MIE $\propto d^3$. For the results shown in Figure 30, polyethylene and aluminum show close to a d^3 dependence, while the other products do not. Dust clouds of particles larger than about 300 – 500 μm are non-explosible[80,19], given any practical igniter energy. Eckhoff[19] points out that metal dusts show ignitability increasing with decreasing diameter all the way down to 1 μm. He cautions that testing which is done for poorly-determined sizes, or at sizes larger than may be involved in actual use can lead to unconservative conclusions being drawn.

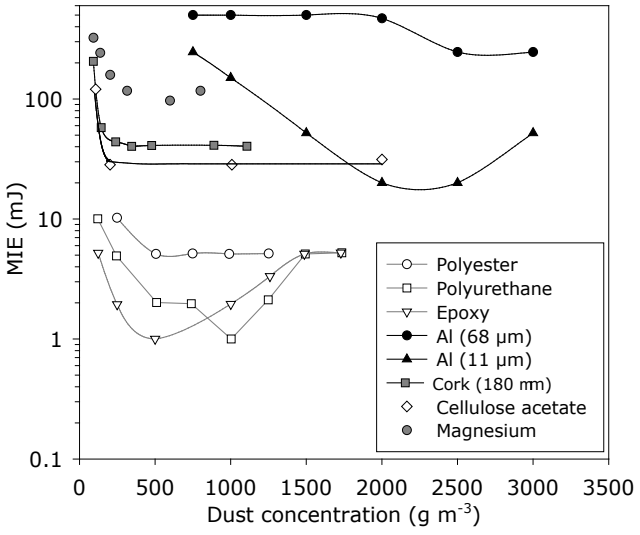

Figure 29 Effect of dust concentration on MIE

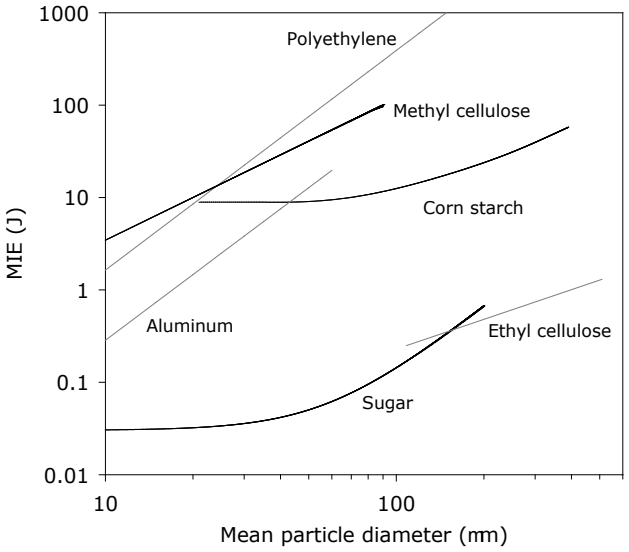

Figure 30 Effect of particle diameter on MIE

TEMPERATURE

Glarner[77] studied the effect of temperature on the MIE of various dusts. His results (Figure 31) show linear behavior on a log-log scale, with lines converging at the value of 0.088 mJ at a temperature of 1000ºC. If the value MIE_{25} is known at 25ºC, then the MIE value at an arbitrary temperature T (ºC) is:

$$MIE_T = 10^{-4.056+(1.873-0.624\log T)(4.056+\log MIE_{25})}$$

Glarner's equation, however, rests on poor theoretical foundation, since it would predict that MIE $\rightarrow \infty$ as $T \rightarrow$ 0ºC. In fact, the behavior of dust clouds at 0ºC is insignificantly different from that at 25ºC. Thus, not surprisingly, some substances do not obey this form at all. BM data[102] indicate that for coal there is a complex temperature/concentration interaction (Figure 28) which would not lead to such simple formulas.

PRESSURE

Over a limited range, Glarner[77] examined the effect of pressure on the MIE. In all cases, he found no difference in MIE at 1.6 atm, versus at 1.0 atm pressure. In tests at 0.65 atm, however, most dusts showed about a factor of 2 increase of MIE, compared to 1.0 atm results. The exceptions were very-hard-to-ignite dusts (e.g., melamine) that require kilojoule levels of energy—these showed no change even at the sub-atmospheric pressures. The conclusion is that values determined at 1 atm can be conservatively used at higher pressures.

MOISTURE

For agricultural dusts, raising the moisture content increases the MIE. This is illustrated in Figure 32; the cornstarch data are from BM[65], the others are from TNO[109]. The minimum MC needed in agricultural dusts to prevent explosion has variously been reported as between 14%[92] and 23%[93]. These values were obtained in small-scale test apparatuses and should not be taken as reflecting real-scale conditions. Grain will rot if stored at excessively high moisture contents (greater than ca. 20%), so a strategy of raising the MC may have limited practicality.

OXYGEN CONCENTRATION

If oxygen concentration is lowered, the MIE values will generally rise. Figure 33 shows some results for various dusts[68,80]. With organic dusts, a steep dependence on oxygen concentration is seen, but with metal dusts, only a very gradual one.

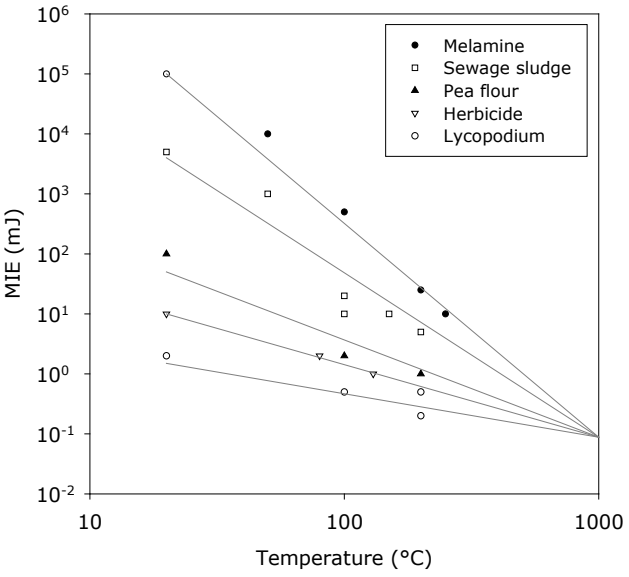

Figure 31 Temperature effect on MIE

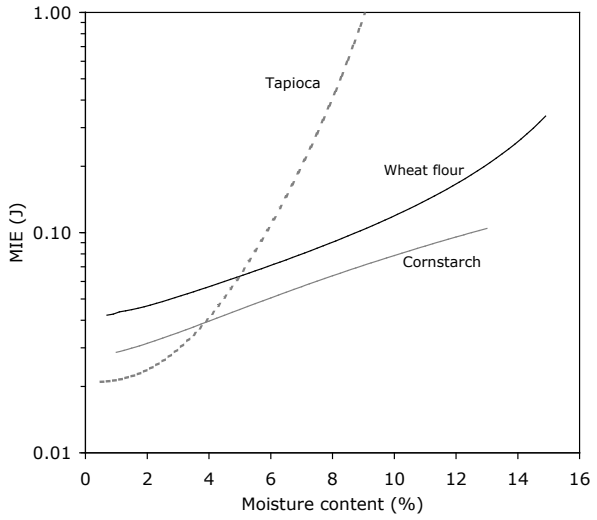

Figure 32 Effect of moisture content on the MIE for several agricultural dusts

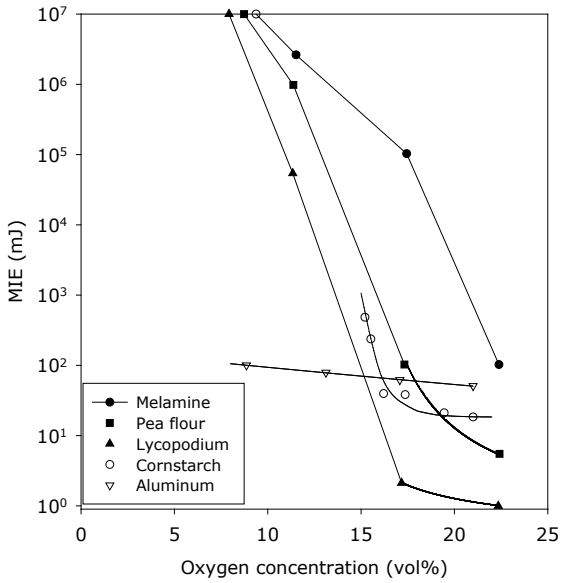

Figure 33 Effect of oxygen concentration on MIE

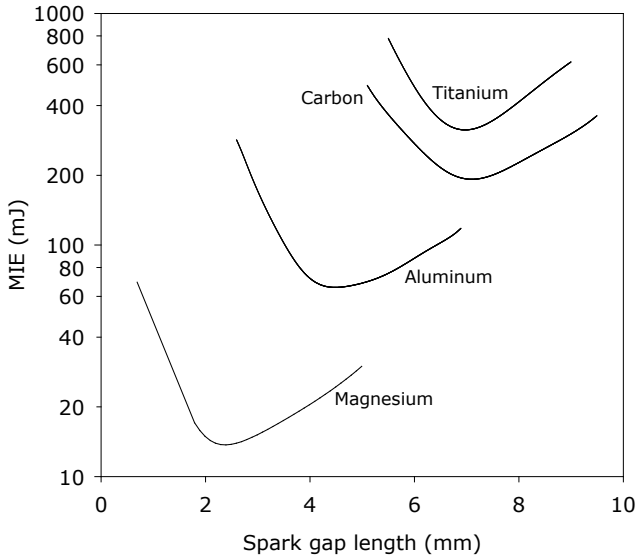

Figure 34 Effect of spark gap length on MIE (equivalence ratio = 0.65; Sauter mean diameter = 40μm)

TURBULENCE

Increased turbulence causes the MIE to rise. This has been documented qualitatively[94], although quantitative relations are lacking. Even if they were available, the turbulence in most real-life scenarios is hardly ever quantified, so the ability to use such relations would be questionable.

CHARGE ON PARTICLES

It has been found that if the particles in a dust cloud are not electrically neutral but are already carrying a charge, the MIE value decreases. Choi et al.[95] tested PAN powder and found that the MIE was about 25% lower for particles carrying a charge of 20 – 30 nC g^{-1} than for neutral particles. The polarity of charge did not make much difference.

SPARK ELECTRODES: MATERIAL AND GAP SIZE

The metal from which the electrodes are made can influence the results, but not drastically. Glarner[77] showed that, of 5 metals tried, tungsten invariably gave the lowest MIE results; other metals typically showed values 1 – 4 times as great. Same as for gases, there exists an optimal spark gap size, with smaller or larger spacings leading to higher reported values of MIE. Some example curves[96] are shown in Figure 34. From relations on this type a gap of 6 mm is commonly chosen as being reasonable for testing a variety of dust types. This gap is several times greater than what is optimally selected for testing gas mixtures. The optimum gap length also decreases when the dust concentration increases; except for very dilute mixtures, however, the latter effect is small[97].

SPARK CIRCUIT PARAMETERS

In 1950 Boyle and Llewellyn[98] found that inserting a series resistor into the firing circuit for capacitive discharge ignition of a dust cloud led to lower MIE values being reported. With zero resistance, it required 490 mJ to ignite an aluminum powder dust cloud, while inserting a 50 kΩ resistor dropped this down to 55 mJ. It is even more remarkable considering that their reported energy values were nominal, taking into account only the energy stored on the capacitor and ignoring the large energy loss within the resistor when a resistor is introduced. The answer was found in the time response of the circuit. When a circuit has only stray resistance, the discharge time will be exceedingly fast (a few microseconds). If the time constant is increased by a series resistor, the energy can be more effectively delivered. This occurs because the role of the discharge time for dust clouds is very different from that for gases. A very fast, vigorous discharge creates a pressure which literally blows the dust out of the spark gap. As the time constant is increased, the force is decreased and more dust remains accessible to ignition. To relate the discharge time to the circuit parameters, the expression for current decay in an RC circuit is:

$$I(t) = \frac{V_o}{R}\exp(-t/RC)$$

where V_o = initial capacitor voltage. If the spark duration time is defined, somewhat arbitrarily, as the time that it takes for the current to drop to 1% of its original value, then the time constant τ is:

$$\tau = 4.6RC$$

Line et al.[99] subsequently found a very similar effect, but the optimum resistance in their case was 100 kΩ.

Hay and Napier[100] conducted tests on polystyrene and cornstarch dusts in a modified Hartmann apparatus where they were able to vary both the capacitance and the series resistance. In addition, they directly measured the voltage and current flowing through the spark gap and computed the

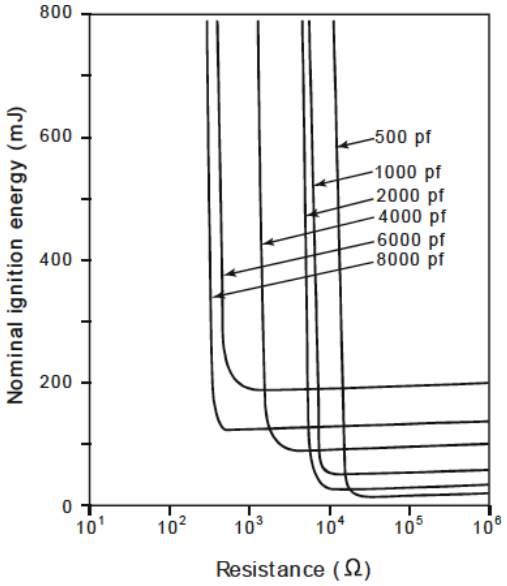

Figure 35 Nominal MIE of stoichiometric mixture (87 g m^{-3}) of polystyrene dust in air

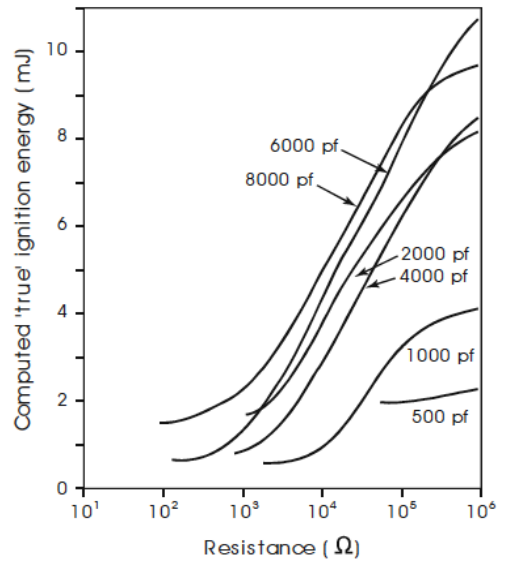

Figure 36 Computed 'true' MIE of stoichiometric mixture of polystyrene dust in air

actual energy delivered. In their rig, they concluded that only 1 – 10% of the nominal energy (expressed as $\frac{1}{2}CV^2$, where C = capacitance and V = voltage) is actually delivered into the spark gap. The rest is presumably dissipated in the circuit, but the authors did not attempt to compute losses in the circuit, which—had it been done—could have been used to double-check the accuracy of their 'true' values. The curves of nominal energy vs. resistance showed an optimal value at ca. 500 – 20,000 Ω (Figure 35), but their computed 'true' energy was found to be monotonically decreasing with resistance (Figure 36). The authors did not try values lower than 500 Ω in their experiment.

At BM, Hertzberg and coworkers conducted studies[101,102] using an arrangement where a charged capacitor is discharged into a spark gap through an intervening step-up transformer. This would be a poor choice of circuit arrangement for understanding the fundamental physics, but it is the one that has traditionally been used in the Hartmann apparatus (see below). For spark energies below 2 J, they determined the spark energy efficiency to be approximately 25%. In other words, if the nominal available energy is defined as $\frac{1}{2}CV^2$, then only 25% of that energy was computed to have entered the kernel. But for larger nominal energies, efficiency dropped drastically, so that at 100 J, the efficiency was only 2%. They found that a significant fraction of the input energy is expended simply in doing work of compressing the gas outside the spark kernel. Typically, 25% was delivered into the spark kernel itself, 7% went into compression work, while the rest represented circuit losses. Concerning effects of the circuit parameters, in their rig, discharge energy was increased mainly by raising the capacitance of the capacitor, rather than raising the voltage. The results indicated efficiency progressively dropped as larger capacitance values were used, but they did not explore the converse possibility of raising voltage rather than capacitance. All of their reported efficiencies were obtained by an indirect technique using a theoretical model which produced the relation:

$$E_{eff} = 2.5 V_o \Delta P$$

where E_{eff} = energy delivered into the spark kernel (J), V_o = volume of test chamber (m^3), and ΔP = pressure rise in chamber (Pa). Values of ΔP were measured and efficiency was then determined by dividing E_{eff} by the nominal spark energy. Most of Hertzberg's results were obtained with a spark gap of 6 mm, but he did find that efficiency generally increased with gap size, up to about 8 mm.

Matsuda and Naito[97] explored empirically the optimal discharge time for lycopodium and cork dust clouds. They found that increased discharge times were needed for greater particle diameters. Their results showed that minimum energies corresponded to spark duration times in the range 0.1 – 1.0 ms. This conclusion, however, depends on the dust type. Eckhoff[19] showed that the optimum time for polyacrylonitrile dust is 0.01 ms, with even lower values for some other dusts. On the other hand, Nifuku and Katoh[103] showed for coal dust that spark durations of 2 – 10 ms give identical (lowest) ignition energy values, whereas if the discharge time drops below 2 ms, the energy needed increases sharply. Without further studies, it is not possible to derive general guidance on a relation between particle diameter and optimum discharge time.

Traditional experience had indicated that to ignite dust clouds requires ignition energies several orders of magnitude higher than for gases. But, starting in the 1970s, several European research groups discovered specialized spark arrangements which lead, in some cases, to values being reported for dust clouds in the same range as for methane

(0.3 mJ). The first research group to develop a super-low-energy method was the one at Christian Michelsen Institute (CMI) in Norway*. Eckhoff observed that sparks of short duration (1 μs) are less incendive than ones of about 0.1 to 10 ms duration[104,105]. Thus, CMI developed a special ignition circuit, described by Alvestad[106]. Basically, capacitors are discharged into the spark electrodes via a transformer, into which is coupled a trigger circuit. Diodes are used to chop the waveform to minimize oscillations. The voltage and current waveforms are highly complex and depend on both the capacitor used and its charging voltage. The discharge time is dependent on the spark energy, being about 0.04 ms for a 1 mJ spark and 2 ms for a 10 J spark. Field[107] compared MIE values obtained using the CMI circuit to those obtained using the circuit of the traditional Hartmann apparatus. This comparison is shown in Table 1 and also plotted in Figure 37. In the figure is also shown the correlation recommended by Eckhoff[19]:

$$MIE(CMI) = \frac{[MIE(Hartmann)]^{4/3}}{21.5}$$

Eckhoff specifically points out that the correlation should only be applied in the range 10 mJ ≤ MIE(Hartmann) ≤ 10,000 mJ, but judging from Field's data the entire correlation must be considered to be only qualitative. Clearly, the MIE values differ greatly between the two circuits. However, it is hard to choose the 'right' one, since the Hartmann circuit has large, unquantified losses, while the CMI circuit represents a 'minimum' that is not likely to ever occur in an accident.

In 1926, Wynne-Williams[108] studied the discharge produced by a three-electrode spark gap. He found that a small spark discharge between an auxiliary electrode (located to one side of a main electrode) and the main electrode would pre-ionize the space between the main electrodes and to allow a later 'main' spark across the primary electrodes to be produced at a lower voltage than otherwise possible. Much later, this principle was put to use by TNO[109] in Holland (Figure 38) and by Glarner[77] and Bartknecht[80] in Switzerland. Glarner's main electrodes have a 6 mm gap. The auxiliary electrode is located 2 mm away (perpendicular) from one of the main electrodes. In operation, a spark is fired across the 2 mm auxiliary gap first, using an energy low enough so that this firing would not ignite the test atmosphere. Since this spark ionizes the gas in main spark gap, a subsequent spark can be fired across the main 6 mm gap using a drastically lower energy than would be necessary for ignition of the atmosphere had the gas not been pre-ionized. Glarner's electrodes are made of 2 mm dia. stainless steel and have pointed tips. The main spark circuit uses an inductance of 1.32 – 46.4 mH but no series resistance. Studies have shown that the MIE values determined with this scheme are about 10 – 100 times lower[80,110] than when using a simple capacitive-discharge circuit. A few dusts however (e.g., melamine and sulfur) are exceptions, and do not show a large decrease in MIE when using this special circuit. The meaningfulness of the data obtained by this pre-ionization scheme is fundamentally questionable, however, since the process does not simulate a sequence of events encountered in accidental explosions. Additional data on the effect of inductance has been presented

Table 1 Effect on MIE of the ignition circuit used

Substance	MIE (mJ)	
	Hartmann	CMI
aluminum flakes	10	0.3
cornstarch	30	0.3
iron, atomized	40	0.12
lycopodium	22	6.0 – 6.5
methyl cellulose	40	4.9
polystyrene	40	0.3
sulfur	15	0.3

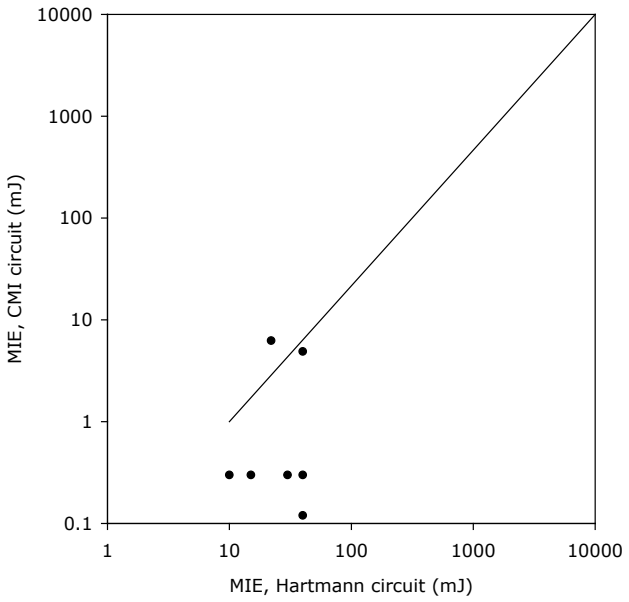

Figure 37 Relation between MIE values obtained using the Hartmann circuit and the CMI circuit; also shown is Eckhoff's proposed correlation

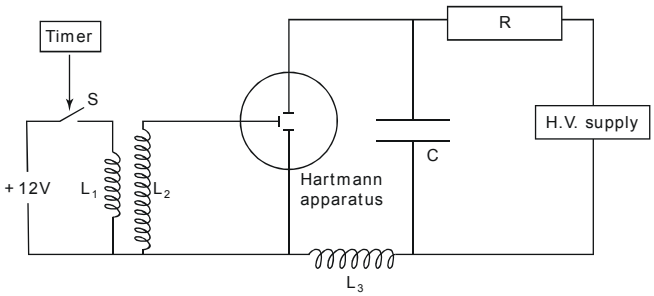

Figure 38 TNO 3-electrode arrangement, as implemented on the Hartmann apparatus

* Now named Christian Michelsen Research.

by Pidoll[111], who showed that MIE values are insensitive to the presence of induction for dusts with very low MIE values. But at higher MIE values, inserting a 1 mH inductance into the circuit often lowered the MIE value by about tenfold. Britton[112] has described several other circuit arrangements, including the trickle charge circuit of BS 5958, a moving electrode method, and a variant of the CMI circuit used at several US chemical manufacturers.

As a conservative measure, one or the other of the above schemes have come into wide use, at least in Europe. However, their use would appear to be unjustified, excessive conservatism, since no studies exist that would relate the values found under these test conditions to explosions that occur in actual accidents. Especially, the 3-electrode device is so peculiar that there does not seem any possibility that it would represent events in an actual accident. Interestingly, Bartknecht recommends that his circuit *not* be used for the testing of flock (Figure 39), for the reason that ignition sources in flock machinery are unlikely to be inductive in nature. Indeed, going further, Eckhoff[19] has advised that the circuit should not be used for electrostatic hazard assessment in industrial plant, since "high inductance values are unlikely to occur in accidental electrostatic discharge circuits in industry." In the same vein Bailey et al.[113] studied a wide variety of equipment used in chemical plants and found that with one exception (a rubber hose with a metal coil, 220 μH) all of the inductances were less than 3 μH. Glor[114] also concluded that equipment with significant inductance is sufficiently rare that general-purpose data should not be based on simulating them. Conversely, Smallwood[115] hypothesized that if discharges are to poorly conducting (e.g. plastics) surfaces, then the discharge time length might be lengthened, making inductive or resistive elements a reasonable surrogate for the lengthened discharge time.

Unlike a gas mixture, a dust cloud does not just stay in place after being created—unless continuously agitated, it settles out quickly. Thus, with any given test apparatus, there will be an optimum time at which the spark should be fired. If it is fired too early, then a uniform mixture will not have had a chance to be created. If it is fired too late, then settling out of the dust will result in non-minimum ignition energy values being reported. Bartknecht[80] documented some of these details. For the Siwek 20 L sphere, a delay time of 0.12 s was found to be optimal; for several other test apparatuses, both larger and smaller, values of around 1.2 – 1.5 s were found best.

AIR VELOCITY AND TURBULENCE

Increasing the air stream velocity raises the MIE value roughly linearly. A modest amount of experimental data exists[19] and can be generalized to the following predictive relation:

$$MIE_2 = MIE_1 + \alpha\left(u_2 - u_1\right)$$

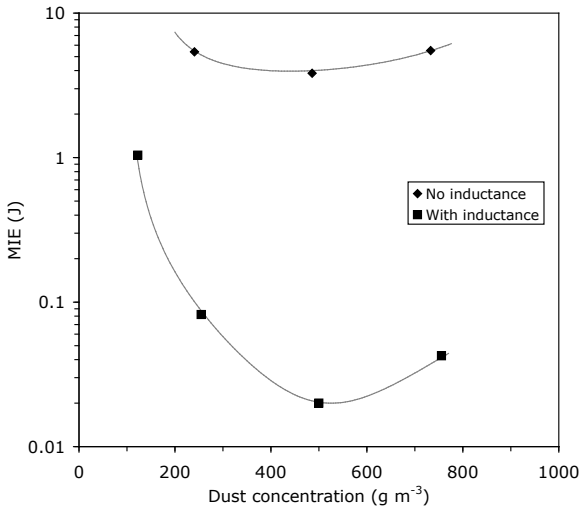

Figure 39 MIE for acrylic flock—effect of spark circuit parameters
(Copyright Springer-Verlag, used by permission)

where MIE_2 denotes the ignition energy (mJ) corresponding to velocity u_2 (m s^{-1}), and similarly for MIE_1. The empirical constant α is in the range 0.3 – 0.5, and a typical value of 0.4 can be used.

Dust clouds are difficult to create in laminar flows. Turbulent conditions are present in all of the test methods and in most practical applications. Since turbulence increases the MIE, the values of MIE associated with dusts will perforce be higher than those for gases, since the latter are measured under quiescent conditions. Bartknecht[80] showed for some materials that going from "low turbulence" to "medium turbulence" conditions increased the MIE values by a factor of about 80. A practical means does not exist to quantify the turbulence in various test apparatuses, nor indeed have even semi-quantitative comparisons been reported. A unique experimental rig[9] has been proposed, however, where dust clouds are in a 'cycling' laminar motion due to an ingenious electrostatic charging arrangement. The apparatus is primarily designed to measure quenching distances, but so far only a single material has been studied.

Line et al.[99] conducted interesting experiments where they ignited dust clouds both in a tube (as in the Hartmann apparatus) and as a free jet in open air. It took significantly more energy to ignite the dust cloud when it was in a tube. The authors explained that this is because the rapid expansion induces significant turbulence in a tube, while expansion in open air is less turbulent.

TEST VESSEL SIZE

The effect of test vessel size on MIE has not been explored in depth. Glarner's study[77] (Table 2) suggests that higher values are reported in a larger test apparatus, which would imply that applying test results to a large-scale end-use environment may be fundamentally conservative.

Table 2 Effect of test vessel size on MIE

Dust	MIE (mJ)	
	20 L sphere	1 m^3 sphere
antioxidant	1	2
lycopodium	2	2
paint A	2	3
paint B	1	5
epoxy polyester	2	5
cellulose	10	50
pea flour	100	1000
melamine polymer	100,000	1,000,000

RISK MANAGEMENT BASED ON THE MIE

A British Standard exists which classifies dust suspensions according to their liability to static electricity ignition. BS 5958[116] classifies dust suspensions according to the minimum ignition energy, as given in Table 3. The precautions listed in this table pertain to dust suspensions having a volume resistivity of less than 10^{12} Ω-m; dusts of higher insulating value require additional precautions.

DILUTING WITH INERT GASES

The effect of inert dilution gases on making a co al dust cloud non-flammable is illustrated in Figure 40 and compared to the effect for methane.

Another way of considering dilution is to examine the *minimum oxygen concentration* (MOC) that is needed for explosion. Krause et al.[117] argued that a similar relation should be found between the LFL and the MOC for dust clouds as for gases (see Chapter 4). The main differences are that the LFL for dust clouds must be measured in units

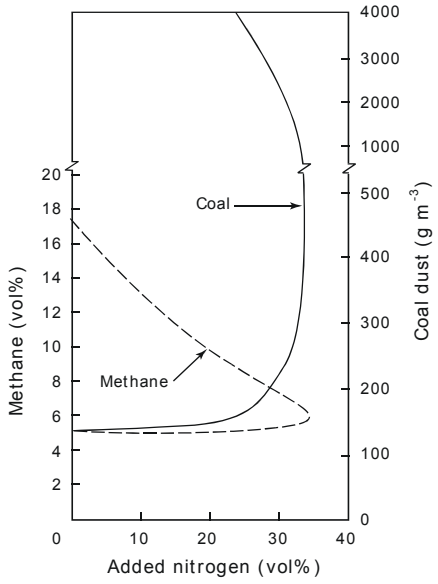

Figure 40 Comparative effect of adding nitrogen to methane and to coal dust atmospheres[78]

Table 3 Recommendations of BS 5958 for dust cloud precautions

Min. ignition energy (mJ)	Recommended precautions
500	Low sensitivity to ignition. Earth plant when ignition energy is at or below this level.
100	Consider earthing personnel when ignition energy is at or below this level.
25	The majority of ignition incidents occur when ignition energy is below this level.
10	High sensitivity to ignition. Consider restrictions on the use of high resistivity non-conductors when ignition is at or below this level.
1	Extremely sensitive to ignition. The presence of explosible dust-air mixture should be avoided wherever possible. Handling operations should be such that they minimize the possibility of suspending the powder in air. All possible steps should be taken to encourage the dissipation of charge and to discourage charge operations.

of g m^{-3} rather than in vol% and that the elemental composition of the fuel is normally reported as mass-fractions. based on requirements of oxygen for combustion. On this basis,

$$MOC = LFL \times \frac{r_o}{\rho_{O_2}}$$

where LFL = (g fuel)/m^3, r_o = stoichiometric oxygen/fuel mass ratio (--), ρ_{O_2} = density of oxygen (g O_2/m^3) and at 298 K it is 1290 g m^{-3}. For a fuel containing only the elements C, H, and O, r_o can be evaluated as:

$$r_o = \frac{32}{12}\mu_c + \frac{32}{4}\mu_h - \mu_o$$

where μ_c, μ_h, and μ_o are the mass fractions (--) in the fuel of C, H, and O, respectively. An analogous expression can be derived for dust that include additional elements. Krause's data are plotted according to this relation in Figure 41 and it is seen that the prediction is generally conservative. However, as Chapter 4 shows, the MOC for most organic gases is in the range of 10 – 12%. By contrast, the dust cloud results show a lot of values in the range 6 – 8% (the two lowest data points represent metal dusts and not organic fuels). Dust cloud MOC values that are below the values for gases are presumably too low due to experimental difficulties.

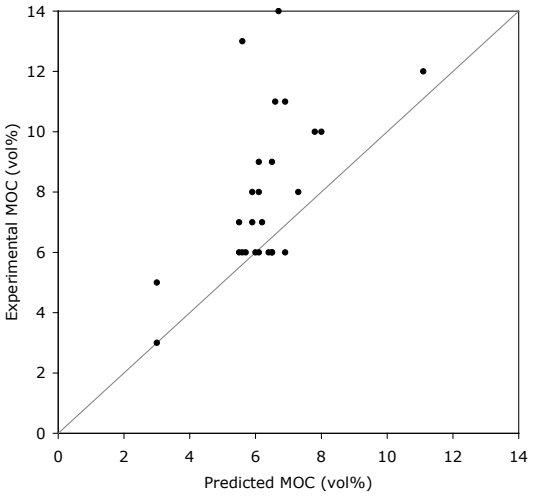

Figure 41 Prediction of MOC for dust clouds based on the LFL

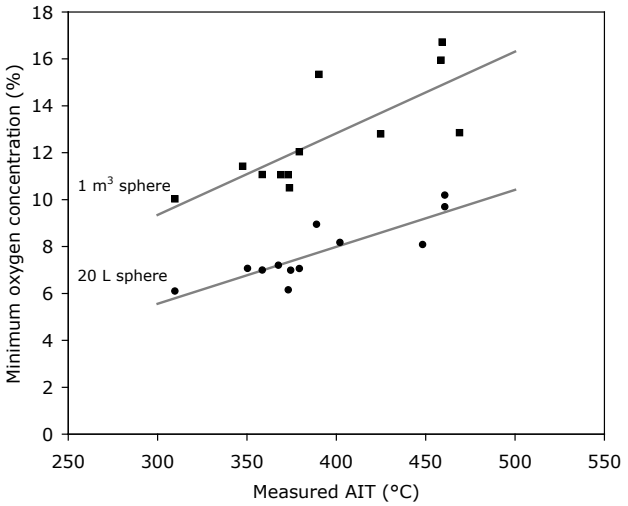

Figure 42 Predicting the minimum oxygen concentration on the basis of the AIT

Bartknecht[80] found that the MOC is roughly dependent on the AIT of the dust, as measured in the BAM oven (Figure 42). The MOC values were measured in the 20 L Siwek sphere and in the Bartknecht 1 m^3 sphere. With only a few exceptions, the values found for gases are 11.5 – 12%, thus the values from the 1 m^3 sphere that are below 12% are presumably attributable to an overdriving of the chamber by the pyrotechnic igniter. Much more striking are the lowest MOC values of 6 – 8% found in the 20 L sphere, which are substantially lower than MOC values for gases. The combustion of a dust cloud cannot be any more efficient than that of a premixed gas atmosphere, although it can definitely be less efficient. Thus, results which suggest contrariwise are evidently due to unrealistic test arrangements. Specifically, the pyrotechnic igniter evidently overdrives the 20 L sphere to a remarkable degree. Siwek and Cesana[70] proposed a correlation for *MOC*:

$$MOC = 12.9 + 1.62 \log\left(MIE\left[1 + \frac{AIT}{273}\right]\right)$$

where *MIE* is in joules and AIT (ºC) is as determined in the BAM oven. Scant details have been made available for the basis of this correlation, so its intended range of validity is not clear.

A correlation between MOC and AIT is also curious on chemical grounds. Gases do not show any such correlation and it would appear that the correlation arises due to some unanalyzed intervening variable. The value of MOC for most organic, non-halogenated gases is nearly constant and bears no relation to AIT values, which span a wide range.

The above results were obtained at 20ºC. If the ambient atmosphere is at an elevated temperature, then lower values of oxygen concentration will suffice for combustion to be possible. This is indicated in Figure 43. The values were obtained by Wiemann in a 1 m^3 sphere[79,118], so the results can realistically be applied to real-scale problems. Most of the data can be represented well by a linear trend, whereby the MOC at any temperature T_2 can be estimated from its value at T_1:

$$MOC_{T_2} = MOC_{T_1} - 0.014\left(T_2 - T_1\right)$$

Essentially identical trends are seen from the 20 L sphere[77], although in the latter case the absolute values do not seem to be applicable.

Wiemann obtained a results for the MOC of a number of dusts at room temperature using the 1 m^3 sphere. These values are given in Table 4. Again, values below 12%, or so, for organic fuels must be viewed as questionable, since they are lower than what is attained by gases.

Table 4 MOC values, as determined by Wiemann

Dust type	Diameter (µm)	MOC (%)
aluminum	22	5
barium stearate	<63	13
bisphenol A	34	9.5
cadmium laurate	< 63	14
cadmium stearate	<63	12
coal, anthracite	17	14
coal, brown	63	13
cornstarch	17	9
dibenzoyl peroxide	59	10
methyl cellulose	70	10
β-naphthol	<30	9.5
pea flour	25	15.5
paraformaldehyde	23	6
polyethylene	26	10
rye flour	29	13
soot	13	12
sulfur	30	7
wheat flour	60	11
wood	27	10

The effect of particle diameter on the MOC was explored by several researchers[68,119]. Figure 44 shows that there is little effect for diameters < 100 µm. For larger diameters, some dusts show strongly rising MOC values, while for others the increase is mild.

Less dilution is needed if the dust concentration is not near its worst-case value, in other words, there is a dust concentration dependence also. The values reported in the literature are generally for dust concentrations giving near-lowest MOC values. Larger or smaller dust concentrations will raise the MOC value. Figure 45 illustrates the effect for phenol formaldehyde dust[120].

The above discussion assumed that the system is composed of only three substances—oxygen, nitrogen, and dust. In some cases, diluting is done not by nitrogen but by water vapor or CO_2. The latter molecules have higher heat capacity and thus, a lesser dilution is required for non-flammable conditions to be reached. Guidance is not as extensive for water vapor, CO_2, or other diluents, but Wiemann has illustrated that coal dust showing at 150ºC an MOC of 10.9% could be inerted with water vapor by dropping oxygen to 12.3% or with CO_2 by dropping oxygen to 13.0%.

DILUTING WITH INERT DUSTS

If it is required to make an atmosphere non-flammable, then inerting with nitrogen is possible, although costly. Diluting with excess air is generally impractical, since additional flow velocities introduced may tend to stir up and create greater dust quantities. In some specific cases, the most practical and economical solution is dilution with inert dusts. This has found application in coal mines for a long time, where limestone dust is used. When the mass fraction

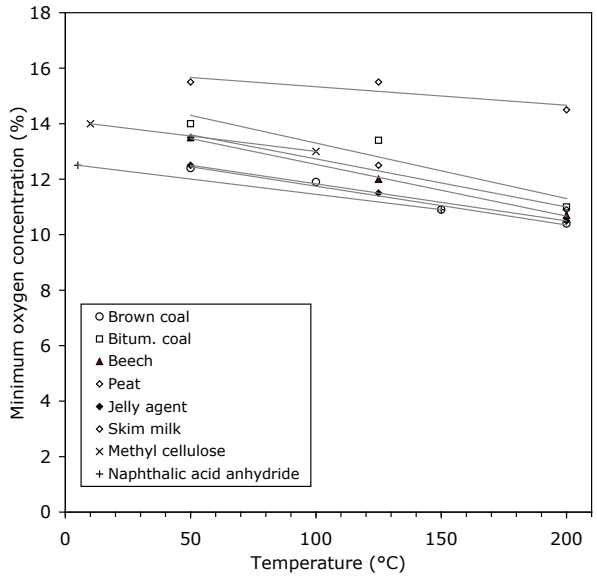

Figure 43 Effect of temperature on MOC using a 1 m^3 sphere

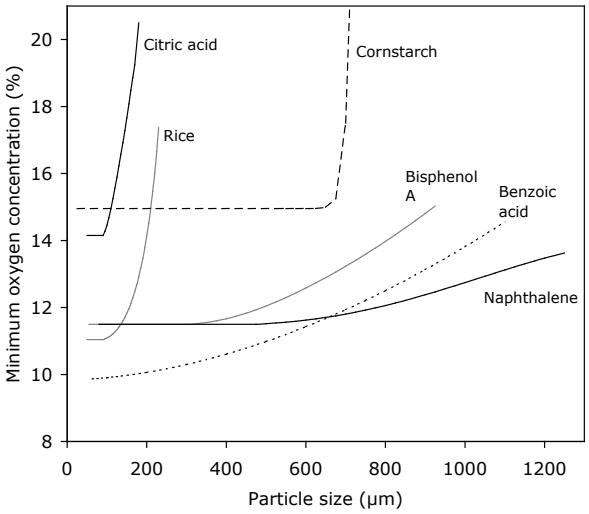

Figure 44 Effect of particle size on MOC

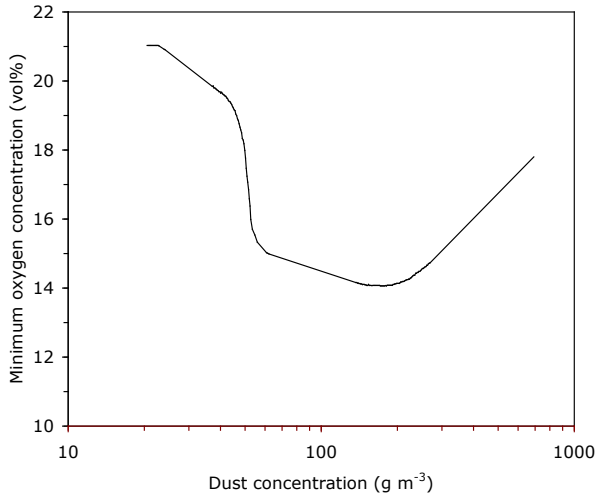

Figure 45 Minimum oxygen concentration for 15 µm phenol formaldehyde dust

of limestone dust reaches about 75-80% of the combined mass of coal+limestone dust, mixtures become non-flammable[78]. Limestone dust, however, is ineffective against methane gas explosions. BM[30] reported on a series of measurements in their 20 L apparatus using a 5000 J pyrotechnic igniter that showed that 92% inert dust was needed for inerting polyethylene dust.

Tests for ignition properties of dust clouds

There is a wide variety of test equipment that has been used to characterize explosible dust clouds. The primary variables which are of interest are:

- minimum ignition energy, MIE
- lower flammability limit, LFL
- autoignition temperature, AIT
- minimum oxygen concentration, MOC
- maximum pressure rise
- maximum rate of pressure rise

The latter two variables are only of post-ignition concern and are not further discussed here. The MIE and the LFL can be measured in any of the devices discussed below. The AIT can be measured in any of the devices which have the capability of being heated.

The methods described below are ones that have received significant use in recent decades. The early history of test methods developed in Germany and elsewhere in Europe has been reviewed by Bartknecht[80]. Brown and Woodhead[121] reviewed the history from an apparatus designer's point of view. Essenhigh et al.[122] reviewed the design principles and details of a majority of the current apparatuses and it is important to note their conclusions. The state of the art of test apparatus design is acceptable, at best, only if comparative values are needed. If data need to be obtained that have fundamental credibility, *all* of the currently-common test methods must be considered as unsatisfactory. This is because:

- cloud uniformity is poor
- motions exist in the system which are uncharacterized and of varying velocity
- particles are rapidly lost from the test section or segregate according to size
- the ignition sources used have an effect on the result, and the effect is neither theoretically characterized nor a realistic representative of the end-use environment
- the residence time of the particles within the apparatus affects the test outcome, but it is neither quantified nor controlled.

Thus, it becomes very difficult to compare test results and theories, if the test apparatuses cannot be relied upon to generate data under known, fixed, simple boundary conditions.

ASTM E 1491

ASTM E 1491[123] is a peculiar standard which does not describe a specific apparatus, but rather lets the user choose from a list of four entirely different test apparatuses: (1) the Godbert-Greenwald furnace; (2) the BAM oven; (3) the heated version of the Bureau of Mines 1.2 L Hartmann apparatus; and (4) the Bureau of Mines 6.8 L furnace. The standard recommends that samples be prepared by sieving to have 95% at the minus 200 mesh size, i.e., smaller than 75 μm. Since it is known that results obtained with these apparatus show systematic differences, and, in some cases, large differences, testing according the standard evidently can yield quite disparate results.

ASTM E 2019

This standard[124] for the MIE of a dust cloud allows for testing in either a Hartmann tube of 0.5 L or 1.2 L capacity, or a 20 L sphere, despite the fact that correlation between those is poor. An electric spark ignition is used, with a spark gap of 6 mm. The value of the capacitance is not specified. The ignition energy is computed as $\frac{1}{2}C\left(V_i^2 - V_f^2\right)$, where V_i is the initial voltage of the charged capacitor and V_f the voltage remaining upon discharge. Energy losses are ignored. Four calibration substances are specified: tetrakis-methylene(3,5-di-(tert)-butyl-4-hydroxyhydrocinnamate)methane: MIE = 1 – 6 mJ; anthraquinone: MIE = 1 – 11 mJ; lycopodium: MIE = 10 – 30 mJ; and Pittsburgh coal: MIE = 30 – 140 mJ. As can be seen from these ranges for standard substances, highly accurate results are not being sought. The minimum ignition energy is computed at the 10% probability level. The results are to be prepared as a plot of concentration vs. MIE. Four entirely different spark circuits are permissible: (1) A 3-electrode system, where a spark breakdown caused by an auxiliary electrode triggers the main discharge. (2) An arrangement where a pneumatic cylinder rapidly moves one electrode into position, causing discharge when a critical distance has been attained. (3) A fixed system where a trickle-charge circuit keeps raising the capacitor's voltage until break-

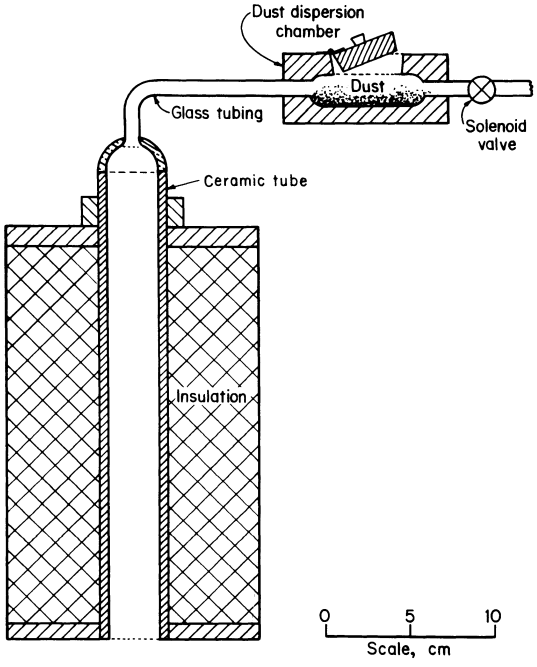

Figure 46 A cross-section view of the Godbert-Greenwald furnace

down occurs. Or, (4) A circuit whereby a secondary charged capacitor is quickly connected to a transformer which received a pulse and couples it into the discharge circuit of the primary capacitor.

GODBERT-GREENWALD FURNACE

The earliest of the apparatuses from which data are still used, this 0.27 L furnace (Color Plate 4) was developed cooperatively by BM and SMRE in 1935[125,126] as an elaboration of a design that was originally described by the French combustion scientist Taffanel in 1911. A dust dispersion tank of 150 mL is connected to the top (Figure 46) and a puff of air through that chamber is used to disperse the dust into the furnace chamber. The furnace itself uses Nichrome wire as the heating element and can be heated up to 1000ºC. The furnace does not have an ignition mechanism and therefore is used only for AIT studies. Milligram-to-gram quantities of dust are injected, using an air pressure which is varied according to the characteristics of the dust. Ignition is taken to occur if flame becomes visible below the mouth of the furnace. The apparatus has been criticized for its poor uniformity of both temperature and dust concentration[63].

BUREAU OF MINES 1.2 L FURNACE

Since uniformity of dust dispersion in the G-G furnace was considered to be poor, in 1981 BM developed a replacement test apparatus, the 1.2 L furnace[34, 63] (Figure 47 and Figure 48). Unlike the G-G furnace, which is only suitable for making AIT measurements, the 1.2 L furnace was developed to allow both AIT and MIE studies to be made, in other words, it was also viewed as a heated replacement for the Hartmann apparatus (see below). The most significant change from the G-G furnace is that dust is blown up, not down, into the apparatus, helping to establish uniformity inside it. The dust is dispersed into the volume by manually loading the disperser with dust, inserting it into the bottom of the chamber, then dispersing it using 60 mL of air, delivered in a 30-ms pulse. Ignition is judged to occur if the fiberglass diaphragm at the top of the furnace ruptures and flame is emitted from the port within 3 s of dispersion.

BAM OVEN

In Europe, and especially in Germany, the BAM oven[127] is commonly used. This apparatus is a horizontal tube oven, at the far end of which is a parabolic metal plate (Figure 49, Figure 50, and Color Plate 2). Testing is started by setting the oven to 600ºC and blowing in 1 to 2 mL of dust using a squeeze-bulb, which is deflected by the parabolic plate. If ignition results, then the heaters are turned off and new samples injected at every 50ºC as the oven is cooling down. If ignition is not obtained at 600ºC, then higher temperatures are used. The temperatures reported from the BAM oven are generally lower than from the Godbert-Greenwald furnace.

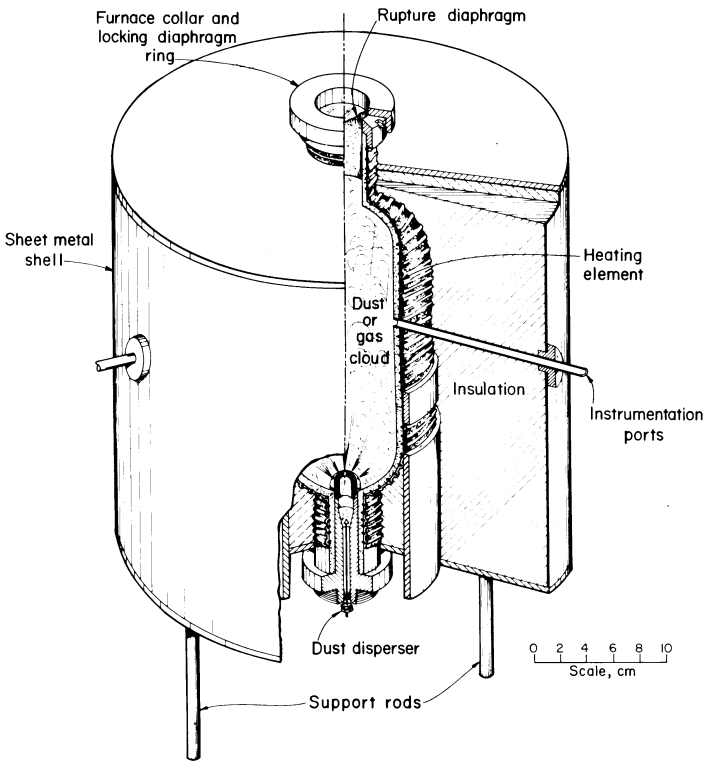

Figure 47 The Bureau of Mines 1.2 L furnace

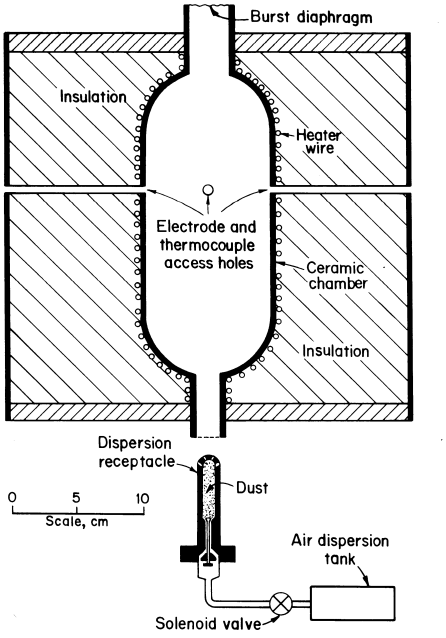

Figure 48 Cross-section view of the Bureau of Mines 1.2 L furnace (the dust receptacle is shown in the loading position; it is pushed up into the chamber just before an air blast is activated to start the test).

HARTMANN APPARATUS

The Hartmann apparatus designation can be confusing, since a number of devices have been described which differ significantly in some of their crucial features. The original device[128], also called the Hartmann tube, is a 1.2 L cylinder, 305 mm tall and 70 mm dia., into which dust is injected from the bottom. The tube is an open-top PMMA cylinder, and the apparatus uses an electric spark ignition source (Figure 51 and Color Plate 5). The bottom contains a cup where a quantity of dust is placed and dispersed with a puff of air from a 1.3 L air reservoir. The pressure to be used for dispersion needs to be determined in preliminary trials. Tungsten spark electrodes are located 100 mm above the base. The spark circuit involves a capacitor which is discharged through a transformer. The discharge time is adjustable, and the operator is required to optimize it by preliminary trials. The criterion of ignition is a flame propagation distance of 100 mm or greater in the tube. The transformer-coupled circuit was adopted for the Hartmann apparatus presumably because it prolongs the discharge time, compared to a simple capacitor discharge.

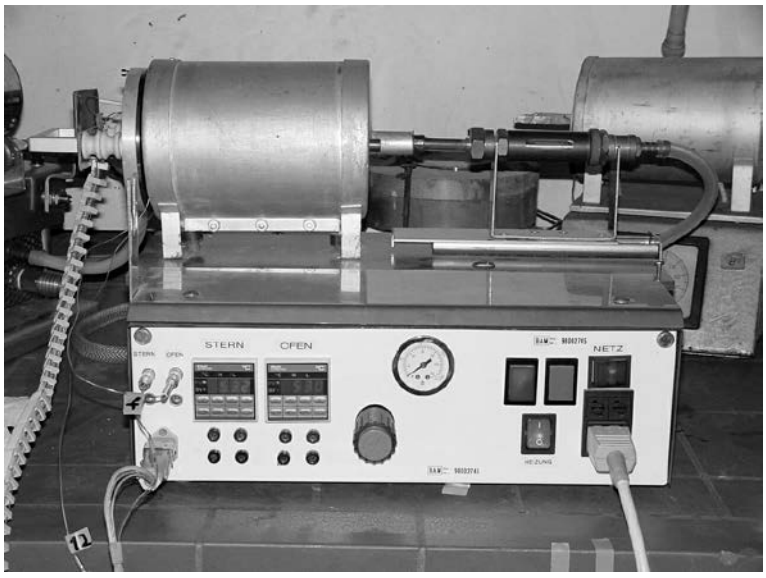

Figure 49 BAM oven, external view
(Courtesy Ulrich Krause, BAM)

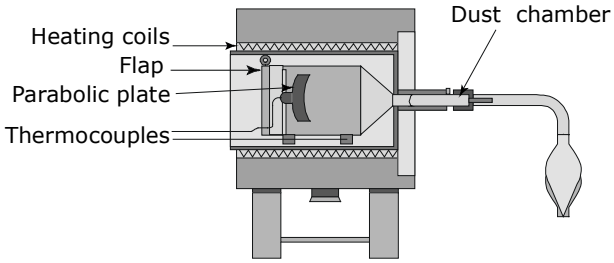

Figure 50 Section view of the BAM oven
(Copyright AIChE, used by permission)

When the LFL (as opposed to the MIE) is to be determined, a filter-paper rupture disk is installed with a locking ring to cover the top of the apparatus. The disk has a 1.6 mm hole in the center to avoid excessive pressure rise due to the introduction of the air puff. The criterion for occurrence of ignition in LFL determinations is the bursting of the disk. Thus, the flame propagation criterion is a pressure rise equal to the bursting pressure of the paper disk, about 0.2 atm. For determining the MOC, the Hartmann apparatus is modified so that a controlled-oxygen atmosphere is presented to the unit.

For determining pressure rise, a steel pressure-vessel version of the Hartmann apparatus is used, often referred to as a *Hartmann bomb*. The latter has been standardized as ASTM E 789[129]. The ASTM version is the unheated steel cylinder. A heated bomb version evolved into the 1.2 L apparatus, discussed above. In 1978 Lütolf[130] described a modified Hartmann apparatus, where (a) the tube of the apparatus is a Pyrex cylinder; (b) an alternative for the electric spark is provided by a Kanthal glow coil, operated at 1200ºC; and (c) a flapper vent is located on the top of the cylinder. The latter is graduated in degrees of opening angle, and is intended to be used for rough preliminary screening. Field[107] recommends that the glow wire be used for dusts that are not readily ignitable by an electric spark. Glarner has concluded the 1200ºC coil can successfully ignite only dusts which have AIT values ≤ 540ºC, as measured in the BAM oven.

The vast majority of the published ignition data using the 'Hartmann apparatus' pertain to the open-top PMMA-cylinder version and not to the later versions. Even though the electric spark ignition used with the Hartmann apparatus is at the extremely weak end of the scale amongst today's test methods, Eckhoff has pointed out that "none of the dusts that were classified as 'non-explosible' in the [spark-ignited Hartmann tube] ever caused any explosions in the chemical industry." This observation certainly implies that tests using more energetic igniters are excessively conservative.

The criteria adopted for the Hartmann apparatus can have a strong effect on the reported values. In studies of the LFL of gases, it is well understood that for the flammability limit to be reached, extensive flame travel has to be observed—flaming in the nearby vicinity of the ignition source is not sufficient. Lunn[131] noted that LFL values reported in the UK at the Fire Research Station using their version of the Hartmann tube are often lower than those from the Bureau of Mines, since, for unexplained reasons, the UK procedures[107] deem the flammability limit to be reached if any flames are observed moving away from the igniter.

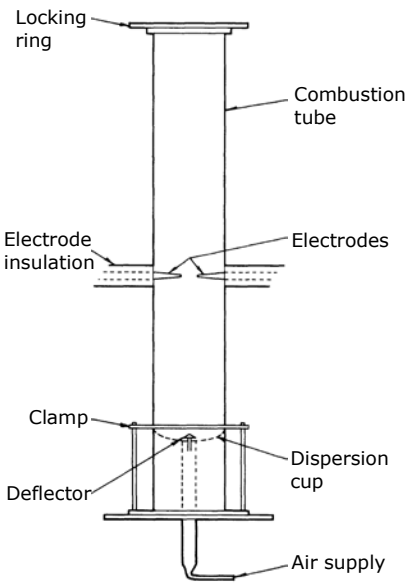

Figure 51 General-use version of Hartmann apparatus

The reproducibility of MIE data obtained in the Hartmann apparatus does not appear to be especially good. In a roundrobin conducted by ASTM in 2000, 9 laboratories agreed reasonably well on the value (ca. 20 mJ) for lycopodium dust. But for Pittsburgh coal, which should also not be a difficult-to-test substance, reported values from 5 laboratories ranged from 50 to 1000 mJ. Part of the problem appears to be attributable to the ignition circuits, which are not all identical at the laboratories using this equipment. Several studies[21,132] document shortcomings of the Hartmann apparatus.

An apparatus conceptually similar to the Hartmann apparatus, although actually not sharing any parts in common has been invented in Norway and described by Eckhoff[133]. The apparatus comprises an open steel tube, 140 mm diameter and 400 mm tall. Dust is introduced by an air blast at the bottom. Also located at the bottom is an igniter, which consists simply of an oxyacetylene welding torch. The apparatus was developed because a number of dust cloud explosions have originated due to careless welding.

BUREAU OF MINES 6.8 L CHAMBER

The BM 6.8 L chamber[63] is very similar to the heated version of the Hartmann apparatus, except for the increased size (Figure 52). The main innovation is an automated device for loading the dust disperser into the chamber. The rupture diaphragm is also replaced with a flapper vent. Ignition is judged to occur if the vent opens and flame is emitted within 6 s after dispersion of the dust. For most dusts, the AIT results are found to be within 30 C of the values obtained with the 1.2 L Hartmann apparatus.

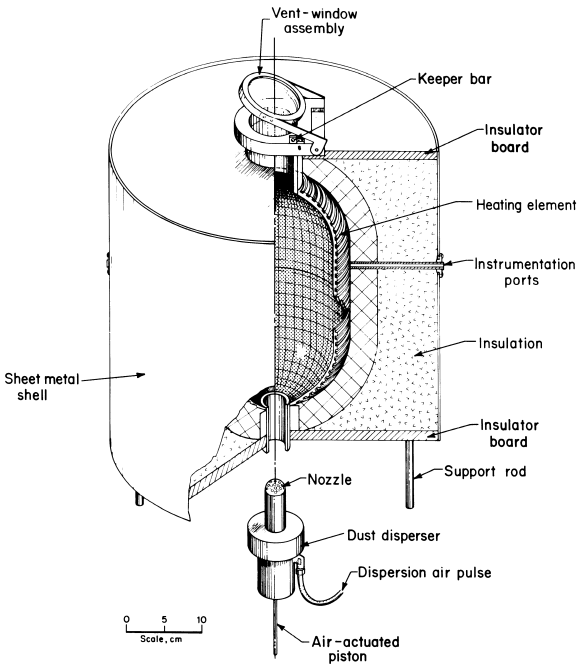

Figure 52 View of the Bureau of Mines 6.8 L apparatus

SPHERES AND OTHER 20 L CHAMBERS

Recent work has shown that values of pressure rate of rise determined in a too-small apparatus cannot be scaled suitably to real-scale applications. Thus, much current research focuses on chambers of 20 L size and greater. Note, however, that this issue does not refer to determinations of ignition parameters, only of explosion pressures. The ASTM E 1515 test method[134] is based on a 20 L chamber developed

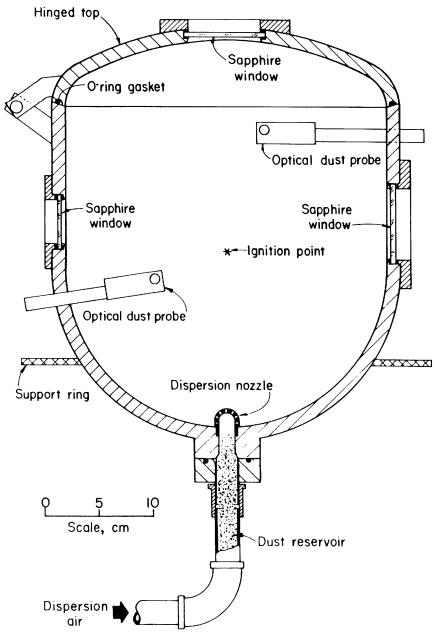

Figure 53 The Bureau of Mines 20 L dust explosion sphere

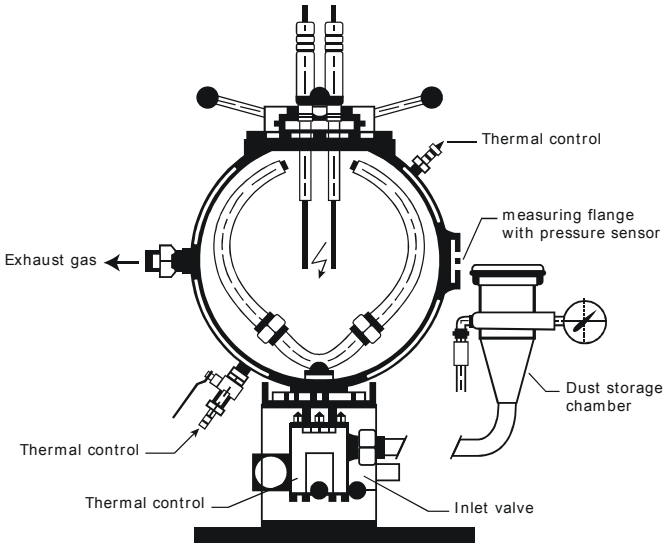

Figure 55 The 20 L Siwek sphere—cutaway view[138]

Table 5 Minimum oxygen concentrations for explosibility of Pittsburgh coal dust

Chamber	Igniter energy (J)	Min. oxygen content (%)
20 liter	1000	13.5
	2500	11.0
	5000	9.5
1 m^3	10,000	13.5

by the Bureau of Mines[135]. The chamber is made of stainless steel and is shaped somewhat between a cylinder and a sphere (Figure 53). Ignition is with a pyrotechnic igniter* of 2500 or 5000 J energy. The ASTM standard recommends that the samples be prepared by sieving to have 95% of the particles at the minus-200-mesh size, i.e., smaller than 75 μm, but that particles much smaller than 75 μm not be included. The moisture is to be below 5%. Concerning ignitability, the test variable reported is the minimum explosible concentration, MEC, which is synonymous with LFL. Other results are also reported from the test that pertain to characteristics of the explosion. The apparatus is not heated, so it cannot be used for AIT determinations.

Table 6 Validation of LFL results in large-scale tests

Test apparatus	Igniter energy (J)	Gilsonite	Pittsburgh coal
20 L	1000	50±5	90±5
	2500	35±5	80±10
	5000	30±5	60±10
	10,000	30±4	50±10
1 m^3	2500	39±3	90±5
	5000	41±3	85±5
	10,000	36±3	80±5
large-scale mine gallery	methane gas explosion	35	60

Going et al.[136] recently reported results from a study using this chamber which indicate that even the 2500 J igniter overdrives the system and that a 1000 J igniter would appear to be more reasonable. This can most clearly be judged from their MOC data for Pittsburgh coal (Table 5). Values ca. 13.5% are typical of many hydrocarbons, while a value of 11.0% would only be characteristic of a few exceptionally flammable ones, amongst which coal dust can hardly be envisioned.

Another way that the realism of ignition energy can be assessed is from large-scale validation. Sapko et al.[137] conducted large-scale mine gallery tests on gilsonite and Pittsburgh coal dust. These results (Table 6) suggest the 2500 J igniter provides the best agreement to large-scale data where the expected real-life ignition source is enormous, i.e., an ongoing gas explosion. For applications where a dust explosion is not foreseeably set off by a gas explosion, these results would not be relevant.

Apart from the very expensive 1 m^3 spheres, the apparatus most widely used in Europe in recent years for testing dusts has been the 20 liter sphere (Figure 54 and Figure 55), developed by Richard Siwek at Ciba-Geigy in Switzerland[138]. The method has a unique way of operation, in that the vessel is first evacuated down to 0.4 atm, then the dust is injected with sufficient air to bring up the starting pressure to

* Pyrotechnic igniters used are a mixture of zirconium (40%), barium nitrate (30%), and barium peroxide (30%). The largest, 10 kJ, contains 1.2 g of mixture, with the other sizes being proportionately smaller.

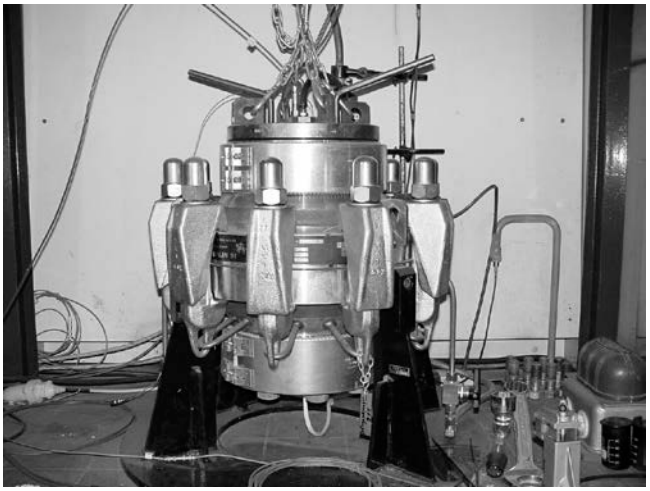

Figure 56 A 20 L bomb, as used at BAM
(Courtesy Ulrich Krause, BAM)

1 atm. The apparatus uses a huge 10,000 J pyrotechnic igniter. Eckhoff[19] points out that "the very strong 10 kJ igniter may cause combustion of dust even if the dust concentration is below that required for self-sustained flame propagation at constant pressure." Dust cloud ignitions occur mainly through cutting, grinding, tramp metal or overheating causes[139], and none of these approach a 10 kJ level. Thus, for situations where a dust cloud explosion is unlikely to be triggered by an ongoing gas explosion, a 10 kJ igniter would be inappropriate. The method is standardized as ASTM E 1226[140]. The method has primarily been used to determine the maximum pressure and the rate of pressure rise that occurs, although LFL determinations can also be made. The apparatus is not designed to be heated to high temperatures for making AIT determinations. However, Bartknecht[80] described a special, heated version which can be operated up to 250ºC for making LFL measurements at moderately elevated temperatures. Another 20 L bomb, as used at BAM, is shown in Figure 56.

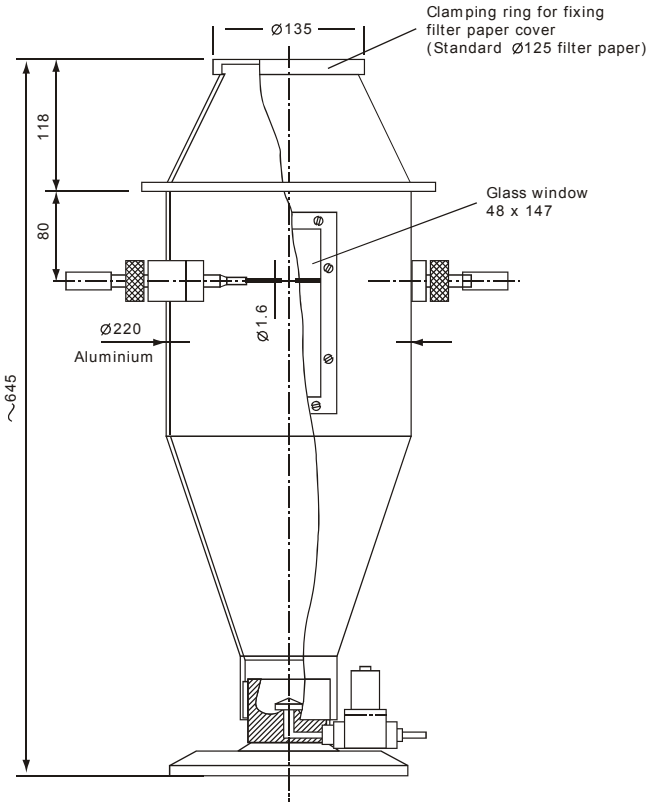

Figure 57 The Nordtest 15 L apparatus

NORDTEST 15 L APPARATUS

A 15 L vessel (Figure 57) was developed by Eckhoff at the Christian Michelsen Institute and adopted by Nordtest as NT Fire 011[141]. An electric arc ignition is used. The criterion for explosion is not clear, but the standard specifies that results are to be reported for the concentration giving ignition at the 50% probability level. The standard uses a clever scheme of a substitute chamber wherein the actual dust concentration is determined in the area near the ignition source by sampling from that area during a dispersion event. Makris and Lee (see above) concluded that this was the most credible of the standard test methods, but it must be noted that they did not consider any of the standard methods to be adequate.

1 M^3 SPHERES

A 1 m^3 sphere (Figure 58) is commonly used in Europe for testing according to the German standard VDI 3673[142]. Some of its development has been described by Bartknecht[80]. A slightly different variant has been described by ISO[143] as ISO 6184-1. Several 1 m^3 spheres of slightly different types have also been used[144]. The 1 m^3 spheres are not heated, so they cannot be used for AIT determinations. Another type of 1 m^3 vessel used at BAM is shown in Color Plate 6.

ASTM E 1232

A specialized question sometimes is asked—Determine whether a smoldering layer of dust in a closed volume can generate enough combustible pyrolysates to create an explosible atmosphere. This is addressed by the ASTM E 1232 test method[145]. The method, whose primary application is to liquids, also contains procedures for granular powdered materials. A 50 cm^3 amount of the test substance is placed in a 5 L heated flask. The flask is heated to a desired test temperature and an electric spark is applied to determine if the atmosphere is flammable. Eckhoff[19] surveyed a number of additional, non-standard tests designed to explore this same question.

IEC 61241-2-3/MIKE 3

An IEC standard[146], IEC 61241-2-3 is based on a highly modified Hartmann tube evolved by Siwek and Cesana[70]. The apparatus is commonly known as 'Mike 3,' after the

model number designation of the commercial version produced by Adolf Kühner AG, in Birsfelden, Switzerland. The test method is developed only for examining the ignitability at certain discrete energy values: 1, 3, 10, 30, 100, 300, and 1000 mJ. For the two lowest energy values, a charging voltage of 15 kV is used and ignition is caused by activating a relay which connects a charged capacitor across a discharge gap. For the higher energy values, a pneumatic activator that quickly moves one electrode from its rest position to the final position, which comprises a 6 mm discharge gap. A voltage of 15 kV is used for 10 mJ energy testing, and 11 kV for higher energies. The apparatus provides for testing either with a 1 mH inductor in series with the charged capacitor, or else with only parasitic inductance (< 0.025 mH). Steel or tungsten electrodes of 2 mm diameter are used. Only a limited amount of data have been published concerning the effect of inductance in this apparatus[113], suggesting that the higher inductance value sometimes—but not always—causes lower MIE values to be reported. The data also suggest that, compared to other test devices, the MIE values from the Mike 3 apparatus are sometimes similar, but sometimes vastly lower. The reasons for this have not been presented.

CMI MECHANICAL IMPACT TEST

No standard test for ignitability of dust clouds from mechanical impact-generated sparks exists. An experimental rig developed at CMI has been described by Pedersen and Eckhoff[53]. A swinging hammer contacts an anvil within a dust-laden environment. The dust dispersion system is a modified version of the dispersion cup used in the Hartmann apparatus.

Rolf K. Eckhoff, **Dust Explosions in the Process Industries**, 2nd ed., Butterworth-Heinemann, Oxford (1997). The only comprehensive textbook in the field of dust explosions is Eckhoff's. He provides both a plethora of experimental data and theoretical development of numerous aspects of dust explosions.

Wolfgang Bartknecht, **Dust Explosions: Course, Prevention, Protection**, Springer-Verlag, Berlin (1989). Bartknecht is a German researcher who has been highly prolific in the dust explosion research area. His book is valuable for the large amount of photographs and for numerous graphs illustrating data trends. Theory is not covered and there are no data tables.

Peter Field, **Dust Explosions**, Elsevier, Amsterdam (1982). Field was the last in a series of researchers at the Fire Research Station of the UK who studied dust explosions. His book summarizes the experimental results from much of the FRS research, and includes extensive data tables. The book is wholly empirical in scope.

Brenn- und Explosions-Kenngrössen von Stäuben, H. Beck, N. Glienke, C. Möhlmann, eds., (BIA-Report 12/97), Berufsgenossenschaftliches Institut für Arbeitssicherheit, Sankt Augustin, Germany (1997). English edition: **Combustion and Explosion Characteristics of Dusts** (BIA-Report 13/97), Hauptverband der gewerblichen Berufsgenossenschaften, Sankt Augustin, Germany (1997). By far the most ambitious compilation of data in this field, this book comprises a set of tables giving data on 4300 dusts, compiled during a project involving five German safety organizations. The LFL data are from the Lütolf-modified Hartmann tube, or the 1 m^3 sphere, or the 20 L Siwek sphere. Indications are not given as to which of the latter two was used; the Hartmann tube values can be imputed by an absence of K_{st} values. In the case of the Siwek sphere, the 10,000 J igniter was used, with its attendant problem of overdriving the apparatus. MIE and MOC values were apparently also obtained from one of the two spheres. AIT data are from the Godbert-Greenwald furnace or from the BAM furnace, or, in some cases, both; these are clearly identified. Also given are dust layer hotplate test results, using a 50 mm layer depth, and from a German platinum-wire 'combustion test.' The latter (which is similar in spirit, but not in detail, to the UN Test N.1) uses a small pile of material that is briefly ignited by the wire and the results are classified into 6 burning classes.

Schofield, C., and Abbott, J. A., **Guide to Dust Explosion Prevention and Protection. Part 2—Ignition Prevention, Containment, Inerting, Suppression and Isolation**, The Institution of Chemical Engineers, London (1988). This practical guide is addressed to the plant safety engineer and offers extensive suggestions on how to lay out and operate facilities to minimize dust explosion hazards.

Highlights and summary of practical guidance

With the exception of certain unstable or reactive substances, liquids do not literally ignite. When ignition of liquids is discussed, this normally refers to vapors which have come from some body of liquid and ignited upon mixing with the atmosphere. If there is a liquid surface exposed to air, at any temperature above absolute zero the liquid exhibits a vapor pressure: it undergoes vaporization. The vaporization is highly temperature-sensitive and also depends on the chemical nature of the liquid. Then, if high temperatures or a localized energy source are present in the air volume into which the vapors have mixed, ignition may occur. Thus, many aspects of ignition of liquids, such as flammability limits or minimum ignition energy are identical to those for gases, and these have been presented in Chapter 4. The reader wishing to study the ignition of liquids is advised to first review Chapter 4. In this chapter, those aspects of the ignition of liquids will be treated that are unique for liquids. The main topics covered in this Chapter are:

- autoignition temperature
- flash point
- fire point
- ignition by hot surfaces
- ignition of droplets, aerosols, and sprays.

In many cases, the temperature limits of flammability are also important. To present together all of the material related to flammability limits, these have been covered in Chapter 4, even though they involve a phenomenon intrinsically dependent on a liquid phase.

Liquids are substances whose vapor pressure at a reference temperature, commonly 25ºC (298 K), is less than 1 atm. However, this does not mean that a substance defined as a liquid cannot be present as a gas, nor that a substance defined as a gas will not be encountered as a liquid. The actual state of a substance—gas or liquid—is dependent on both its pressure and its temperature. Propane is defined as a gas, even though it is commonly sold in liquid form. At 25ºC, its vapor pressure is greater than 1 atm (it is actually 9.5 atm), but if it is compressed it liquefies. NFPA has definitions of flammable and combustible liquids. The 'liquid' portion of these definitions is not identical to the normal chemistry definition (see Chapter 2).

The flash point is the temperature at which a liquid must be raised in order to produce sufficient vapors for flash-ignition and it can be measured by one of many standardized test apparatuses. These devices can either be open-cup or closed-cup arrangements. In North America, ever since 1977 closed-cup testers have been mandated for official purposes. The flash point determined in a closed-cup apparatus is normally somewhat lower than in an open-cup apparatus, but the exact difference varies somewhat with the nature of the substance. Strong regulatory focus is placed on the flash point due to an implicit assumption that ignition of liquids will not readily occur if the flash point of the liquid is above that of its environment. This assumption is only approximate, for three reasons: (1) the flash point as determined by a specific test apparatus is not necessarily

the flash point of the liquid in its end-use environment. (2) Liquids with flash point temperatures greater than the temperature of the liquid or of the environment can sometimes be ignited by wicking, spraying, or other means. (3) Liquids that are mixtures, rather than pure substances, may show a tendency for preferential vaporization and loss of one component, and this process will be different in the real environment compared to the tester.

Flash points can be estimated very roughly by means of a variety of estimating formulas, but such estimates must only be used for preliminary guidance, not for actual quantitative determination.

The vapor above a liquid will establish an equilibrium pressure only in a closed space. For a vessel that is open to the atmosphere, there is a continuous loss of liquid through evaporation. In such a case, also, there is concentration gradient above the liquid—as the height above the surface gets greater, the concentration gets lower. Thus, if an ignition source is brought near an open vessel of a flammable liquid, ignition will not be possible except at certain heights. For large heights, the concentration of the mixture will be below the LFL. Then, approaching the surface there will be a region where ignition is possible (it is assumed here that the vapor pressure of the substance is high enough at the ambient temperature). Finally, as an ignition source is brought yet closer to the surface, ignition will no longer be possible again. The above discussion presumed that the atmosphere is quiescent. If the vessel sits in a place where there is significant motion of air, then concentration gradients may be largely eliminated.

Vehicular gasoline tanks are normally capable of exploding only when welding is attempted on an 'empty' tank. If the tank contains any amount of liquid fuel, the vapor inside the tank is above its UFL, except in extremely cold climates. In a crash, an explosion becomes possible if the tank gets broken apart, and the liquid runs away or enough air mixes in so as to lower the vapor concentration below the UFL.

There is no relation between flash point and AIT. The AIT is primarily determined by a fuel's reactivity (its rate of oxidation) while the flash point is primarily determined by its volatility. Thus, for example, methane shows one of the highest AIT values, 640ºC, and one of the lowest flash point values, –188ºC. Methane is so volatile that, at ambient pressure, it is a gas and not a liquid; but it is of exceptionally low chemical reactivity. Flash point and boiling point, on the other hand, are highly correlated since both are governed largely by the same phenomenon—volatility.

Hot-surface ignition is affected both by the chemical reactivity and the volatility of the fuel. If the hot surfaces create an enclosed volume, then ignition will take place at approximately the AIT. But this condition is relatively rare and assuming that the hot-surface ignition temperature is 200ºC above the AIT generally provides a more realistic estimate.

Finally, it must be kept in mind that there are some liquids used for industrial purposes that can ignite and explode directly as a liquid, without first vaporizing and mixing with air. These are highly specialized and are treated with other unstable substances in Chapter 10.

Accidental ignitions of liquids

A 1975 study[1] examined the fuel involved in ignitable liquid accidents; the results are given in Table 1. It is seen that gasoline outranks all others by a very wide margin. The primary activities associated with the ignitions are listed in Table 2.

Table 1 Consumer injuries from ignitions of liquids

Substance	Percent
gasoline	68.4
lighter fluid	5.3
cooking grease	4.4
alcohol	4.0
adhesives	1.9
paint thinner	1.9
solvents	1.9
kerosene	1.6
fuel	1.2
oils	1.2
charcoal/starter fluid	0.7
cleaning fluid	0.7
cooking oil	0.7
paint	0.7
turpentine	0.7
mix of chemicals	0.6
paraffin and candle wax	0.6
other or unspecified	3.1

Properties of liquids

Liquids are not unique substances, but simply a *state* of matter. In the case of simple, low molecular-weight substances, at low temperatures the substance will be a solid, then a liquid at higher temperatures, and finally a gas at higher temperatures yet. Many practical substances, however, degrade, that is, change chemically, as they are heated, instead of just changing their state. For example, at a pressure of 1 atm, methyl alcohol is a solid below –98°C, then a liquid up to 65°C, and then a vapor only. But wood is a solid at room temperature which, when heated, breaks down into smaller molecules which are liquids or gases. Wood itself does not become a liquid or a gas. A map delineating the states of matter that are possible for a given substance is called a *phase diagram* and these are published in chemical handbooks. In Chapter 4, the principles and applications of gas and vapor ignitions was presented. Thus, in this Chapter only issues directly connected with the liquid state will be discussed.

Table 2 The activities associated with injuries due to accidental ignition of liquids

Activity associated with ignition	Percent
starting/tending open fire	20.1
playing with flammable liquid and an ignition source	10.8
spilling flammable liquid	9.9
using flammable liquid as cleaning agent	6.7
knocking over/dropping flammable liquid	6.6
cleaning/repairing equipment	5.7
priming carburetor	4.8
using matches or lighter	4.4
transporting flammable liquid	3.8
using machinery/equipment	3.2
using work tools	3.1
riding/driving vehicle	2.5
using flammable liquid as adhesive	2.2
other	2.2
refueling equipment	1.8
playing with matches or lighter	1.6
playing with flammable liquid	1.6
standing by an open fire	1.5
standing near flammable liquid	1.5
transferring flammable liquid	1.5
using flammable liquid as exterminating agent	1.5
disturbing open fire	0.9
unknown	0.9
using flammable liquid to ignite heat source	0.7
assault/suicide	0.7

The unique aspect of liquids which affects their ignition is the vapor pressure. At room temperature, solids, except for subliming solids such as naphthalene, have exceedingly low vapor pressures. Thus, solids typically ignite due to pyrolysis, i.e., a reaction which is a chemical degradation and which results in a vapor being generated. Liquids, however, do not need to degrade (although some do) in order to exhibit a substantial vapor pressure. The vapor pressure is a unique function of temperature. The simplest dependence of vapor pressure on temperature is the Clapeyron equation:

$$\ln P_{vp} = A - \frac{B}{T}$$

where P_{vp} = vapor pressure (atm), T = temperature (K), and A and B are constants specific to each particular gas. Most substances are sufficiently non-ideal that the Clapeyron equation is not an accurate representation of vapor pressure. A variant of it, termed the Antoine equation, however, often suffices to represent the data:

$$\ln P_{vp} = A - \frac{B}{T + C}$$

where there are now three constants to be tabulated for each substance: A, B and C. A number of real gases can be satisfactorily represented with the Antoine equation. Not all reference sources are uniform, and data in a number of them use the form $\log_{10}(P_{vp})$, instead of $\ln(P_{vp})$. For many substances, however, more complicated expressions are needed to accurately represent the vapor pressure than is possible using a 3-constant scheme. The book by Reid et al.[2,3] provides a large collection* of these.

Figure 1 shows some typical vapor pressures, as function of temperature. Figure 2 illustrates that by plotting the pressures as a function of 1/T and using a semilogarithmic scale, plots for many liquids will provide very close to straight lines[3,4]. Straight lines in this plot are equations of the form of the Clapeyron equation. Thus, unless results of the highest accuracy are needed, the simple Clapeyron equation will usually suffice.

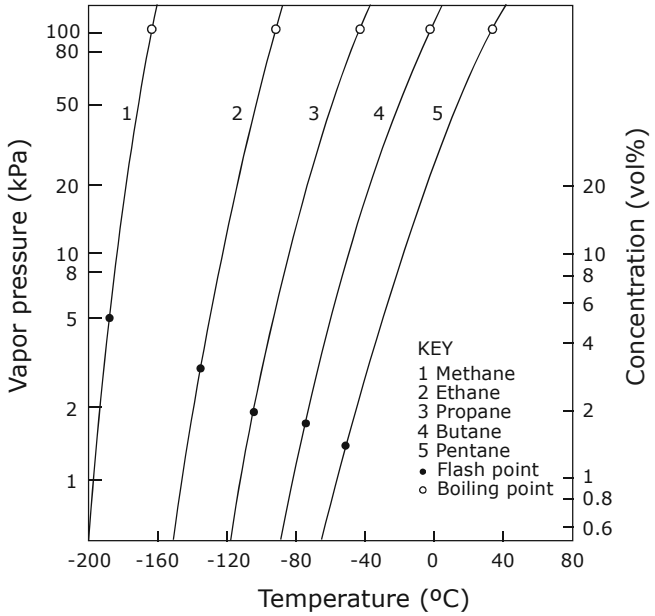

Figure 1 The vapor pressures of some *n*-paraffin series hydrocarbons[5]

For pure hydrocarbons (that is, molecules with only C and H atoms), Butler et al.[6] suggested a universal expression that is suitable for preliminary estimating purposes:

$$\ln P_{vp} = 10.6\left(1 - T_b / T\right)$$

where P_{vp} = vapor pressure (atm), and T_b = boiling point (K).

If a closed volume contains a reservoir of a liquid, the system is not in motion, and the liquid surface is flat, then there can only be a single unique pressure of the vapor above the liquid. This pressure is determined by the temperature of the system. For example, cyclopentene (C_5H_8) obeys the relation:

$$\ln P_{vp} = 9.3154 - \frac{2583.07}{T - 39.70}$$

* The third edition of Reid's book gives simple Antoine-form expressions for many compounds for which the fourth edition only provides more complex expressions. When using the third edition formulas, note that the values of pressure are mm Hg. To convert to atmospheres, subtract 6.6333 from the Antoine constant A.

At a temperature T = 298, ln P_{vp} = –0.687, giving P_{vp} = 0.503 atm. If a tray of this liquid is placed in a closed volume and the amount of liquid is sufficient for there to remain a liquid phase, enough liquid will evaporate so that a vapor pressure of 0.503 atm will be established. Since partial pressures and mole fractions are equal in a gas mixture, this also means that the mole fraction of cyclopentene in the vapor space will be 0.503, and that its concentration will be 50.3 vol%. The equilibrium pressure is referred to as *saturated vapor pressure*. The only way that an equilibrium with smaller concentration of the cyclopentene can be established is by putting in so small an amount of liquid that all of the liquid will evaporate and not enough will be present to establish a liquid/vapor equilibrium. The only way that a larger amount of cyclopentene could be introduced would be by atomizing and spraying the liquid into the air. However, while higher amounts can be introduced in this manner, they are in the form of an aerosol and not a vapor. If time is allowed for equilibration after such a spraying has occurred, the excess amount will rain out into the reservoir of liquid at the bottom of the container.

The *boiling point*, T_b, of a pure liquid, by definition, is the temperature at which its vapor pressure is equal to the ambient pressure. The ambient pressure of interest is generally 1 atm. A liquid which is the mixture of several components does not have a unique boiling point. Instead, as temperature is raised, the lower-boiling-point fractions start boiling off first, with the higher-boiling-point fractions following later. This principle is utilized in the process of fractional distillation, where several relatively-pure substances can be recovered from a mixture.

Normal flammable or combustible liquids are not capable of ignition *as a liquid*. A high-temperature oxidation reaction (combustion) can occur only with the vapors of such liquids, not the liquids themselves. In other words, evaporation must occur first, only then followed by combustion. This process is intrinsically more complicated than the ignition of gases, where no change of state of the substance needs to be considered. While the knowledge that the vapors of flammable liquids burn, rather than the liquids themselves, is now very basic, it was not until 1931 that this fact was conclusively demonstrated.

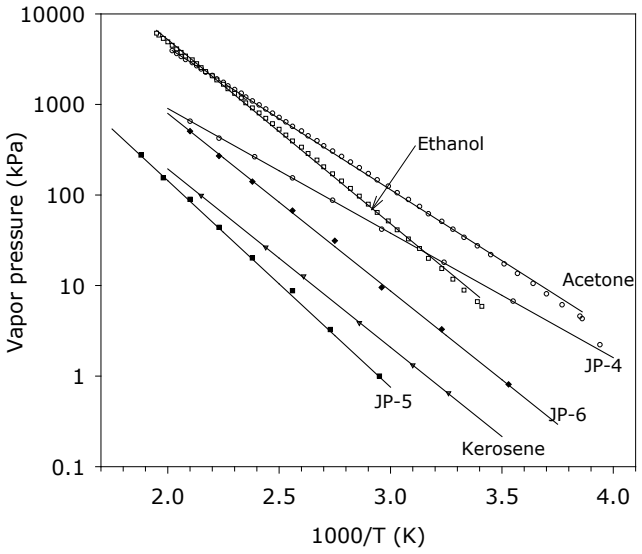

Figure 2 Vapor pressures represented according to the Clapeyron equation

Autoignition of liquids

In the ignition of gases, autoignition is very simple to understand conceptually. A fuel/oxidant mixture is not exposed to any localized energy sources. The temperature of the mixture is raised until ignition occurs. Not only is this notion relatively simple conceptually and experimentally, it also lends itself to a straightforward theoretical treatment. At the start of this Chapter, however, we observed that, apart from certain reactive substances, liquids do not show an ignition event by themselves. As its temperature is raised, a liquid will vaporize more rapidly. If the vapors are removed, however, all of the liquid will boil away and no ignition event will happen. Thus, clearly, just raising the temperature is not a sufficient way to provoke autoignition of liquids.

In fact, autoignition of liquids might best be considered to be a misnomer. To see what actually happens, we need to consider details of how engineering tests for 'autoignition of liquids' are conducted. These are considered in detail at the end of this Chapter. Here, we can succinctly summarize a typical test used for autoignition of liquids. An empty cup, exposed to air or with an air stream directed through it, is heated to a given temperature. One or more drops of the liquid are dropped into the heated cup. An observation is recorded whether ignition occurred. This process is clearly peculiar for several reasons:

(1) While the cup and air may be at a relatively uniform temperature, the rest of the system is clearly not; especially, since the droplet is normally introduced while it is still at room temperature.
(2) Contrary to the notion that autoignition involves the use of no localized sources of high temperature or external energy, the heated cup surface is clearly of a much higher temperature than are the vapors being released from the droplet.
(3) The fuel/air ratio is a fundamental variable affecting the ignition temperature in the gas phase. Yet, the fuel vapor concentration is undefined and uncharacterized.

Thus, perhaps it is best to simply consider 'autoignition' of liquids to correspond to a certain type of empirical testing, but not to be a rigorous, theoretically definable process. A practical question then is: What is the relationship between that AIT of the liquid's vapors and the results of one of the liquid-droplet tests? The answer, unfortunately, is that not enough data is available to make general conclusions.

IGNITION OF SINGLE DROPS

At some temperature above the flash point temperature, an ignitable liquid's vapor that accumulate in a closed space can ignite without the presence of any external pilot. This is known as the autoignition temperature (AIT). To determine the AIT in a practical test, a maximum waiting time (ignition delay, ignition time, or induction period) has to be defined for how long observations are continued in the absence of a flash. For temperatures higher than the AIT, the ignition delay will be shorter than this arbitrarily defined waiting time. An illustration of the relation between temperature, T (K) and the ignition delay t_{ig} (s) is given in Figure 3[7]. If vaporizing liquid drops obeyed the theory presented in Chapter 4 for gases, plotting $\ln(t_{ig})$ against $1/T$ should give straight lines; experimental results show that distinct curvature is found.

Ignition of single drops has been studied for a long time, but without conclusive results of broad generality being achieved. In 1954, Nishiwaki[8] studied the ignition of single drop inserted on a silica filament into a furnace. His data indicted that, at a fixed temperature, the ignition time t_{ig} could be expressed as:

$$t_{ig} = a + bd$$

where d = diameter, and a and b are constants for any particular fuel type. He also found that, in the case of two droplets, there was a proximity effect, and droplets separated by 4 – 5 times their diameter showed a faster ignition time than did droplets spaced closer or farther apart. Similar data were also presented by Masdin and Thring[9], who show that:

$$t_{ig} = a + cd\exp(E/RT)$$

where c is another constant, E = effective activation energy (kJ mol^{-1}), R = universal gas constant (= 8.314 J mol^{-1} K^{-1}), and T = temperature (K). Thus, a single expression is developed which takes into account both diameter and temperature dependence, although they caution that their expression should not be applied to residual oils and other high-molecular-weight petroleum products. By comparing the above equation against the results of Figure 3, it can be seen that straight lines would be achieved if $a \equiv 0$. But the a term will normally be non-zero because it effectively expresses the time needed to vaporize the drop, before reactions in the vapor-phase can commence.

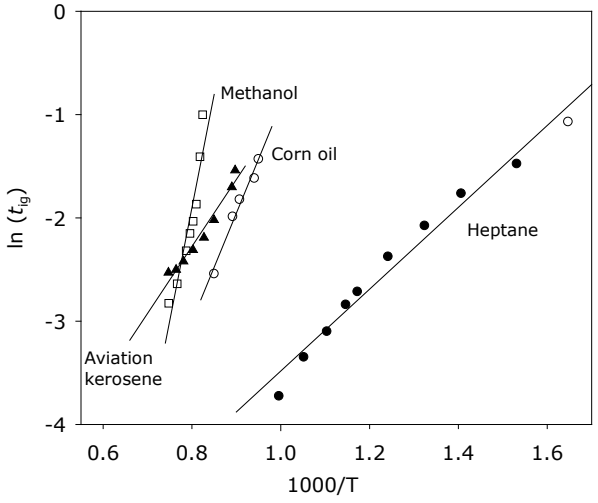

Figure 3 Ignition times for autoignition of single 1.5 mm drops

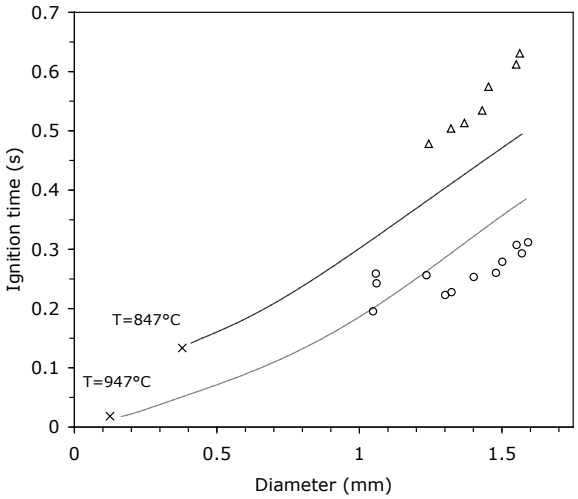

Figure 4 Effect of diameter on ignition for *n*-hexadecane drops in an air stream with 2 m s^{-1} velocity and at two different air-stream temperatures; solid lines indicate predictions from theory; × denotes smallest ignitable diameter *(Copyright The Combustion Institute, used by permission)*

Taylor and Burgess found that the ignition temperature of small drops of residual fuel oil follows the relation[10]:

$$T_{ig} = \frac{76.6}{d} + 218$$

where T_{ig} = temperature of the drop at ignition (ºC) and d = diameter (mm).

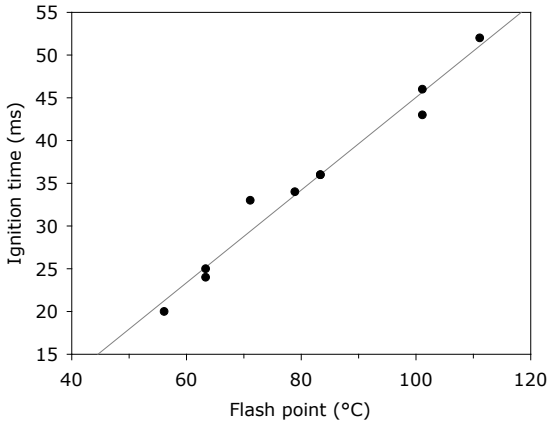

Figure 5 Effect of flash point on ignition time of 1.2 mm drops

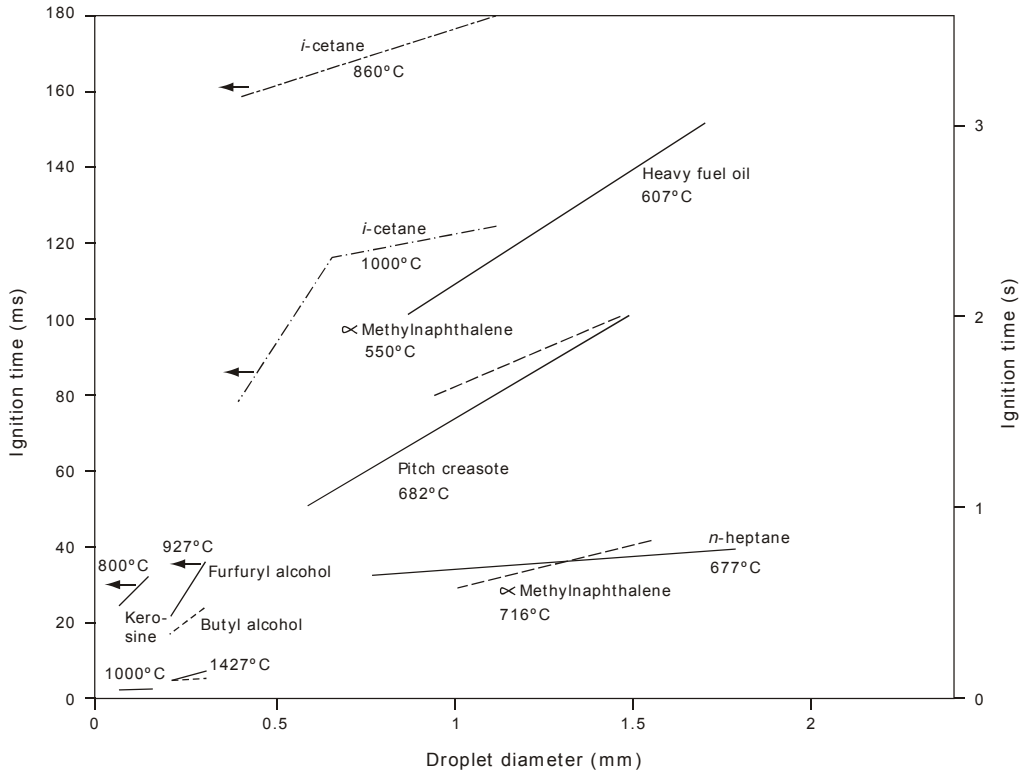

Figure 6 The effect of droplet diameter on ignition time. Note that some fuels are plotted against the left-side time axis *(Reproduced with the permission of The Institute of Energy, London)*

The ignition of single droplets in a forced-convection hot-air stream was studied by Wong et al.[11] They developed a theory (solved numerically only) along with some experimental data (Figure 4). Note that there is a minimum diameter below which the droplet vaporizes without ignition. For the cases where ignition does occur, it generally happens while the droplet diameter is still nearly its original size (>90%). Figure 4 also illustrates that the minimum temperature of an air stream is higher to achieve ignition of a small drop than for a larger drop. The reason is because a small, single drop cannot provide as much flammable vapor as can a larger drop. This relation only holds for single drops in isolation; as will be seen below, for liquid aerosols the opposite trend is found. There is, in general, not much data on critical droplet diameter, but Molero de Blas[12] found a critical diameter of ca. 1.0 mm for a variety of residual oils, when injected into a 600ºC furnace, dropping to 0.5 mm for an 800ºC temperature.

Saitoh et al.[13] conducted experiments with *n*-heptane and *n*-hexadecane. For both fuels, they showed that the minimum furnace temperature needed for ignition decreased, as the droplet diameter increased. For *n*-hexadecane, the ignition time increased with diameter, similar to Nishwaki's findings. But for *n*-heptane, ignition time was roughly constant, except at the smallest diameters, where it increased. Tanabe et al.[14] showed that *n*-heptane droplets undergo a two-stage ignition process, with hot-flame ignition preceded by a cool-flame reaction taking place at ca. 480ºC. Moriue et al.[15] studied the ignition of single droplets of *n*-decane at pressures from ambient to 2 MPa. They found regions of cool-flame, hot-flame and two-stage ignitions, along with interspersed zones of non-ignition. At ambient pressure, they found: below 310ºC, no ignition; 310 – 440ºC, cool-flame ignition; 440 – 650ºC, no ignition; over 650ºC, normal-flame ignition. Two-stage ignitions were found only at pressures over 2 atm.

Bryant[16] studied the ignition of single, 1.2 mm drops suspended on a thin wire and ignited by rapidly presenting the hot exhaust gases of a burner below the specimen. His results (Figure 5) showed an ignition time proportional to the flash point. This was considered reasonable since it requires more time to reach a flammable vapor concentration if the flash point is higher. The actual hot-gas temperature was not characterized, nor were different heating regimes explored. The liquids examined were primarily proprietary. Points for JP-5 (not shown) did not fall on the line and Bryant attributed this to the very wide range on volatilities represented in the fuel mixture.

Goodger[17] reviewed a number of studies on ignition time of liquid droplets. The main trends that he found are shown in Figure 6. Typically, a linear increase in ignition time is found with increasing droplet diameter. This occurs because larger droplets need a longer heating time before their sur-

face reaches a temperature at which an adequate mass flux of vapors is being produced.

The effect of *fuel stoichiometry* on the induction period has also been studied by Goodger, but no general trends emerge. For very short ignition times, however, the mixture ratio appears to be a relatively unimportant variable. For single droplets of iso-octane, Faeth and Olson[18] found a *pressure* effect of the form $t_{ig} \propto P^{-2.6}$. Additional data are shown in Figure 7.

Within a given chemical family, the ignition time tends to increase with the *number of carbon atoms*[19]. This effect is due to physical reasons and not chemical. As shown in Chapter 4, the AIT of vapors generally decreases as the number of carbon atoms increases. But molecules with a larger number of carbon atoms are less volatile and a longer time is needed for a sufficient amount of vapor to be released. *Multi-component fuels* tend to have a complex drop-size/ignition time relationship. Takei et al.[20] explored this for several binary fuel combinations and summarized the general trends in Figure 8.

A number of workers put forth autoignition theories for single-drop ignition[21-24] and Mawid[25] reviewed the efforts up to 1989 in some detail. Thus far, however, none are both validated and reasonably tractable (i.e., not requiring that the user set up and solve differential equations on a computer). The problem is complex due to its highly unsteady nature, so that simple approximations, if made, do not tend to lead to good predictions. The effect of water in a fuel droplet, i.e., an *emulsion*, was studied by means of theoretical model by Jeng[26]. He found that, for water content of less

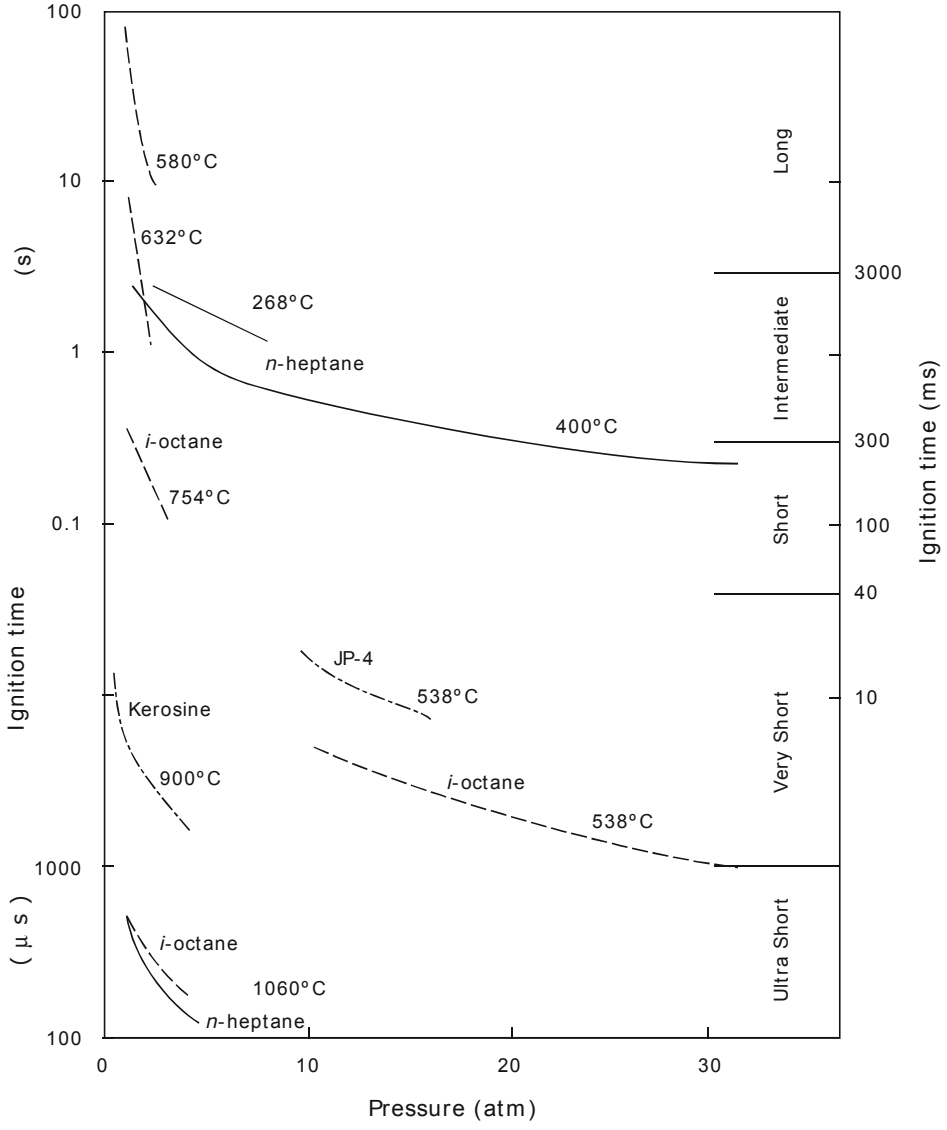

Figure 7 The effect of pressure on ignition time of liquid aerosols
(Reproduced with the permission of The Institute of Energy, London)

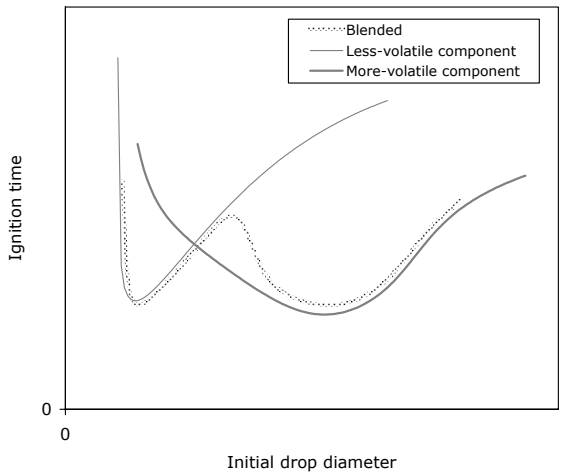

Figure 8 Effect of drop diameter on ignition time of blended fuels

than 20%, the effect on ignition time was negligible; higher water percentages caused an increase in the ignition time.

LIQUID AEROSOLS OR SPRAYS

Boilers, furnaces, and other forms of wanted combustion commonly used liquid fuels in the form of aerosols (also known as *mists* or *clouds*). Unwanted fires involving aerosols often happen subsequent to a piping system springing a leak. Nozzles and other atomizing devices can normally produce droplets in the range 5 – 300 μm although droplets below about 30 μm are more difficult to produce. Smaller diameter particles are often created as *condensation mists*, when an evaporated material begins to cool; for a number of liquids, mists of 0.2 – 2.0 μm can be produced by condensation[27].

Liquid aerosols are sometimes characterized by C, defined as $C = \dfrac{\text{inter - drop distance}}{\text{drop diameter}}$. Thus, a classification has been suggested[28]:

$C >> 10$	Aerosol traits are minimal and droplets behave as individual droplets.
$C \approx 10$	Strong inter-drop interaction, ignites and burns with a flame surrounding entire cloud. Hayashi et al.[29] showed that for *n*-decane the regime corresponds to $C < 30$.
$C < 5$	Very dense sprays; not a common situation.

Wong et al.[30] however showed that C is not the only geometric variable and that the drop diameter continues to play a role. Their experimental investigations led to the conclusion that liquid aerosols can autoignite in one of three modes:

- *Local ignition* – aerosols of large-diameter droplets ignite in a manner similar to single droplets, where there is minimal interaction from adjoining droplets.
- *Global ignition* – for aerosols of smaller-diameter droplets, the reaction zone is distributed between the droplets and droplets no longer behave in an isolated way. When the aerosol ignites, flame surrounds the outside of a region encompassing many drops, while the inside does not exhibit flaming since it is too fuel-rich.
- *Homogeneous ignition* – aerosols of smaller-yet droplets, when exposed to high temperatures, vaporize before igniting; thus, their ignition is indistinguishable from that of a uniform vapor.

These different modes are illustrated in Figure 9. The designations H, G, and L denote the three ignition regimes; the numbers at each curve denote the overall equivalence ratio of the aerosol, with values of C being given in parentheses. The data in the figure pertain solely to an air temperature of 1500 K. At that temperature, the homogeneous ignition regime occurs for droplets smaller than 25 – 45 μm, with the exact value depending on the stoichiometry and the droplet spacing. The air temperature does affect the minimum size; at 1300 K, the regimes goes out to ca. 70 μm, while at 1800 K it exists only below 20 μm.

Rah et al.[31] studied the ignition of aerosols of *n*-dodecane and No. 6 fuel oil as a function of oxygen concentration. Their results (Figure 10) show that the ignition time varies approximately as $t_{ig} \propto C_{O_2}^{-0.5}$.

Wood and Rosser[32] studied the ignition of hexadecane drops in several arrangements—as single drops, as a group of 3 – 5 drops, and as a stream of 60 drops/s. Their results (Figure 11) show that all of the arrangements can be correlated by an equation of the form:

$$d^2 = g \exp(-E/RT)$$

where d = drop diameter (mm), g = a constant which depends on the arrangement, E = effective activation energy

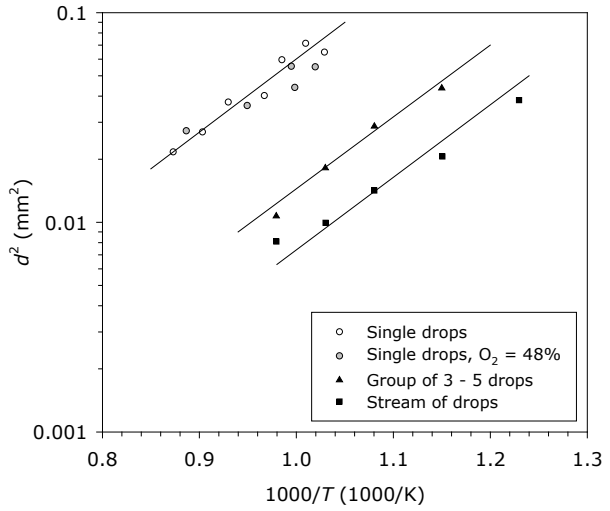

Figure 11 Relation between drop diameter and furnace temperature needed for ignition of hexadecane drops

(kJ mol^{-1}), R = 8.314 J mol^{-1} K^{-1}, and T = furnace temperature (K). For hexadecane, the slope is found to be 8.05, giving E = 1000×8.314×8.05 = 67 kJ mol^{-1}. It is also interesting to note that there was no detectable difference between the results obtained at 21% oxygen concentration and at 48%, although Wood and Rosser point out that theoretically a very small effect should exist.

Hiroyasu[33] measured autoignition times for sprays (of unspecified droplet diameter) in a high-temperature, high-pressure environment and obtained the following equation giving a reasonable correlation of results:

$$t_{ig} = AP^B \varphi^C \exp(D/T)$$

where t_{ig}= ignition time (ms), P = pressure (atm), φ = equivalence ratio (--), and T = temperature (K), with the constants A, B, C, and D being given by:

Fuel	A	B	C	D
light oil	0.276	–1.23	–1.60	7280
heptane	0.748	–1.44	–1.39	5270
dodecane	0.845	–1.31	–2.02	4350
hexadecane	0.872	–1.24	–2.10	4050

Some examples of the effect of droplet concentration are shown in Figure 12, as measured by Laster and Annamalai[34]. Octane becomes progressively easier to ignite as the concentration increases, while dodecane shows a minimum value, and becomes more difficult to ignite at higher concentrations. The authors attribute this difference to the fact that dodecane has a higher boiling point than octane and, thus, is more difficult to vaporize—thus, a large fuel mass effectively acts as a heat sink.

Turbulence decreases the AIT for liquid aerosols[35]. Ignition times for liquid droplets in *microgravity* are shorter than in normal gravity[36]. This is due to the absence of convection.

Because of the large number of variables involved, no simple theories for the ignition of clouds of liquid droplets have emerged. Sichel and Palaniswamy[37] developed an elaborate theory which they solved numerically for the case of an 0.1 m diameter cloud of octane droplets, present at a number density of 10^9 particles/m^3. Their solution gives a cloud ignition temperature of around 190ºC, as compared to 630ºC for a single 100 μm droplet. McIntosh et al.[38] developed a variant of Semenov theory which includes fuel in both droplet and vapor phases. Several reviews[39,40] are available of theoretical models for the autoignition of liquid

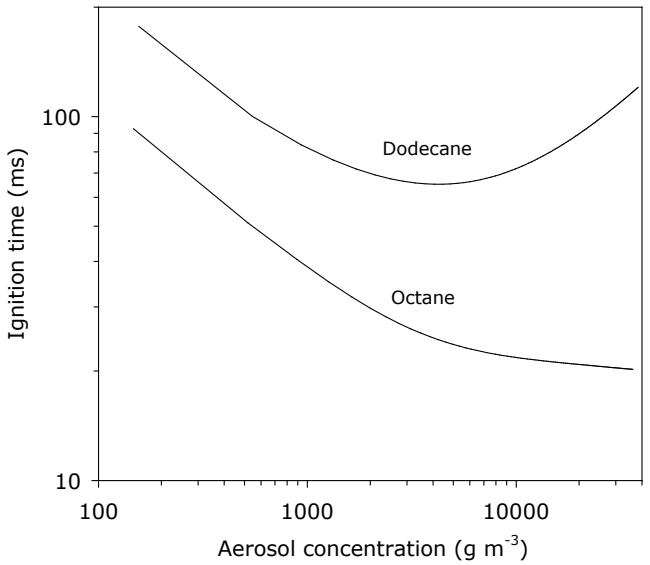

Figure 12 Autoignition time for aerosols of 100 μm dodecane and octane droplets at a furnace temperature of 927ºC

aerosols, but unfortunately it is seen that most of these models are not accompanied by validation against experimental data.

Flash point and fire point

FLASH POINT

The most basic question to be considered in the ignitability of liquids is the following. An open dish of a certain liquid is placed in a certain atmosphere. What are the conditions under which it will ignite from a small flame? To deal with this question, we will first assume that the atmosphere into which the dish is introduced is fully mixed, that is, that there are no concentration gradients anywhere before the dish is introduced. Furthermore, it will be useful to assume that the atmosphere is still. Let the dish contain methanol and the atmosphere be 21% oxygen/79% nitrogen. There are no methanol vapors in the atmosphere before the dish is introduced. In a thought experiment, let us introduce a pilot flame slightly above the methanol dish at time $t = 0$. Ignition will clearly not occur, at any temperature of the atmosphere, because there are yet no methanol vapors in the atmosphere. So, first, evaporation and diffusion must occur. Because the atmosphere is 0% methanol and the dish is 100% methanol, a flow of methanol vapor will start to leave the liquid dish and move into the atmosphere. Piloted ignition will occur—in the gas phase—when at some particular place in the atmosphere,

1. an adequate concentration of the liquid's vapor exists above the liquid,
2. an adequate concentration of an oxidizer is mixed in with the fuel vapors,
3. a localized heat source of sufficient magnitude is present.

If the dish is small and the space into which it is introduced is large, there may be only a very small zone where a flammable mixture will be found. We may also run out of fuel and not reach a significant fuel vapor concentration in the atmosphere. Consider now the more specialized case. Suppose the dish is introduced into a rather small space. Let the space be closed, but with a small hole, so that its pressure will always equilibrate with atmospheric pressure. Under these conditions, it will be easier for the fuel vapors to fill the whole space more quickly and to reach higher ultimate concentrations. The former case may represent a fire accident in a processing facility. The latter case represents a closed-cup flash point test. The conditions have been arranged to represent, more or less, a worst case situation.

If the volume of the space is small, and if we wait for a sufficiently long time, a steady-state concentration of fuel vapor will be found in the atmosphere. The volume percent of fuel vapor y_f is the atmosphere will be:

$$y_f = 100 \times p / P$$

where p is the saturated vapor pressure of the liquid at the temperature T, and P is the atmospheric pressure. Provided that the temperature is not too close to the critical temperature, the vapor pressure of a liquid can be represented as a simple function of T by the Antoine equation, as given above.

If the temperature T is low enough, a steady-state fuel vapor concentration will be achieved, but a small flame introduced into the atmosphere will not cause ignition. This will happen if at T the value of y_f is below the LFL. As the liquid reaches a certain temperature, however, the first possibility of ignition will occur. This temperature is called the *closed-cup flash point*. Thus, theoretically it should be possible to compute the closed-cup flash point by knowing the LFL of the substance, converting it to fuel vapor pressure, and then solving the Antoine equation for T. Such a calculation of the flash point typically gives a value which is close to the measured one, but sometimes significantly farther away than would be due to just the repeatability of the test[41]. This is because both the LFL and the flash point determinations are somewhat dependent on the apparatus details. While these can be standardized, there is no single 'right' way that the test equipment can be constructed.

It is loosely considered that the flash point temperature corresponds to the value LTL (the concept of LTL was explained in Chapter 4). Such a relation is only conceptually true. In practice, the actual value of both the flash point temperature and the LTL are apparatus-dependent and the determinations are made in two entirely different apparatuses: a flash point tester and a flammability limits apparatus. In neither type of apparatus are there absolutely perfect test conditions. The vapor concentrations are not perfectly uniform, there are wall effects, etc. The *ignition source itself* will be a source of turbulent mixing and localized concentration variations. The small flame, spark, etc., causes extremely high temperature gradients and this, in turn, disturbs any pre-existing vapor concentration levels.

In an *open-cup* configuration, a cup holding the liquid is situated in essentially an open atmosphere. The concentration of fuel vapors is highest near the liquid's surface, but progressively diminishes towards zero as the height above the cup increases. Since the igniter cannot be placed directly at the liquid's surface, the location at the igniter has a lower vapor concentration and, consequently the OC flash point is higher than the CC. It is generally found that the CC flash point is several degrees Celsius higher than what would be predicted from the LFL/vapor pressure relationship. In turn, the OC flash point is several degrees higher than the CC value. Factory Mutual[42] tested a number of compounds for which they gave both OC and CC results. Figure 13 shows these data along with the correlation:

$$T_{FP(OC)} = 1.12\, T_{FP(CC)} + 7.1$$

but it has to be remembered (see below) that there are systematic differences between test apparatuses, not just OC vs CC conditions alone.

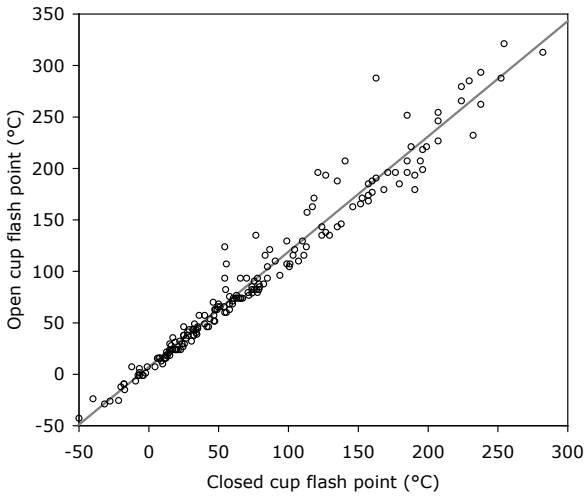

Figure 13 Relation between OC and CC flash point values

A substance does not necessarily have to have its flash point be above its freezing point. While this is true for the vast majority of organic substances, cyclohexane is a notable exception. Its open-cup flash point is –17ºC, while its freezing point is 6.5ºC.

By definition of NFPA 30, a liquid is termed *flammable* if it its flash point is less than 100ºF (37.8ºC), and *combustible* if the flash point is equal or greater than 100ºF. These definitions are somewhat confusing to many people, since it is often desired to refer to liquids that are capable of burning, but whose exact flash point is unknown or unimportant. The term *ignitable liquid* can be used to cover both flammable and combustible liquids, but its use is likely to not be understood by the layman. Flash point values must not be assumed to apply to aerosols, since these can often ignite at lower temperatures than the flash point determined for quiescent liquids.

The flash point is measured in apparatuses using very small quantities of liquids. Since the possibility of explosions will usually concern kilogram, not gram, quantities, the question arises whether the small-scale results adequately represent a large-scale reality. Shepherd et al.[43] concluded that they do not, at least for the Jet A fuel that they examined. In their work, they found that flashing occurred in larger-scale apparatuses at about 10 – 15ºC below the measured flash point. Now, jet fuels are highly complex mixtures, and it is not clear that this conclusion can be generalized to other fuels; nonetheless, the finding is troubling. The authors also pointed out that, with complex mixtures, a stable fuel essentially does not exist, and that they encountered flash point shifts in their work that were not explainable.

UPPER FLASH POINT

For some specialized applications, it is also possible to determine a rich-limit flash point or upper flash point. This corresponds to a temperature so high that the equilibrium vapor mixture of the liquid's vapor and air is at the rich flammability limit. Such a limit can be demonstrated with gasoline by dropping a lighted match into a gasoline can which is equilibrated with air at room temperature. If the mixture is indeed in equilibrium and has not been otherwise stirred or ventilated, it should be possible to watch the match extinguish. An explosion will result, however, if the vapor mixture is not above the rich flammability limit, for instance, by stirring in air into the can.

Measurements of the upper flash point are not commonly made, but Hasegawa and Kashiki[44] reported on a series of results obtained using the closed-cup Setaflash apparatus. Empirically they also derived:

$$T_{ucc} = UTL + 6.4$$

where T_{ucc} = upper closed-cup flash point and UTL = upper temperature limit of flammability (see Chapter 4). The scatter of this relation was reported as ±5.3ºC.

THE FIRE POINT

The fire point of a liquid, in contrast to its flash point, is the minimum temperature at which a *sustained* flame will result upon application of a pilot flame. It must be measured in an open vessel (e.g., an open-cup flash point test apparatus), since oxygen depletion in a closed-cup device would prevent sustained burning from being achieved. The definition is not complete without specifying a time limit for distinguishing between flashing and sustained flaming. ASTM test methods use a 5 s value. Some illustrative values are given in Table 3. The examples given in Table 3 are for simple, non-halogenated liquids. For some other liquids, the fire point can be greatly higher than the flash point; Figure 14 illustrates this for some aviation hydraulic fluids and lubricating oils[45].

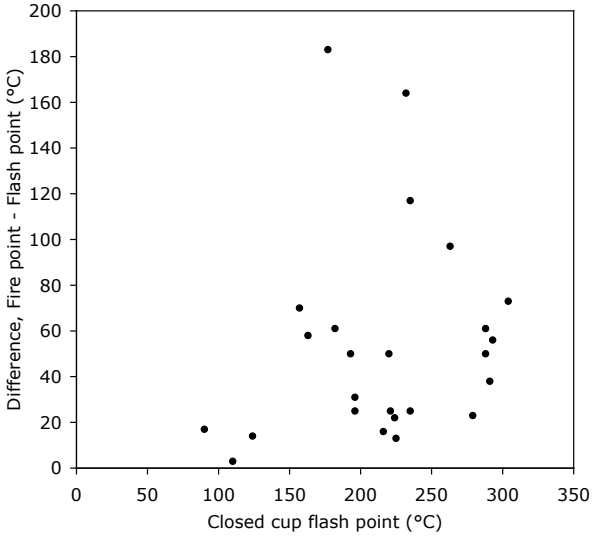

Figure 14 Relation of fire point to flash point—some trends for aviation hydraulic fluids and lubricating oils

Table 3 Example values of closed-cup flash point, open-cup flash point, and fire-point temperatures

Substance	Closed cup FP (°C)	Open cup FP (°C)	Fire point (°C)
n-hexane	–22	–26	
n-heptane	–4	–1	2[47]
methanol	12	1.0[54], 16[42]	1.0[54], 17[47]
n-octane	12	17[51]	18[51]

o-xylene	32	36	42[51]
JP-6		38	43[49]
n-decane	44	52	61.5[54], 66[48]
decalin		57	63[49]
tetralin		71	74[49]
bicyclohexyl		74	79[49]
dodecane	74		103[48]
fuel oil, No. 2	124		129[50]
fuel oil, No. 6	146		177[50]
glycerol	160	176	207[48]
motor oil	216		224[50]

The combustion process associated with the fire point is different from that for a flash point. When a flash point is being determined, a premixed fuel-air mixture has been created and a flame rapidly propagates through the mixture. The fire point, however, is associated with steady burning. For a vaporizing liquid, such steady combustion comprises a diffusion flame. Thus, there is not necessarily a simple, physical relationship between the flash point and the fire point. In general, the relation among the various temperatures pertinent to liquid ignitions is:

$$T_{flash\ point} \quad T_{fire\ point} < T_{s.s.\ surface} < T_b$$

It is clear that there is no more liquid above the boiling point T_b, therefore all of the other characteristic temperatures for a liquid must be lower. Also, from the definition of fire point, it cannot be lower than the flash point. As illustrated in Table 3, for liquids with $T_{flash\ point}$ below about 40°C, the fire point is commonly about 3 – 10ºC above the CC flash point. For liquids with high flash points, however, the difference becomes progressively greater. In the case of certain alcohols, however, the flash point and the fire point have been found to be identical.

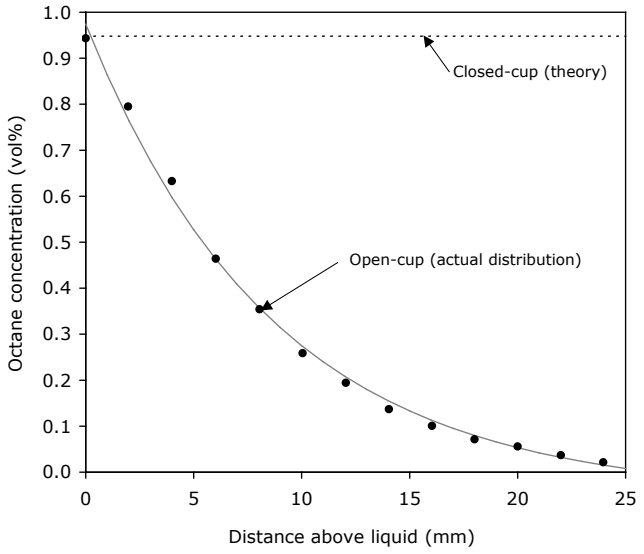

Figure 15 Fuel vapor distribution above an open cup of *n*-octane at 14ºC

Finally, it should not be surprising that if the liquid is ignited and burns in a steady state, $T_{s.s.\ surface}$, the liquid's surface temperature will be higher than $T_{fire\ point}$, but slightly lower than T_b. If a liquid is vaporizing, without burning, then $T_{s.s.\ surface}$ will be slightly lower than the ambient temperature. This occurs because vaporization is an endothermic process, so since heat is removed from the system, its temperature must drop.

THE PRE-FLASH 'HALO'

It is well-known that when some fuels (but not alcohols) are tested in a flash-point apparatus, a blue halo can be seen around the igniter at some temperature slightly below the flash point temperature. This halo does not propagate beyond the immediate vicinity of the igniter and, thus, according to standard testing instructions, does not constitute the flash point. The nature of this halo has been documented[51], but the mechanism is not explained. With other fuels, the ignitor flame gets enlarged and turns from blue to yellowish-green; again, in the absence of overt flame propagation, this is not considered to constitute a flash point. The changed color is attributed to thermal decomposition of the fuel vapors[46].

THE DISTRIBUTION OF FUEL VAPORS ABOVE THE SURFACE

The concentration of fuel vapors above the liquid surface is constant if the vessel is closed, but decreases with height for an open-top vessel. Figure 15 shows a measured concentration distribution obtained for octane filled to the top of a 50 mm diameter open cup[51]; the temperature of the liquid is slightly below its flash point. The vapor pressure of octane is 960 Pa at 14ºC, which is 0.948% of 1 atm. The data shows that a fuel vapor concentration of approximately 0.948% is indeed found next to the surface, with an exponential decrease for other heights. In about 6 mm, the concentration has dropped off to half its value at the surface. Because the concentration changes greatly with small changes in height, it may be surmised that highly precise placement of the ignition flame would be needed in an open-cup flash point tester if reproducible results are to be obtained. Experimental results confirm this (see below).

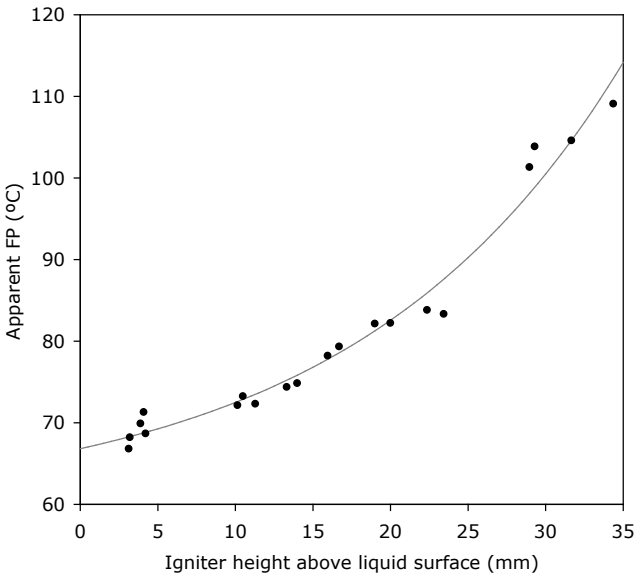

Figure 16 Effect of igniter height on the apparent flash point of hexanol found by using an electric igniter in the Pensky-Martens flash point tester (solid line represents best fit through data points, not a theoretical prediction)

The fuel vapor concentration above an open dish is hard to compute theoretically because 3-dimensional diffusion is involved. But for simpler geometries, the concentration distribution can be computed. The classical problem—called the *Stefan problem*—involves a straight-sided, open-topped tube with a layer of liquid on the bottom. It is assumed that there is a strong cross-wind at the top of the beaker, so that the fuel vapor concentration is zero at the top. With this assumption, the problem can be solved, since the diffusion of vapor is only 1-dimensional. The vapor distribution is exponentially decreasing with height in such a configuration, and details of the solution can be found in textbooks on mass transfer[52]. Additional aspects of the Stefan problem are considered in Chapter 13.

Burgoyne et al.[53] developed a more refined model for predicting the open-cup flash point by (a) examining the effect of tube heights equal to either the actual lip height above the liquid surface, or a height of infinity; and (b) solving a transient problem as occurs in flash-point testers where the liquid is continuously raised in temperature, instead of being preset at a given value. The model was used to predict flash point values as a function of igniter height above the liquid surface. The results from the model only roughly corresponded to the measured values, but the latter are interesting by themselves and are shown in Figure 16. In their tests, the authors used a Pensky-Martens tester modified to use an electric igniter instead of a flame, since a flame was found to have a sizable disturbing effect on the temperatures within the apparatus.

Based on data such as the trend line shown in Figure 16, it might be supposed that the most conservative height for placing a pilot flame would be infinitesimally above the surface. But if the flame is placed very close to the surface, much of its energy is imparted to the liquid phase and becomes unavailable for igniting the vapors. The minimum height for the igniter to be placed is termed the *quench layer height*. Glassman and Dryer[54] measured the effect of igniter location for samples of decane (Figure 17). The flash point determined with the igniter at 6.35 mm above the surface (the standard igniter height in the ASTM D 1310 Tag open-cup flash point test) is 55ºC. However, the lowest flash point found was 52 – 53ºC, which occurred when the igniter was placed closer to the liquid. Placing the igniter closer than about 3 mm produced only a blue 'halo' around the ignition flame, but did not lead to a flash propagating over the surface. Thus, a quench layer height of about 3 mm was found for decane. In principle, a different quench layer height might be obtained in the determination of the fire point. Once above its quench layer height, however, the results suggest there is a plateau over which the fire point value determination would not change. This is different from the flash point, which is seen to increase monotonically with increasing height. At large heights, the flash point

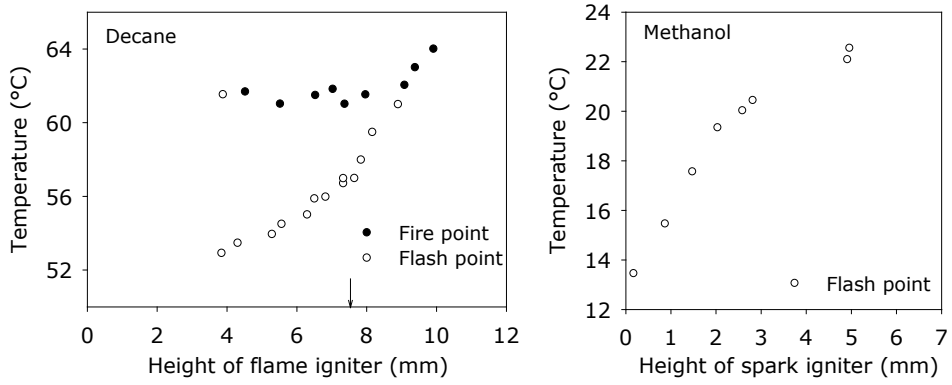

Figure 17 The effect of igniter height for decane and methanol. Arrow indicates height of flame igniter in ASTM D 1310 Tag open-cup test
(Copyright Elsevier Science, used by permission)

keeps increases with height, as shown by Zinn[55] for pools of JP-4 and JP-5. His experiments covered the range of 25 – 125 mm.

Table 4 Flash points and quench layer heights for alcohols determined by Glassman and Dryer

Fuel	T_T (°C)	T_{cc} (°C)	T_{oc} (°C)	$T_{oc\text{-}sp}$ (°C)	δ_q (mm)
methanol	9.5	11.1	1.0	13.5	0.25
ethanol	11.9	13	6.0	18.0	0.25
n-propanol	22.8	26	16.5	26.0	0.30
n-butanol	31.8	35	36	40.5	0.40
45% ethanol/ 55% water	--	27.8	27	29.0	0.30

T_T – theoretical flash point, computed from LFL and vapor pressure curve
T_{cc} – closed cup flash point
T_{oc} – open cup flash point
$T_{oc\text{-}sp}$ – open cup flash point determined by spark
δ_q – quench layer height, determined for spark ignition

Glassman and Dryer also examined in detail the ignition behavior of a series of alcohols. For most fuels, the open-cup flash point is several degrees above the closed-cup value. Thus, their contrary results (Table 4) needed to be explained. The anomaly was found to lie in the fact that, for alcohols, even a minimal igniter flame, placed at the height giving the lowest temperature, causes enough of the heat flux to impinge on the liquid to preheat it locally. Thus, Glassman and Dryer conducted additional open-cup tests using a spark, instead of flame, ignition source. With the exception of *n*-propanol, these results now show the expected relationship that $T_{oc\text{-}sp} > T_{cc}$. The anomalous flash point behavior of alcohols is related to their extremely small quench layer heights, which is a fraction of the value (say, 3.0 mm) seen with other fuels. The study did not elucidate, however, a chemical reason for the anomalous behavior of alcohols. The values of the quenching distance for vapors of alcohols, measured in the normal way, are not particularly different from those for hydrocarbons. Thus, some other relationship governs the quench layer heights measured above liquid pools.

Provided that the igniter is above the quench layer, then flash or sustained ignition will occur if the igniter is placed in a region where the vapors are between the LFL and the UFL. If there is a *cross-draft*, then ignition is possible provided that the draft velocity is less than the laminar flame speed. The flame speed to be evaluated is one which pertains to the local concentration of vapors at the igniter location. Zinn[55] showed that the effect of wind velocities up to 4 m s^{-1} was to cause a moderate increase in the flash point value, provided that the pilot was placed at the leeward edge of the pool.

Bunama and Karim[56] conducted an interesting study where they modeled the transient effect associated with quickly pouring a liquid into the bottom of an open-top tube then following the change of fuel concentration with time at various heights. Initially, all of the volume within the tube will be below the LFL. But then a flammable zone will be established and the heights at which LFL and the UFL are located will rise. Thus, a flammable zone will 'detach' from the bottom and move upwards. Figure 18 shows their calculations for pentane, illustrating that the flammable zone (difference between the LFL height and the UFL height) also expands as it moves upwards. Since the UTL of pentane is below room temperature, eventually the flammable zone moves out of the tube and the entire volume is too rich to ignite. In the calculated results, time was expressed as a dimensionless quantity:

$$\tau = \frac{D_{ab} t}{L}$$

where D_{ab} = diffusion coefficient of the fuel vapors in air (m^2 s^{-1}), t = time (s), and L = tube height (m). Similar calculations for methanol showed an upward movement only of the UFL height—the tube never develops a fuel-rich zone and the final outcome is that the entire volume is within the flammability limits.

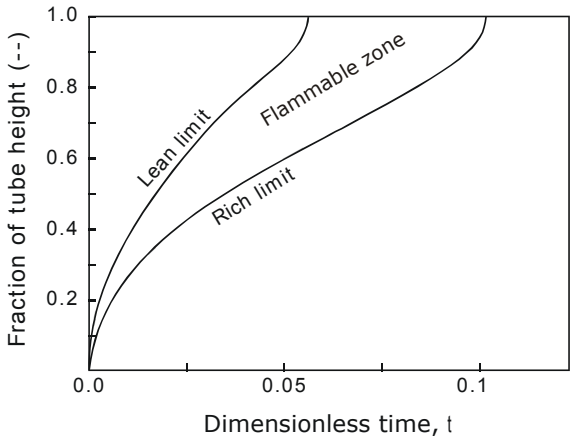

Figure 18 Heights of the LFL and the UFL in a tall tube containing pentane at 22ºC

ESTIMATIONS OF FLASH POINT

For a homologous series of straight-chain organic compounds (e.g., the *n*-paraffins: hexane, heptane, octane, nonane, etc.) flash points form a simple, predictable and extrapolatable series. Thus, if flash points for a number of the members are known, they can be plotted as a function of the number of carbon atoms in the molecule, and unknown members estimated by interpolation or extrapolation. For a group of organic molecules within one chemical family, it is generally found that the flash point:

- increases with increasing number of carbon atoms
- increases with increasing boiling point
- increases with increasing heat of combustion, if the latter is expressed per-mole, rather than per-mass, units.

Relations derived for straight-chain molecules, however, cannot be applied to branched-chain molecules. For instance, when plotted against number of carbon atoms or

boiling point, primary *n*-alcohols (methyl, ethyl, *n*-propyl, etc.) form a smooth curve which, apart from methyl alcohol, is a straight line. But isomers (e.g., isopropyl, isobutyl alcohols) do not necessarily fall on the same line. For impure liquids (e.g., crude oil) the flash point generally increases with increasing specific gravity.

To a rough extent, the flash point varies directly with the boiling point. Figure 19 shows that an approximate, generally conservative estimating rule can simply be given as a linear relationship:

$$T_{FP} = 0.655T_b - 53 \qquad (1)$$

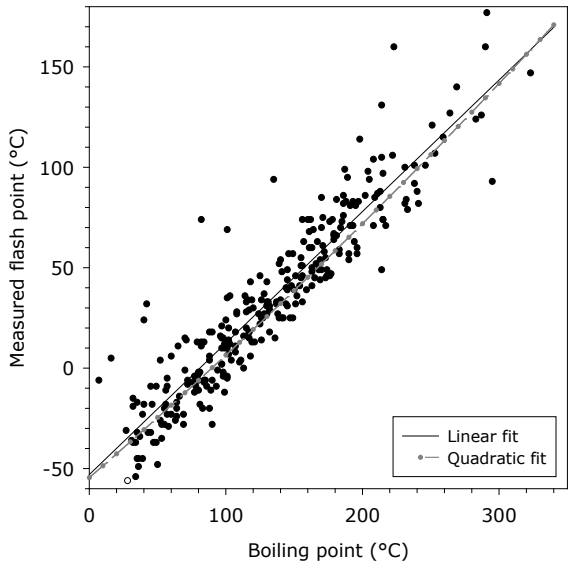

Figure 19 Effect of boiling point on flash point, showing linear fit and Hshieh's equation (quadratic fit)

A number of investigators[57,58] sought more accurate prediction schemes by introducing the possibility of curvature into the prediction line. The latest of these, by Hshieh[59], proposed:

$$T_{FP} = -54.5377 + 0.5883T_b + 0.00022T_b^2$$

His equation is also shown in Figure 19, but, based on 290 organic liquids for which data are plotted, the fit is actually worse. It has sometimes been suggested that a good correlating variable is the *number of carbon atoms* in the molecule, however, these are less successful than simple boiling point correlations, since effects of isomerization, which are ignored when plotting against the number of carbon atoms, can be reasonably taken into account by using the T_b. Another variation on the boiling point theme was suggested by Metcalf and Metcalf[60] who introduced a term for the density of the substance and providing a separate equation for hydroxyl compounds (compounds having an R–OH group):

$$T_{FP} = -87.77 + 0.6223T_b + 0.0383\rho$$

except for hydroxyl compounds

$$T_{FP} = -81.02 + 0.5544T_b + 0.0527\rho$$

for hydroxyl compounds

where ρ = density (kg m^{-3}). Their proposal has not been extensively tested. The *heat of combustion* was proposed as a supplementary variable by Shebeko et al.[61] Their paper gives an erroneous equation, but a correlation based on 290 organic liquids from Table 1 of Chapter 15 gives:

$$T_{FP} = -46.6 + 0.739T_b - 0.00484\Delta h_c$$

where Δh_c = gross heat of combustion (kJ mol^{-1}). The goodness of fit is shown in Figure 20, for which the standard error is 14.52ºC. This compares to a standard error of 16.22ºC for Eq. (1) given above which uses only the boiling point. Hsieh's method gives 17.17ºC, but unlike in his study, no silicone liquids were included in this correlation. The results of Figure 20 show that the larger excursions are almost all on the conservative side, so the corrected Shebeko method appears to be the best of the 'simple' methods.

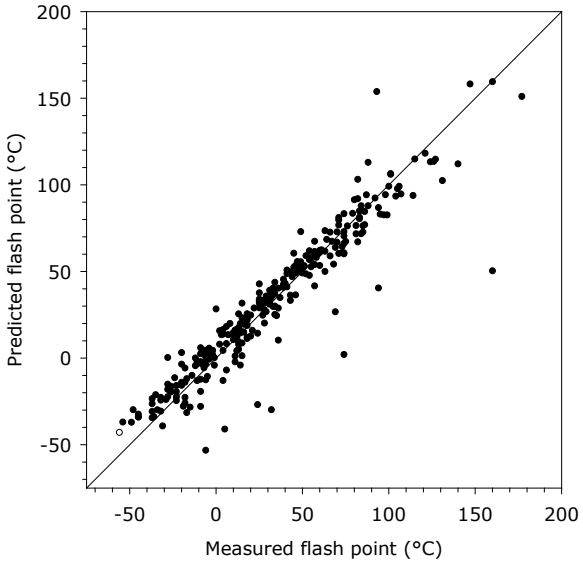

Figure 20 Flash point prediction for 290 organic liquids, based on inclusion of heat of combustion

A large number of researchers have assumed that the flash point ought to correspond to a *fixed value of vapor pressure*, at least within certain chemical families. But for a wide variety of pure chemical substances, Kueffer and Donaldson[62] documented that the vapor pressures at the flash point are mostly in the range from 1.0 to 4.0 kPa, which is a range broad enough to make the concept useless. If attention is focused on a single chemical family, however, more reasonable predictions may be achieved. For example, Fujii and Hermann[63] concluded that average vapor pressure corresponding to the flash point temperature = 1.2 kPa, but the 'family' constant ranges from 0.55 (for alkenes) to 2.3 (for alcohols). Both they and other authors noted that there is no hope of applying a rule of this type to products that are mixtures of substances. This is illustrated

for aviation fuels in Figure 1, which shows that the vapor pressure at the flash point ranges from 0.7 to 2.0 kPa; for low-viscosity petroleum oils, the values range from 0.5 to 2.0 kPa[4].

In 1927, Leslie and Geniesse[64] suggested that an improved predictivity can be obtained by using a value of vapor pressure which contains information on the stoichiometry:

$$p_v = \frac{P_{tot}}{k\gamma_o}$$

where p_v = vapor pressure (atm), P_{tot} = total pressure (typ., 1 atm), k = empirical constant ≈ 8, and γ_o = (moles of oxygen)/(moles of fuel) for stoichiometric combustion (see Chapter 3).

A similar formula was later published by Blinov, the Russian researcher famous for his studies on the burning of liquid pools[65]:

$$T_{FP} = \frac{A_B}{\gamma_o \, p_{FP} D_o} - 273$$

where T_{FP} = flash point (°C); A_B = 4 for calculating the closed-cup flash point, 4.5 for open-cup flash point; and 5.25 for the fire point; p_{FP} = vapor pressure of the substance at the flash point temperature (atm); D_o = diffusion coefficient ($cm^2\ s^{-1}$); and γ_o is the same as before. The equation must be solved iteratively, since the vapor pressure at the flash point will not be known until the flash point temperature is known. The diffusion coefficient D_o will not be found tabulated for uncommon substances, thus, the following equation is used to estimate it:

$$D_o = 1/\sqrt{\sum_i k_i m_i}$$

The constants entering the above equation all come from examining the fuel molecule. The values m_i are the number of atoms of element i present in the molecule, with the summation being over all fuel-molecule elements. The constants k are obtained as follows:

Element	Value of k
hydrogen	1
oxygen	17
nitrogen	16
sulfur	48
chlorine	37
bromine	79

For carbon atoms, however, a more complex strategy is used. For carbon atoms in a benzene ring, k = 25. For carbons in other ring structures, $k = 25 + 2m_C$ if $m_C < 8$, and k = 42 if $m > 8$. For carbon atoms not in ring structures, $k = 25 + 3m_C$ if $m_C \quad 8$, and $k = 50$ if $m_C > 8$.

Two schemes based on vapor pressure data have been offered by DIPPR[66]. One is an iterative scheme similar to Blinov's, but based on more recent Russian research. The second one assumes that the flash point temperature is the temperature at which the vapor pressure reaches its LFL value, that is:

$$P_f(T_{FP}) = LFL \cdot P_{tot} \qquad (2)$$

where LFL is in units of volume-fraction. Since LFL is normally tabulated in units of vol%, using the latter, the relation becomes:

$$P_f(T_{FP}) = \frac{LFL}{100} P_{tot}$$

where $P_f(T_{FP})$ = vapor pressure of fuel at the flash point (Pa) and P_{tot} = total pressure (Pa). To use this scheme, it is necessary to know (1) the LFL, and (2) the vapor pressure for the substance, as a function of temperature. The solution is made by trial-and-error, plugging in various values of temperature and finding the temperature for which the above relation is satisfied. Figure 21 shows that, apart from a small number of outliers (which may well be due to errors of measurement), the method gives reliable results. In practice, however, it is easier to measure the flash point than the LFL, so the method would be more useful for estimating the LFL from a known flash point value.

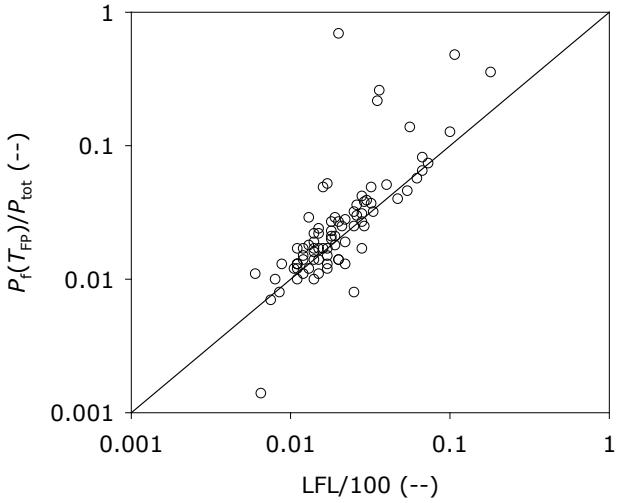

Figure 21 Prediction of T_{FP} according to a DIPPR method (for 81 pure substances[62])

While reasonable predictions may often be achieved, the practicality of schemes based on knowing the vapor pressure of the substance is questionable. Vapor pressure data are available for fewer substances than are flash points; in addition it is much quicker and less expensive to send a sample to a laboratory for flash point testing than it is to experimentally determine a vapor pressure vs. temperature curve.

FLASH POINTS OF MIXTURES

Two liquids may be miscible or not. If they are not, in quiescent conditions one liquid will float on the other. The flash point of two immiscible liquids is determined solely by the flash point of the lower density liquid, that is, the one which floats on top.

For mixtures of miscible fluids, both ideal and non-ideal, Le Chatelier's Law is obeyed. Le Chatelier's Law states that for a multi-component mixture the LFL will be such that:

$$\sum_i \frac{X_i}{LFL_i} = 1 \qquad (3)$$

where X_i is the vapor-phase volume fraction of component i, and LFL_i is its lower flammability limit, expressed as a volume-fraction. Further relations depend on whether the mixture is ideal or not. A rule of thumb is that mixtures are generally ideal if the components are all from the same family of organic compounds (e.g., all alcohols, all ketones) and non-ideal otherwise.

IDEAL MIXTURES

Le Chatelier's Law is not sufficient to compute the flash point of a mixture, since it does not tell us the vapor pressure (and therefore, X_i) of a particular component in the mixture. For an ideal mixture, according to Raoult's Law, the total vapor pressure of the mixture, P_{tot} is:

$$P_{tot} = \sum_i X_{Li} P_i \qquad (4)$$

where X_{Li} = liquid-phase mole fraction of component i in the mixture, and P_i = vapor pressure of the pure component i. From Eq. (2), it is possible to substitute LFL_i by $P_i(T_{FP,i})/P_{tot}$, where $P_i(T_{FP,i})$ = the vapor pressure of component i at the flash point of pure i. On substituting this equality, along with Eq. (4) into Eq. (3), gives:

$$\sum_i \frac{X_{Li} P_i(T_{FP})}{P_i(T_{FP,i})} = 1 \qquad (5)$$

This equation is implicit for T_{FP}, but it can be solved by trial-and-error iteration. As mentioned above, reference sources are available that give Antoine equation expressions for $p(T)$. Thus, since T_{FP} is known for each pure component, $P_i(T_{FP,i})$ can be found for each from its pertinent Antoine equation. A trial value of TP for the mixture is then assumed. T_{FP} values are tried iteratively until the summation in Eq. (5) comes out 1.

Example

An example of an ideal mixture is the ethylene glycol/methanol system. The mixture is ideal, since both components are alcohols. Experimental flash point results are shown in Figure 22[67]. Note that flash points do not follow a linear relation, even for ideal mixtures. The estimated values were obtained by using the following Antoine equations for vapor pressure:

$$p = \exp\left(13.63 - \frac{6022}{T - 28.25}\right) \qquad \textit{ethylene glycol}$$

$$p = \exp\left(11.88 - \frac{3613}{T - 34.85}\right) \qquad \textit{methanol}$$

where p = vapor pressure (atm) and T = temperature (K). The measured flash point for pure ethylene glycol is 114ºC and for methanol 11ºC. The calculated values agree reasonably closely with the measured ones for intermediate compositions.

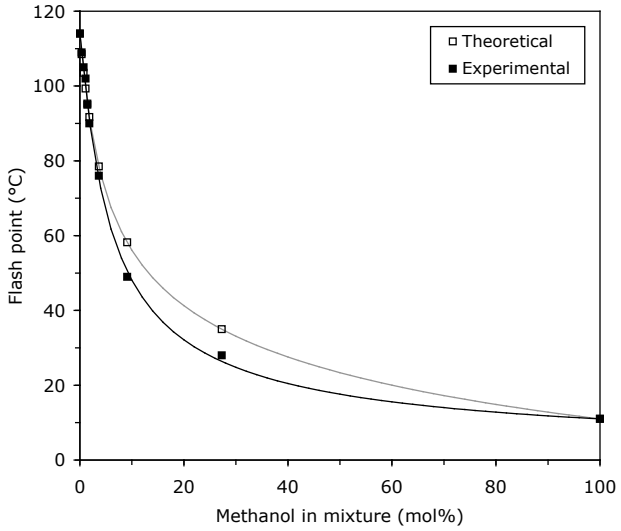

Figure 22 Flash points of ethylene glycol/methanol mixtures

Numerous accidents have occurred when a heater was fueled with kerosene fuel into which gasoline was added. The dominant effect is one of forcing out the fuel from the device due to internal overpressurization, since the vapor pressure of gasoline is higher. Ignition is then promoted due to a lowering of the flash point. Lentini showed[68] that adding 4% gasoline into kerosene drops its flash point from 49°C to ca. 6°C, as measured in the ASTM D 56 flash point apparatus. Data on open-cup flash points and fire points of mixtures of gasoline with automatic transmission fluid, brake fluid, engine oil, and power steering fluid have been reported[69]. The results indicate that (a) about 15 – 20% of gasoline mixed into any of the above fluids brings down their open-cup flash point to room temperature; and (b) while the fire points are significantly higher than the open-cup flash points for the pure fluids, the two values become indistinguishable once 15 – 20% of gasoline is added.

NON-IDEAL MIXTURES

Non-ideal mixtures show behaviors which can be surprising, if the user has not expected it. Adding a higher-flash-point compound may fail to raise the flash point of a particular compound, or even lower it. For example, adding up to 50% of *n*-butanol (FP = 29ºC) to *n*-octane (FP = 14ºC) fails to change the flash point of the mixture.

For non-ideal mixtures, an empirical correction is made to Raoult's Law by introducing an activity coefficient:

$$P_{tot} = \sum_i \gamma_i X_{Li} P_i$$

where γ_i = activity coefficient of component i (--). The activity coefficient varies with the concentration and also depends on the other molecules present in the mixture. Values

greater than 1 denote substances which have a greater vapor pressure in a mixture than proportional to its mole-fraction. The difficulty in using this equation is that activity coefficients may be hard to find for binary systems and impossible for systems of more components. To overcome this problem, Walsham[70] developed an empirical method of prediction based on activity coefficients assigned to different chemical families. He further found that an empirical factor for molar mass improves the correlation. With this additional factor, Eq. (5) becomes:

$$\sum_i \frac{\gamma_i X_{Li} P_i(T_{FP})}{P_i(T_{FP,\,i}) \cdot M_i^{5/4}} M_{mx}^{5/4} = 1.0 \qquad (6)$$

where M_i = molar mass of component i, and M_{mx} = molar mass of the mixture. For a binary mixture, the values of γ_i are found from Table 5. The column headings denote the solute while the row headings denote the solvent. Thus, for example, γ_i for alcohol in water is = 48.0. Apart from tabulated generic values such as Walsham's, group-contribution calculation schemes for activity coefficients exist and more sophisticated predictions can be based on them[71].

Normally, if a non-volatile solid is added to a solvent, the vapor pressure will be reduced and, consequently, the flash point can be expected to be raised. This generalization is implicitly based on Raoult's Law, but Kamarchik[72] has shown it not to be obeyed for xylene/polystyrene mixtures. When polystyrene, which has a negligible vapor pressure, is dissolved into xylene, the flash point of xylene is decreased, and is decreased linearly with the amount of polystyrene dissolved.

If a non-flammable liquid is miscible with a flammable one, there is usually a fraction reached beyond which the mixture becomes non-flammable (i.e., has no flash point), but this limit usually requires a very large amount of the non-flammable liquid. For example[73], pure methanol has a FP of 7ºC; a 40/60 mixture of methanol/water has 30ºC; and it requires reaching a 5/95 mixture before a non-flammable condition is obtained (Figure 23).

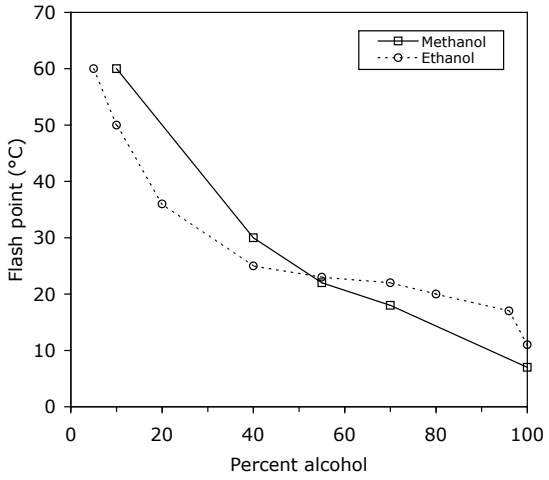

Figure 23 The flash points of alcohol/water mixtures

MIXTURES WITH HALOGENATED COMPONENTS

Great care must be used in interpreting flash point measurements on mixtures containing halogenated substances (substances containing chlorine, bromine, or other atoms from the halogen series of the periodic table). Halogen atoms serve to retard combustion by breaking the chain reactions; thus, mixtures containing halogenated components may show high flash points in a closed-cup flash point tester. However, if the halogenated component is more volatile than the remaining fraction, in case of a spill of the substance in open air, the halogenated component will evaporate first and will subsequently be gone. The non-halogenated portion remaining will then be able to ignite at temperatures significantly below the reported T_{cc} value. A

9 – water

number of serious losses have occurred when users were falsely reassured by high T_{cc} values of paint thinners containing methylene chloride. ASTM flash point standards do not give guidance on this issue, but Department of Transportation regulations do address the problem. The DOT regulations (49 CFR 173.120) specify that if the substance is a mixture and if $T_{cc} > -7°C$ is measured, then a second test must be made of a partially-evaporated substance, and the reported T_{cc} must be the lower of the two. The evaporation regimen requires placing the liquid in an open beaker such that the ratio of the volume to the exposed surface area is 6:1. Before sampling, the beaker is to sit at ambient conditions for 4 h, or until 10 vol% has evaporated, whichever comes first.

Apart from validity of measurement, when solvents contain a significant component of methylene chloride, anomalous flash point test results are obtained[74]. In closed-cup testing, a greatly enlarged pilot flame is seen, while in open-cup testing a blue halo results. Either condition prevents a definite flash point from being determined.

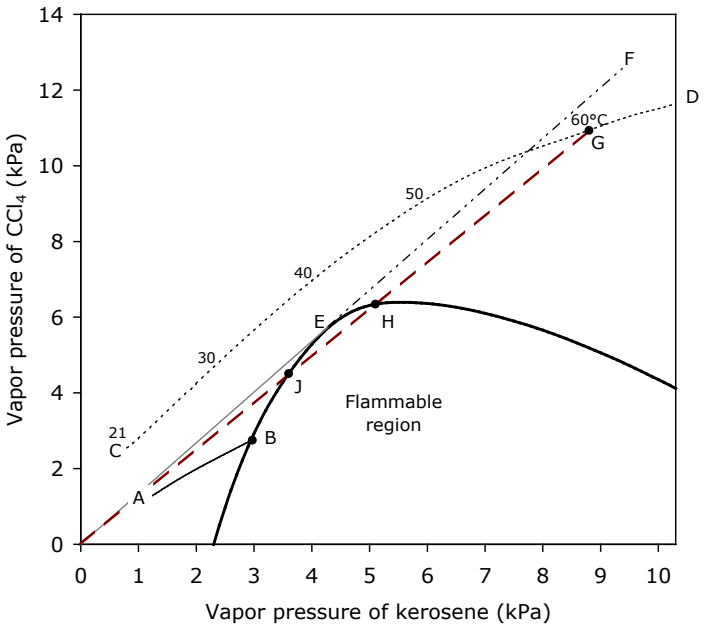

Figure 24 Flash point relations for a mixture of kerosene and CCl_4 (the Gerstein anomaly)

ASTM flash point standards do caution the user about a second mis-application of flash point results for mixtures. For mixtures where the more volatile component is also the more flammable one, vaporization losses from a sample will mean the sample being tested exhibits an incorrectly high flash point result. Thus, sampling procedures must be in place to assure that the more volatile components have not been lost. Unrepresentativeness of tested sample becomes a serious problem when using open-cup flash testers with heavier petroleum products[75].

In addition to the above issues with both the correctness and the meaningfulness of test procedures, a different problem has been found by Gerstein and Stine[76]. When a halogenated component is added to a hydrocarbon, it is possible to observe anomalous results on occasion in using a flash point tester. It will be assumed for illustration that the halogenated component which has no flash point is incapable of burning, although this, of course, is not an iron-clad rule, by any means. Such a mixture may exhibit no flash point, yet, may ignite at locations in the test apparatus where the vapor vents to the outside. This burning does not qualify as a flash point according to the test procedures, yet clearly demands to be understood.

The anomalous behavior can be understood by referring to Figure 24. Suppose the proportions of kerosene and carbon tetrachloride (CCl_4) in the liquid phase are such that the relative vapor pressures at room temperature are at point A on the diagram. This means that the mixture is non-flammable at room temperature. As the temperature of the liquid in the flash-point tester cup is raised, the vapor pressures will move along the line A-B. At point B, the temperature will have just attained its flash point value and a flashing will be observed. Any higher temperatures would move into the flammable region and they would also register flashing, at least until the upper flash point is reached.

Suppose now that there is less kerosene and more CCl_4 in the liquid, so the vapor pressures at room temperature are at point C. As the temperature is progressively increased, the vapor pressures will move along the line C-D. At 60ºC, the vapor pressures will be at point G. The kerosene/CCl_4 vapor at this value of temperature and of relative vapor pressures is non-flammable. Suppose now that some air is mixed in with this vapor. Mixing in air does not change the relative kerosene/CCl_4 proportion, but reduces both by the same measure. Thus, the diluted mixture will now follow the straight line G-0, where 0 is the origin. When the mixture is sufficiently diluted to reach point H, combustion will occur. This is the 'anomalous' behavior identified by Gerstein and Stine. It occurs because the line C-G which was followed by raising the temperature of the liquid and the vapor equilibrated with it is curved, while line G-0 is straight. The behavior will occur any time that a fuel/diluent vapor mixture passes to the right of line E-F. The line E-F is a straight line that starts at the origin and is tangent to the flammability curve (the solid black line).

To discover why line C-G-D is curved, we can consider a mixture where Raoult's Law and Clausius-Clapeyron equations hold. Then the partial pressures of the fuel *f* and the inert *i* in the vapor phase will be:

$$p_f = X_f \, p_f^o$$

$$p_i = X_i\, p_i^o$$

where X_f = mole fraction of fuel in liquid = $(1 - X_i)$, and p^o denotes the vapor pressure of a given temperature of the pure liquid. The pressure-temperature relation can be obtained from the Clausius-Clapeyron equation:

$$p_f^o(T) = \exp\left[\frac{\Delta h_{v,f}}{R}\left(\frac{T - T_{b,f}}{T \cdot T_{b,f}}\right)\right]$$

$$p_i^o(T) = \exp\left[\frac{\Delta h_{v,i}}{R}\left(\frac{T - T_{b,i}}{T \cdot T_{b,i}}\right)\right]$$

where h_v = latent heat of vaporization, and T_b = boiling point. For a given X_f, the above four equations represent a non-linear relation between p_f and p_i, since the temperature effect is non-linear. Thus, the line C-G-D is curved. The Gerstein anomaly is not dependent on the validity of Raoult's Law or the Clausius-Clapeyron equation. Thorne[77] has provided a number of illustrative calculations of the phenomenon for mixtures that do not obey Raoult's Law or the Clausius-Clapeyron equation.

FLASH POINTS OF PETROLEUM DISTILLATES

For paint thinners that are petroleum distillates without significant gaps in their distillation curve, a very good approximation is[78]:

$$T_{cc} = 0.719(T_b - 101)$$

where T_{cc} is the Tag closed-cup flash point (ºC) and T_b is the *initial* boiling point, as determined by ASTM D 86[79]. (For a mixture, the boiling point rises as boiling continues and more volatile fractions are boiled off).

For mixtures of 'middle' distillates (i.e., fractions boiling in the range 90 – 370ºC), a formula was developed by Butler et al.[6] that allows the closed-cup flash point T_f of the mixture to be estimated, if the flash points are known for the constituents:

$$e^{4722/T_{FP}} = \sum_i X_i e^{4722/T_{FP}(i)}$$

where X_i = mole fraction of the i^{th} component, and $T_{FP}(i)$ = flash point (K) of the i^{th} component.

RELATION BETWEEN FLASH POINT AND MIE

For a fuel-gas/air mixture which is at a fixed fuel/air ratio, the MIE decreases with increasing temperature, as shown in Chapter 4. But the situation becomes more complicated when a fuel-vapor/air mixture is established in a closed space, in equilibrium with the liquid. As the temperature changes, the fuel/air ratio also changes under those conditions. This is exactly what happens in a closed-cup flash point tester, but flash-point testers are not equipped with means for changing the energy of the ignition source presented to the sample. In experimental arrangements where a spark of variable energy can be presented to the sample, it is found that there is an optimum sample temperature which gives the lowest value of MIE. Not only does lowering the fuel temperature raise the MIE, but so does raising it. Figure 25 illustrates a correlation developed on the basis of experimental data for Jet A fuel[80]. The high-temperature branch of the curve occurs because the mixture is becoming fuel-rich. For this particular fuel, the optimum temperature is about 11ºC above the flash point, but will vary for other fuels.

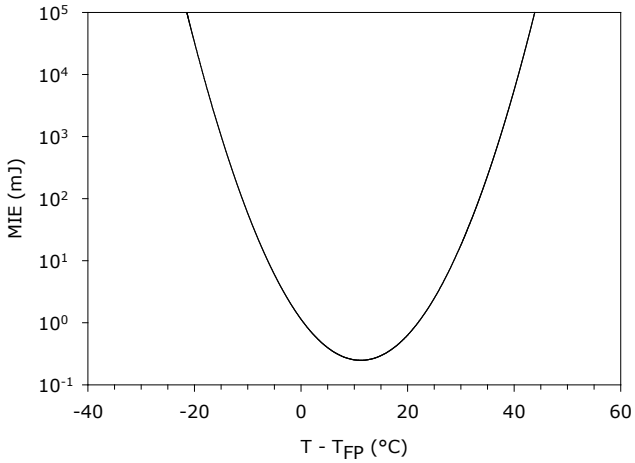

Figure 25 MIE needed for ignition of Jet A fuel in closed tanks, as a function of the difference between the fuel temperature and the flash point temperature

Piloted ignition of liquids

SPARK IGNITION OF LIQUID AEROSOLS OR SPRAYS

A *liquid aerosol* is a suspension of liquid particles in air fine enough (typically < 200 μm) that they are able to stay suspended, at least for a while. A *liquid spray* is generally the term used if the aerosol is being examined at a location close to where it is being generated, so that significant discharge velocities are present. Experimental work[81] has shown that if the droplets have a diameter smaller than 10 μm (0.01 mm), the combustion behavior is identical to the vapor of that substance. Droplets with a diameter > 40 μm burn individually, with a separate flame surrounding each droplet. Once initiated, a flame does not propagate if the nearest droplets are very far away; thus clearly there exists a LFL. The mean distance between droplet centers in the limit mixture is about 22 times the droplet diameter for droplets < 10 μm and about 31 times the droplet diameter for droplets > 40 μm. But larger-diameter aerosols are able to ignite and burn at lower fuel/air ratios, as discussed below. Liquid aerosols can be *detonated*[104], although this is difficult in laboratory experiments and would evidently be rare in real life. Bowen and Cameron[82] have reviewed many aspects, such as flame speeds, of explosions in clouds of liquid aerosols, but not their ignition aspects.

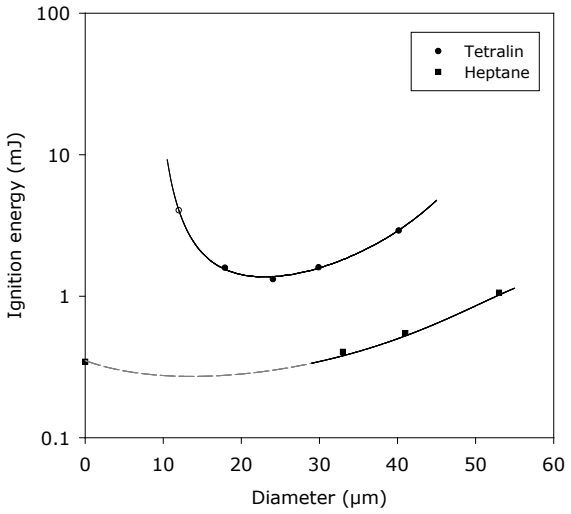

Figure 26 The effect of droplet diameter on the needed ignition energy of two aerosols

A majority of the studies on ignition of liquid aerosols have been done using *monodisperse* (i.e., all droplets are of the same size) particles, since this leads to the easiest interpretation of results. In practice, however, aerosols are commonly *polydisperse* (i.e., all droplets are not of the same size). There are many different ways in which an 'effective' diameter can be defined for an aerosol having a range of particle sizes, but not all will produce quantity which correlates ignition data from polydisperse aerosols with data from monodisperse aerosols. Unfortunately, there is not an agreement on the correct measure. Dietrich et al.[83] concluded that the Sauter mean diameter must be used. The Sauter mean diameter, D_{32}, is defined as:

$$D_{32} = \frac{\int_0^\infty D^3 n(D) dD}{\int_0^\infty D^2 n(D) dD}$$

where D = diameter (m), and $n(D)$ = probability of a particle having a diameter between D and D+dD. By contrast, Aggarwal[84] claims that another variable, D_{20}, is the only one that will give correct results. This is because D_{20} represents the average surface area presented by the particles and Aggarwal suggests that this is the true governing variable.

MINIMUM IGNITION ENERGY

The minimum energy for ignition depends on the *droplet diameter*. For spark ignition of liquid aerosols, droplets of 10 – 30 μm tend to require the least energy. Figure 26 shows this for tetralin[85] and heptane[86]. These results suggest that aerosols with the optimum droplet diameter are more readily ignitable than a pure vapor, but the data for this conclusion are not extensive. In other experiments on the tetralin aerosol, the spark gap width was varied and a shallow optimum of ca. 3.5 mm was found for the spark gap width. An analysis of the flame kernel for a liquid aerosol is very similar to that for gases, since the energy expended in vaporizing the liquid is only a few percent of the total spark energy. The combined effect of stoichiometry and droplet size[87] is illustrated in Figure 27 for tetralin and in Figure 28 for heptane. Over the range that it has been explored, fuel concentration has a monotonic effect on the MIE. In addition to the results shown in Figure 28, a study by Dietrich et al.[83] showed that over the range of equivalence ratios from 0.7 to 2.2 increasing *fuel concentration* invariably decreased the MIE. More limited data show that raising the *oxygen concentration* reduces the MIE[83].

For the regime of particle diameters ≥40 μm, Ballal and Lefebvre[88] obtained data (Figure 29) showing a power law relation:

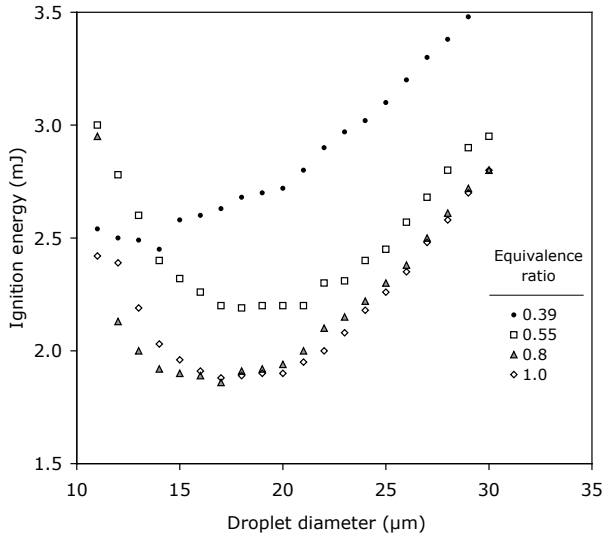

Figure 27 Effect of stoichiometry on ignition energy for tetralin aerosols of various droplet sizes

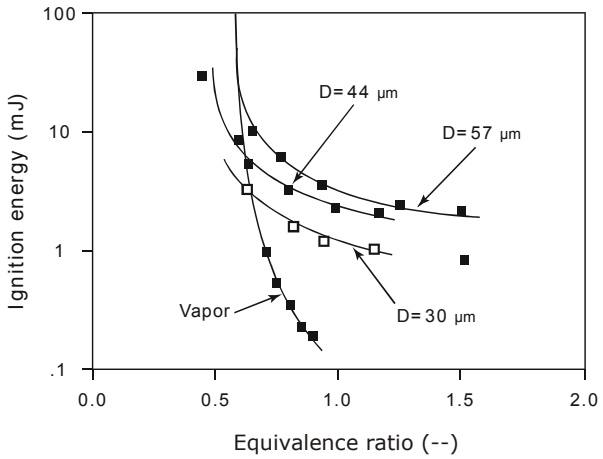

Figure 28 Effect of stoichiometry on ignition energy for *n*-heptane aerosols and vapor

$$MIE \propto D_{32}^{4.5}$$

where D_{32} is the Sauter mean diameter (μm) of the droplets. They, along with other authors[89], consider that $MIE \propto d_{\|}^3$. Ballal and Lefebvre also produced theories for $d_{\|}$ in both stagnant and flowing conditions. Their theory for stagnant conditions or low-velocity conditions[90] gives that:

$$d_{\|} = D_{32}\left[\frac{\rho_f}{\rho_a \varphi \ln(1+B)}\right]^{1/2}$$

where ρ_f = density of liquid (kg m^{-3}), ρ_a = density of air (kg m^{-3}), φ = equivalence ratio (--), and B = Spalding B-number* (--):

$$B = \frac{\Delta h_c / r + C_{pa}(T_f - T_b)}{L + C_{pf}(T_b - T_a)}$$

where Δh_c = heat of combustion (kJ kg^{-1}), r = stoichiometric air/fuel mass ratio (--), C_{pa} = heat capacity of air (kJ kg^{-1} K^{-1}), C_{pf} = heat capacity of liquid fuel (kJ kg^{-1} K^{-1}), L = latent heat of fuel vaporization (kJ kg^{-1}), T_f = flame temperature (K), T_b = boiling temperature of fuel (K), T_a = ambient temperature (K). Their theory for turbulent air stream conditions[88] gives:

$$d_{\|} = \frac{0.32 C_{pa}\rho_f}{\lambda_a \varphi \ln(1+B)}\left[\frac{D_{32}^3 u' \mu_a}{\rho_a}\right]^{1/2}$$

where λ_a = thermal conductivity of air (W m^{-1} K^{-1}), u' = root-mean-square velocity fluctuation component (m s^{-1}), and μ_a = dynamic viscosity of air (18×10^{-6} kg m^{-1} s^{-1} at ambient temperature). In both cases, the authors suggest additional corrections for aerosols which are not monodisperse.

In a related study, Ballal and Lefebvre[91] obtained data which point to the importance of the spark gap distance. Figure 30 shows that the MIE of aviation kerosene is nearly identical for gaseous mixtures and for aerosols of 40 μm diameter. But this presumes that the mixtures were tested at their optimal spark gap distance. If the spark gap is kept constant while droplet diameters are varied, some anomalous results may be found. Note also that the optimum gap distance is smaller for aerosols than for gases. These tests were run with plain-tip spark electrodes, thus they do not show the 'flat-bottom' curves characteristic of data obtained by the Bureau of Mines with flanged electrodes. Chan[87] obtained experimental data on the optimum spark gap distance for monodisperse tetralin aerosols. His results can be approximately represented as:

$$d_g = 0.04 d_p + 0.7$$

where d_g = spark gap distance (mm), and d_p = particle diameter (μm). A comparison to the aviation kerosene results of Figure 30 shows that the same equation would not apply

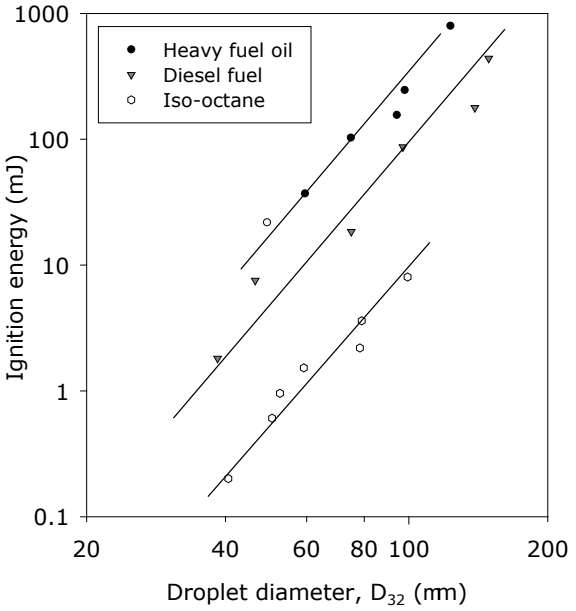

Figure 29 Effect of droplet diameter on MIE of aerosols with larger droplet sizes

to kerosene, but it can at least be concluded that increasing particle diameters will generally require an increased spark gap, if true MIE values are to be obtained.

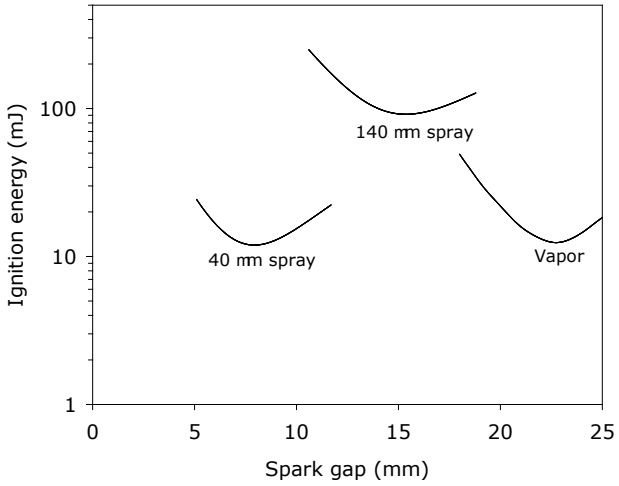

Figure 30 Effect of spark gap width on aviation kerosene vapor and sprays mixtures at 0.2 atm

The minimum ignition energy also depends on the *temperature*. This is illustrated in Figure 31 for various fuel sprays. The data are from Kuchta[92] and from Liebman et al.[93] Kuchta's droplet size was specified as less than 10 μm, while Liebman's drop size distribution was unspecified. Presumably the large differences between results are attributable to different drop size populations. Note that the temperature effect is much greater for liquid sprays than it is for gases (see Chapter 4).

* The Spalding B-number is a flammability parameter commonly used for liquids; a comprehensive presentation of the concept is provided in the textbook by Kanury, cited in *Further Readings*.

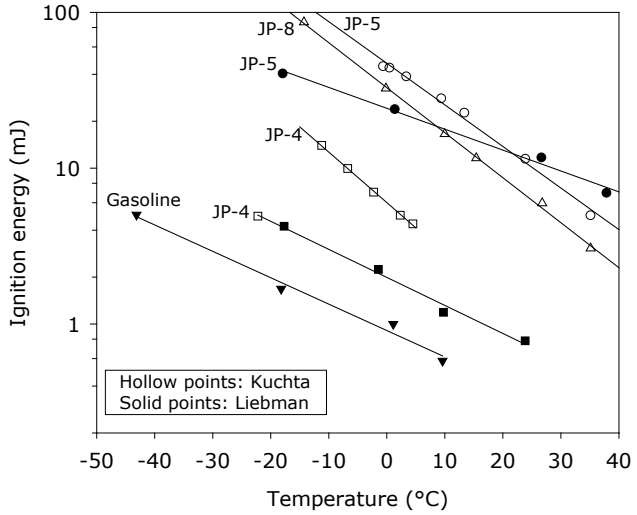

Figure 31 The MIE for various sprays

Reducing the *pressure* tends to raise the MIE, as shown by the data of Ballal and Lefebvre[91] in Figure 32.

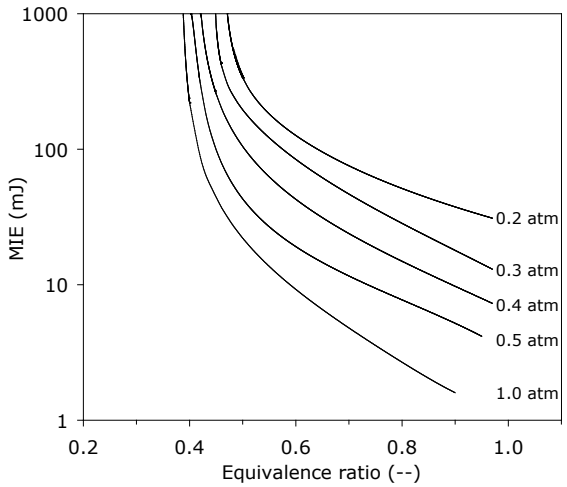

Figure 32 Effect of pressure on the MIE of sprays of aviation kerosene
(Copyright The Combustion Institute, used by permission)

Spark duration has a strong effect on the MIE needed, at least as found in experiments on kerosene sprays[94] in a flow-through environment with velocities of 20 – 50 m s^{-1}. Minimum values were found for spark durations of 35 – 80 μs, depending on various experiment conditions. If spark duration was increased or decreased by a factor of 2 from its optimum value, the needed ignition energy typically rose by roughly 50%.

Flow velocity generally increases the MIE, at least for large velocities. SubbaRao et al.[95] investigated the velocity effect for kerosene and found a steady increase in MIE with velocity for velocities greater than 30 m s^{-1}. Their data were limited in the low-velocity regime, but it seems that perhaps for velocities less than 20 m s^{-1} the effect would not be significant.

HIGH FLASH-POINT LIQUIDS

The flash point temperature of liquids does not apply to situations where the liquid is in the form of a spray, and it has been demonstrated that liquid sprays can be ignited at temperatures well below their flash point[96]. A number of experimental studies illustrate this for a variety of high-flash point liquids. Hydrocarbon mixtures with flash points of up 120ºC have been shown to be ignitable at room temperature by electric sparks when sprayed as large (millimeter-size) droplets[97]; similarly, petroleum products with flash points up to 130ºC have been reported[98] to be readily flammable in air as aerosols. It is also reported[99] that ignition of hydraulic fluid sprays under ambient pressure/temperature conditions is readily achieved with a small natural-gas pilot flame for both MIL-H-5606 (FP = 89 – 102ºC) and MIL-H-83282 (FP = 210 – 221ºC). Cook et al.[100] sprayed OM 13 and OM 33 oils with hypodermic needles into a version of the BM glass-tube flammability tube. These are UK military hydrocarbon oils having flashpoints > 160ºC. Drop sizes were 80 – 300 μm and the authors did not have any difficulty in creating flame propagation. The most important early study was that of Eichhorn[101], who found that mists of peanut oil (FP = 324ºC) could be ignited and burned "as readily" as Stoddard solvent (FP = 43ºC). In his experiments, the aerosol was sprayed into an open glass vessel, so it appears that preheating of the walls was not required for combustion. Eichhorn ignited his sprays with an electric spark, but did not measure the size distribution of the droplets. He also showed that six other liquids, with intermediate flashpoints of 71 to 229ºC, burned readily.

Recently, Hirsch et al.[102] also conducted a study using a wide variety of liquids. They used an open-spraying rig in which a nozzle was simply used to spray the liquid horizontally as a free jet. In addition, they measured explosion pressures by repeating tests inside an explosionproof vessel. Drop sizes were typically 0.35 – 0.9 mm. The test fluids involved a variety of dry-cleaning chemicals and cutting oils which had flash points ranging from 45 to 240ºC and AIT values of 215 – 375ºC; actual identities of the fluids were not given. Their results were:

- No effect of flash point was found on the explosion pressures developed.
- Liquids with FP < 100ºC were all ignited with an electric spark of 1.1 J.
- Liquids with FP > 100ºC were all successfully ignited with a spark of 10 J (intermediate values were not explored).
- Mechanical grinding sparks from a cerium-based (igniter 'flint') rod ignited all sprays; mechanical grinding sparks from 12 different steel alloys ignited no sprays.
- Hot spots created by mechanical rubbing or grinding ignited all liquids if they showed a red glow. Fireballs several meters in diameter were produced in this way.

- Steel rods electrically heated to 800 – 900ºC ignited all sprays (Color Plate 7); the needed ignition temperature bore no relation to the AIT of the liquid.
- When sprayed liquid was deposited as a film upon a surface, low-FP liquids (50°C) resulted in sustained, difficult-to-extinguish fires, but high-FP (> 200ºC) liquids did not sustain this type of surface burning.

In addition, they conducted another series of experiments where ignition sources were introduced into a closed chamber which was filled with mists of very small diameter (< 10 μm) but with actual spraying stopped before introducing an ignition source. No ignitions were obtained in these non-replenished atmospheres and it appeared that it was not possible to reach the LFL under such stagnant conditions. Apart from the study by Hirsch et al., there are additional data which suggest that it is very difficult to create a flammable cloud in air from a high flash point liquid if the spraying is not continuous. Earlier at the same institution, Förster and Steen[103] studied this problem for octanol (FP = 81ºC). Eckhoff[104] summarized their study and noted that coagulation generally prevents such clouds from being flammable a short time after spraying is stopped. He concluded that the inter-drop distance in the explosible range may typically be as small as 10 drop diameters, which leads to rapid coagulation of an initial population of small drops. These now-larger drops will then rain out and the mixture will no longer be in the flammable zone.

A case history of an explosion of a tanker truck being filled with a 65°C flash point gas oil has been described[156]; it occurred due to 'splash filling,' which creates an aerosol in the tank. This appears to be a relatively rare accident, and typically ignitable concentrations of high flash-point fuels such as diesel oil are not reached, except if there is extreme frothing[161]. In the latter case, the froth may become ignitable and, if ignition occurs, flames may then propagate to the previously-too-lean mist above it. *Foams* or *froths* of flammable liquids can be created by mechanical agitation or by depressurizing a vessel which contains dissolved gases. In the latter case, gases which are now no longer able to be dissolved froth up to the surface. Foams share some traits of liquid aerosols, but there are very few ignition studies. BM conducted a few experiments[105] where kerosene, which has a flash point over 38ºC, was foamed up inside a closed container at 20ºC. It could be readily ignited from a spark and led to a full propagating fire of the contents. Britton[161] documented a few case histories involving liquid foams. He also pointed out that if a froth is produced by decomposition of an oxidizing agent (e.g., hydrogen peroxide), the oxygen-enriched froth may be flammable even if within an originally-inerted vessel. Additional laboratory studies with liquids of above-ambient flash points are considered in the next Section. Aerosols of *frozen liquid droplets* can be ignited, if present in sufficient concentration, even though the vapor pressure of a frozen liquid is nearly zero[161].

LIMITS OF FLAMMABILITY FOR LIQUID AEROSOLS

As with other dispersed combustibles, limits of flammability exist for liquid aerosols. Perhaps the earliest study was by Haber and Wolff[106], who reported in 1923 that the LFL for aerosols is the same as for vapors. Later studies showed that for droplets smaller than 10 μm, the LFL is indeed identical to that of the vapor at the same temperature. But for larger diameters, the results apparently vary according to the fuel type. Figure 33 shows that for tetralin[81,107,109] (FP = 71ºC) the LFL decreases with droplet diameter, but for kerosene[105] it rises. The results of Zabetakis that are shown for kerosene may be questionable, however, since Mizutani et al. obtained results for No. 2 fuel oil that were quite similar to their tetralin results (e.g., a straight, downward sloping line) and chemically, fuel oil behaves rather similarly to kerosene. For *n*-decane[29] (FP = 46ºC), the LFL drops from 43.6 g m^{-3} for a gas, to about 10 g m^{-3} for aerosols of droplets having a diameter of 40 – 140 μm. The measurements involved are difficult to make and curves such as shown in Figure 33 should only be viewed as approximate, since using a different experimental method tends to produce significantly different results[100].

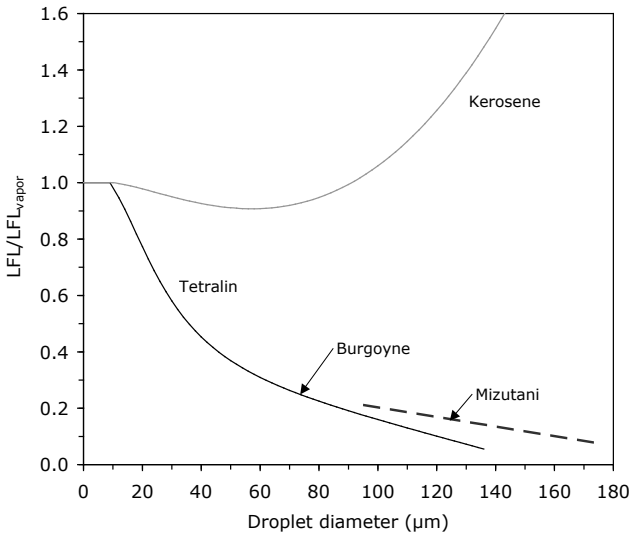

Figure 33 Dependence of LFL on droplet diameter for two liquid aerosols

To consider why larger droplets having a lower LFL than the corresponding vapor, the measuring apparatus must be considered. An apparatus very similar to BM flammability tube (Chapter 4) been used for studying liquid aerosols[108]. A mixture is established in a long cylinder having an open bottom. A small flame is applied at the bottom and it is observed whether a flame can propagate all the way up to the top. If it can, the mixture is considered to be flammable. A diameter of ca. 50 mm is considered to give suitable results. The LFL for an aerosol is expressed in fuel-concentration units (g m^{-3}). This can be presented as a curve of LFL versus mean droplet diameter. In this test environment, Burgoyne[109] explained that the diameter effect is due to sedi-

mentation motion of the larger droplets. The fuel concentration at the flamefront, in fact, remains nearly constant irrespective of diameter. But the flamefront concentration, for such large droplets, is no longer identical to its volume-average concentration. Instead, it is expressed as:

$$c_f = c_m \frac{v_f + v_a + v_s}{v_f + v_a}$$

where c_f = flamefront concentration, c_m = volume-average concentration, v_f = upward flame velocity, v_a = downward air flow velocity, and v_s = sedimentation velocity of the droplet relative to the air. The two concentrations are identical if $v_s \rightarrow 0$, which is true only for very small droplets. For droplets up to ca. 50 μm,

$$v_s = \frac{d^2 \rho g}{18 \mu}$$

where d = droplet diameter (m), ρ = droplet density (kg m^{-3}), and μ is the dynamic viscosity of air (18×10^{-6} kg m^{-1} s^{-1} at ambient temperature). The above results all refer to upward propagation. A limited study was performed by Burgoyne[110] for *downward* propagation of tetralin mists where he found that the LFL did not decrease with diameter and, for large diameter drops (> 0.5 mm), no flame propagation was possible at all, although individual burning droplet could drop down. A theoretical analysis by Mizutani[107] suggests that *horizontal propagation* results may be similar to those for downward propagation, but experimental data are not available.

The LFL of liquid mists is affected by *turbulence*. Förster and Steen[111] conducted tests with 50 μm diameter 1-octanol (FP = 81ºC) droplets. As the turbulent fluctuation velocity was increased from 0.44 m s^{-1} to 1.89 m s^{-1}, the LFL dropped by 60%. Other mists have not been studied in a similarly quantitative manner. A similar effect was found for *flow velocity*—raising the flow velocity of the mixture caused a drop in the LFL[94]. In a high-velocity flow, Anson[112] obtained some anomalous results with kerosene—raising the droplet diameter from 60 to 150 μm caused a monotonic *increase* in the value of the LFL; this issue has not been studied further.

There is one old study on the minimum oxygen concentration needed for combustion of liquid sprays. Sullivan et al.[113] tested a wide variety of liquids in a rig where the spray was spark-ignited at ambient temperature, but with variable oxygen content of the test chamber. For most hydrocarbon liquids, MOC values of 12 – 14% were found. But for chlorinated liquids, silicones, and other FR formulations, some quite-high values (up to 85%) were seen.

MESG OF LIQUID AEROSOLS

On rare occasions, the MESG of liquid aerosols has been studied. Using the procedures of the Health and Safety Executive in the UK, Capp[114] measured the MESG for three sprays of three liquids and found that they were 15 to 23% higher than MESG values on the corresponding vapors. The droplet size of the sprays was around 30 μm. The actual values will depend on the particle diameter, but it was concluded that the increase is generally modest. For design purposes, using the values obtained for the vapor would be conservative, but not excessively so.

HOT SURFACE IGNITION OF DROPLETS, SPRAYS OR SPILLS

SINGLE DROPLETS OF A PURE FUEL

The basic phenomenology has been studied for a single droplet, released at low speed in still air onto a hot surface[115-118]. With many ignition phenomena, ignition time decreases monotonically with increasing temperatures. This—dramatically—is not true with droplet/hot surface ignition. To understand ignition, it is first necessary to study the evaporation of droplets hitting hot surfaces. There are 6 different regimes for the evaporation process, as shown in Figure 34.

(a) When the hot surface temperature is below the fluid's boiling point, the droplet assumes a plano-convex shape and slow evaporation takes place.
(b) At the boiling point, a vapor bubble forms in the center of the drop.
(c) At a certain temperature, the maximum evaporation rate occurs, many small bubbles form within the droplet, and the evaporation process is violent.
(d) At higher temperatures, the drop breaks up into one large drop surrounded by small drops.
(e) At a higher temperature (approximately corresponding to the Leidenfrost temperature*), the droplet lifts entirely off the surface and resembles a squashed sphere.
(f) At the highest temperatures, the drop is spherical and is separated from the surface by a vapor film.

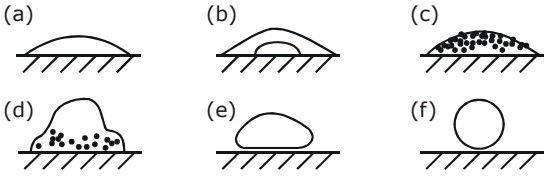

Figure 34 The regimes of drop evaporation on a hot surface

The nature of these six different regimes helps explain the relation between hot-surface temperature and the droplet vaporization time (Figure 35). There is a pronounced minimum in the curve which is, in effect, an optimal temperature for droplet vaporization. The curve of ignition time vs. temperature has a very similar shape, but is offset substantially towards the higher temperatures (Figure 36). The ignition time corresponds to the time that it takes to vaporize a specific drop mass, irrespective of the temperature. Roughly speaking, the ignition time is controlled by chemi-

* The concept of the Leidenfrost temperature is explained in most textbooks on heat transfer.

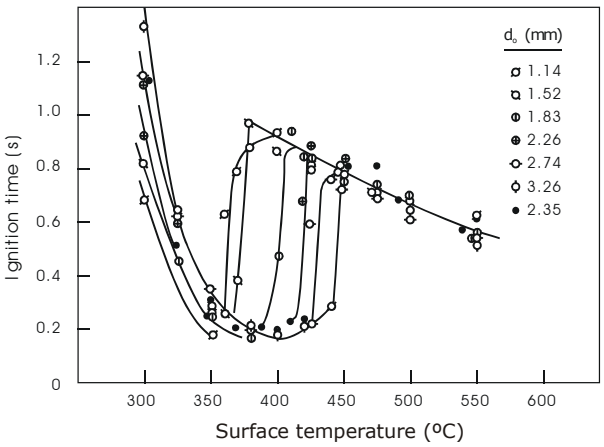

Figure 35 The time for evaporation of a cetane drop of a hot surface

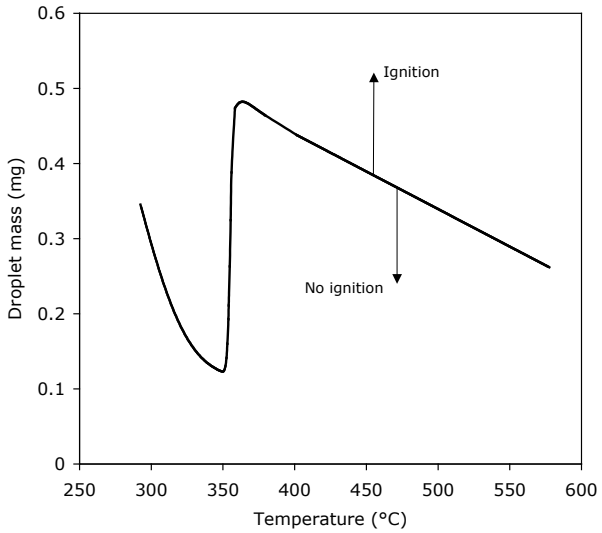

Figure 36 The time for ignition of a cetane drop on a hot surface

cal kinetics for temperatures less than the Leidenfrost temperature, and by physical processes at higher temperatures.

The abrupt increase in ignition time always corresponds to the time at which the drop ceases to have contact with the surface. Finally, there is a cr itical drop size below which ignition cannot occur (Figure 36). This critical size (expressed as either mass or diameter) is dependent on the surface temperature.

When viewed not from the point of view of the physics of evaporation but considering only the temperature needed for ignition, Cho and Law[119] concluded that there are four regimes for most hydrocarbon liquids (Figure 37), with the following temperature limits being roughly characteristic of dodecane:

Temp. (ºC)	Behavior
< 200	no ignition at all
200 – 290	vapor pocket ignition—no ignition is possible while drop is still present; ignition occurs immediately after drop finishes evaporating; flames are conical and sooty
290 – 650	ignition is possible only if atmospheric pressure exceeds a certain minimum value
> 650	no ignition while drop is still vaporizing; some time after completion of vaporization a flash fire is noted

The above results pertain only to 2 mm diameter drops; the authors also stated that for other pressures or diameters, it can be assumed that pd = constant, at least over some range, but the extent of the applicability was not stated.

Karasawa et al.[120] studied the ignition of single droplets in the range of 1.7 – 2.0 mm impinging on a hot surface. They found that heptane and diethyl ether drops could undergo either a n ormal or a co ol-flame ignition; however, most other tested fuels could not, as shown in Table 6, where AIT values are also shown for comparison, taken from Chapter 15.

Sommer[121] propelled single droplets of decane vertically upwards and close to, but not touching, a h eated metal plate. The minimum hot surface temperature needed for ignition was 800ºC for 53 µm particles, and 820ºC for 104 µm particles. Of more interest was the fact that ignition occurred at the lowest plate temperature not when the plate was directly next to the flight path, but rather when it was horizontally a certain distance away. For the smaller droplets, the optimal spacing was 0.2 mm, while for the larger it was 0.4 mm. The interpretation is that at too-close spacings,

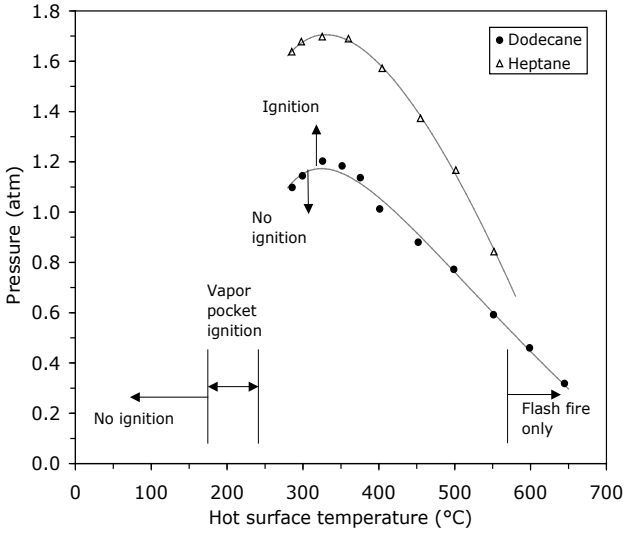

Figure 37 Hot-surface ignition regimes for 2 mm drops, as determined by Cho and Law

Table 6 Single-drop hotplate ignition temperatures found by Karasawa et al.

Fuel	AIT (ºC)	Hot surface ignition temp. (ºC)	
		Cool flames	Hot flames
diethyl ether	195	240	670
n-butanol	345	none	650
heptane	223	360	670
methanol	470	none	690
iso-octane	415	none	704
ethanol	365	none	717
styrene	490	none	738

an overly rich mixture was being created at the locations where temperature would have been optimal for ignition.

Satcunanathan[122] put forth a theory for ignition time of droplets on hot surfaces, but the simple theory, could, at best, only account for the left-hand branch of the curves in Figure 36. Several authors[123-125] developed more advanced theories, but these still ignore the non-spherical shape of actual droplets, their solutions are wholly numerical in nature, and validation data were not presented for the minimum hot-surface temperature needed for ignition of real fuels.

The broad conclusion that can be reached from the above studies is that, except for fuels which show a cool-flame ignition mode, the T_{ig} for a single drop falling onto a hot surface is typically 200 – 300ºC above the AIT.

HOT ENGINE SURFACES AND RELATED PROBLEMS

In this section, we consider the potential ignition of liquid sprays, streams, mists, etc. that come into contact with a heated surface. Here, the fuel originally starts as a liquid. Additional pertinent information in Chapter 4 may be consulted for cases where the fuel is fully pre-vaporized so that only a vapor contacts a hot surface. Ignitions of liquid fuels from hot surfaces most commonly occur in connection with a hot engine exhaust manifold. Exhaust manifold temperatures in passenger cars can vary over a large range[126] of 200 – 600ºC. The dull-red-hot temperature of 600ºC will only be reached if there is a serious engine problem; for a vehicle that is not malfunctioning, the upper limit is considered to be 500ºC[127]. Even 300ºC is above the AIT of many common liquids, thus researchers have needed to explain why such ignition incidents are relatively rare.

In one of the earliest studies on this subject, Wiezevich et al[128] reported in 1935 that individual drops of gasoline and of motor oil, dropped onto a 510ºC hot plate failed to ignite. But it later became clear that the amount of liquid discharged is an important variable, as evident from the experiments of Knowles, who used various quantities of turbine oil falling on a hot surface (Table 7). This is consistent with

Table 7 Ignition of spills of turbine oil on a hot surface[130]

Quantity	Min. ignition temp. (°C)
2 drops	450
5 mL	380
30 – 60 mL	315

a report[129] that lubricating oil ignited when 'poured' over a pipe which was at 293ºC.

In a 1951 report, Scull[131] reviewed the early literature on the subject and concluded that the temperature of a hot surface must greatly exceed the AIT of the fuel in order for ignition to occur. Some of the data he collected on ignition using non-enclosed environments, i.e., heated flat plates, are shown in Table 8. The wide data scatter is noteworthy and is still found among more recent research. The results shown in Table 8 were obtained using iron, steel, or nickel plates. In another study reviewed by Scull, it was reported that ignition temperatures using a copper plate were about 140ºC lower than for an iron plate. Scull hypothesized that this might be a thermal conductivity effect. He also noted that the high temperatures obtained are due to the geometric nature of the problem: only one surface is hot, and the rest of the surrounding environment is essentially at ambient temperature. The standard autoignition tests for liquids, by contrast, release a drop into a geometry where both the surface and the surrounding air are at, roughly, the same elevated temperature.

Table 8 Early research on hot surface ignitions summarized by Scull

Substance	Hot surface temp. (°C)
gasoline	560; 718 – 760
aviation gasoline	454; 585
ethanol	690
kerosene	650
diesel fuel	718 - 760
motor oil	718 - 760
hydraulic fluid	400
lubricating oil	430

Ferguson[132] studied the explosions of crankcases, in which connection he conducted experiments on mists of paraffinic-base and naphthenic-base lubricating oils. The oil was heated, then passed through an atomizing nozzle and into a cylindrical explosion tube which was heated to 65ºC. Air was preheated to the same temperature and supplied at varying velocities. A minimum temperature of 870ºC was needed for a Nichrome strip, 25 × 50 × 0.5 mm, to ignite the mixture. He found negligible effect of the oil type, the air flow rate (over the range 0.13 – 0.6 m s^{-1}) and the fuel/air ratio, provided the mixture was rich enough to ignite. When the system temperature was raised to 121ºC, the ignition temperature dropped to 760ºC. For air velocities higher than about 0.6 m s^{-1}, there was a gradual rise in the

Nichrome strip temperature needed for ignition. Increasing the size of the strip to 25 × 250 × 0.5 mm lowered the ignition temperature by about 110ºC. Adding up to 20% diesel fuel into the lubricating oils did not change the hot-strip ignition temperature. Ferguson's experiments were interesting in that he had an fully-enclosed geometry, and a heated one, at that, yet the T_{ig} values were much greater than the AIT. It emerged that enclosing the volume, by itself, is not a significant contributor towards lowering the ignition temperature. It is necessary that the enclosing surfaces themselves be at a high temperature and not just moderately heated.

The Tokyo Fire Department[133] found that gasoline leakage onto a manifold at 564ºC was not sufficient to cause its ignition, but that electric sparks due to leakage from a high-tension cord did suffice. They also found that engine oil would not ignite when sprayed on an exhaust manifold, but ignited when it collected in a low spot on the surface of the manifold.

Battista et al.[162] used two different test rigs to examine the ignitability of various fuels. For each fuel, 5 mL was applied by a pipette onto the heated surface—a simple heated tube and an actual diesel engine manifold. The results (Table 9) show that the only fuel which ignited at a relatively low temperature was methanol containing 4% of an unspecified 'cetane improver.'

Table 9 Results obtained by Battista et al. using two different hot-surface ignition rigs

Fuel	Hot-surface temp. (ºC) needed for ignition	
	Simple tube	Exhaust manifold
methanol (96%)/ cetane improver (4%)	450	300
methanol	620	> 700
methanol (85%)/ gasoline (15%)	635	> 700
diesel oil	> 650	700
gasoline	> 650	> 700

Goss[134] examined the ignition of several fluids on a hot steel manifold (Table 10), but with test details not specified. Snyder et al.[135] conducted tests on a number of hydraulic fluids tested using Federal Test Method Standard 791 (Method 6053). Their full results are given in Chapter 14; the only two common, commercial fluids were MIL-H-5606 (flash point 102º, manifold ignition 388ºC) and MIL-H-83282 (flash point 230ºC, manifold ignition 322ºC).

Phillips[136] reported results (Table 11) from various hydraulic fluids tested using the European CETOP RP 65H test[137]. In this test, 10 mL of fluid is discharged drop by drop onto a heated manifold.

Severy et al.[138] constructed a manifold simulation rig which was enclosed on 5 sides and open on the front (Figure 38). Using 10 drops of liquid and no forced air flow, they defined two levels of ignition—'consistent' and 'marginal.' Their results are shown in Table 12. A number of their values are identified here as approximate, since the authors only gave those results in a poorly drawn figure.

Table 12 Hot surface ignition temperatures obtained by Severy et al.

Fluid	Marginal ignition (ºC)	Consistent ignition (ºC)
brake fluid	ca. 410	ca. 500
diesel fuel	521	549
gasoline, leaded	ca. 510	610
gasoline, unleaded	ca. 520	627
motor oil	ca. 320	ca. 420
propane (liquid)	ca. 675	ca. 775

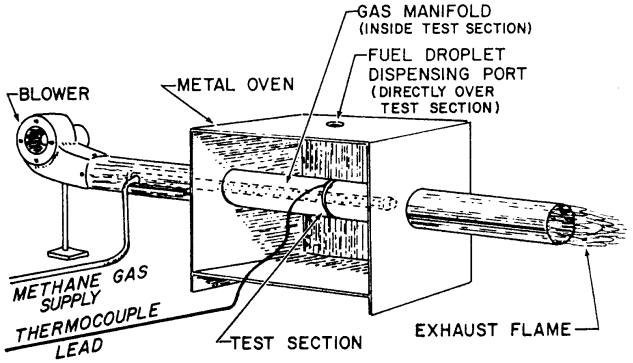

Figure 38 Hot manifold simulation rig used by Severy et al.

Goodall and Ingle[139] examined the hot surface ignition of various fuels in a stainless-steel test rig where the fluid spray was confined between two plates, a bottom plate heated to a higher temperature and a top plate heated to a lower temperature. Thus, it appears that the rig was a half-way mark between a hot plate being hit by fluid in open air, and the all-heated environment of an AIT test apparatus. Under conditions where the upper plate was at room temperature, about 335ºC was required for the ignition of JP-1. Room temperature values for the upper plate were not reached for JP-4 and mineral-base hydraulic fluid, but it appears, by extrapolation, for that case the hot-plate temperatures would have been about 400ºC. As the cold-plate temperature was progressively raised, a lower hot-plate temperature was needed for ignition. For a cold-plate temperature of 270ºC, JP-1, JP-4 and hydraulic fluid all showed hot-plate ignition temperatures of ca. 240ºC. Silicone-based hydraulic fluid and an ester-based turbine oil gave much higher temperatures under similar conditions (270ºC upper-plate temperature), to wit, 440ºC for the turbine oil and 490ºC for the silicone oil. Goodall and Ingle also ran some experiments with various wind velocities and found, as did other researchers, a monotonic increase of minimum ignition temperature with wind velocity. They also examined the effect of substituting aluminum surfaces for stainless steel and found no detectable difference. A comparison of their general results for JP-4 with Clodfelter's data (see below) suggests that their rig provided such a high degree of confinement that their geometry, in fact, approximated that of an AIT test.

A slightly different arrangement was studied by Graves et al.[140], who injected fuel into a forced air stream moving upwards in a circular duct. Downstream of the injection point, the duct walls were heated. The fuel mist was of very small drop size, on the order of 20 to 200 μm (0.02 to 0.2 mm). Under those conditions, they found that the fuel droplets were fully evaporated before they could impact to the walls. For Jet A fuel flowing at a stream velocity of 1 m s^{-1}, the results are illustrated in Figure 39. The wall temperature necessary for ignition was found to depend on the air stream velocity; at a flow velocity of 3 m s^{-1}, needed temperatures were about 70ºC higher.

Several studies focused on the ignition of fluid sprays in *a jet engine nacelle* of an airplane in flight. Since there is a non-zero air velocity in that environment, the studies focused on the effects of velocity. Atkinson and Eklund[141] used a flat plate arrangement, where small streams or sprays of jet fuels were directed onto a horizontal heated plate in various wind conditions. Their ignition results are shown in Figure 40.

A much more realistic geometry, in fact, an actual jet engine located in a wind tunnel, was used by Westfield[142], who was able to simulate flight Mach numbers up to 0.70. Temperatures along the engine were surveyed and a spray

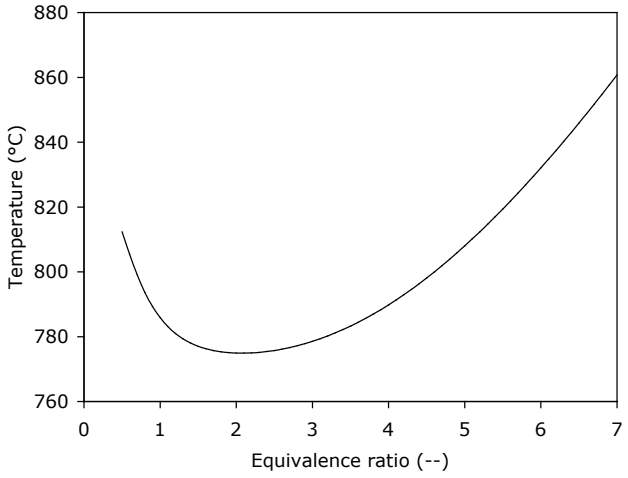

Figure 39 Effect of equivalence ratio on wall temperature needed for ignition of Jet A fuel (flow velocity = 1 m s^{-1})

nozzle was placed at the hottest location. At zero air flow rate, the hot surface temperatures needed for ignition were 450ºC for Jet A, 460ºC for Jet B, and 490ºC for MIL-H-5606 hydraulic fluid. Increasing the air flow rate generally made ignition more difficult, but the relation was not necessarily linear. Based on these results, Westfield concluded that a long-standing aviation industry guideline that hot-surface ignitions are unlikely if the surface temperature does not exceed 260ºC (500ºF) was conservative enough.

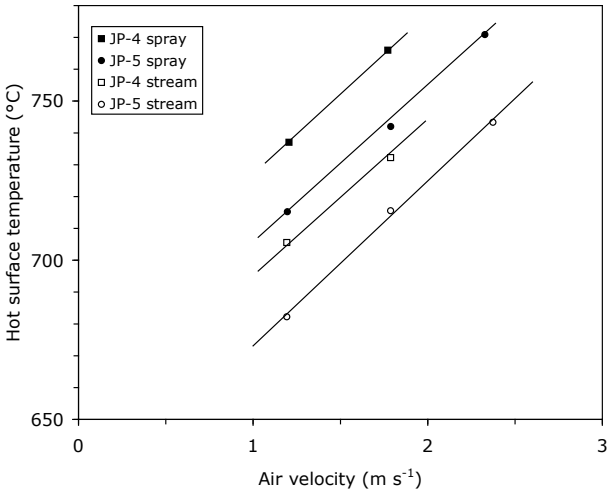

Figure 40 Hot surface (plate) ignition tests of Atkinson and Eklund

Myronuk[143] first conducted flat-plate experiments, but discovered that the residence-time was a critical factor. In his experiments, he was unable to retain the mixture for a sufficient time for ignition to occur. Thus, he then mocked up the fin-like obstructions that can be found on a real engine surface. He considered that the more realistic test geometry both prolonged the residence time and helped to create a

stagnation mixing region. His test results showed that there was no significant difference between the ignition of JP-4 and JP-5 aviation fuels and MIL-H-5606 hydraulic fuels, thus the results are shown in Figure 41 as one band. On the other hand, he found that the type of metal used made some difference. He attributed this to a combination of catalytic effects and of thermal insulation by an oxidation layer. Figure 42 shows ignition time results for JP-4 sprays in the same series of experiments.

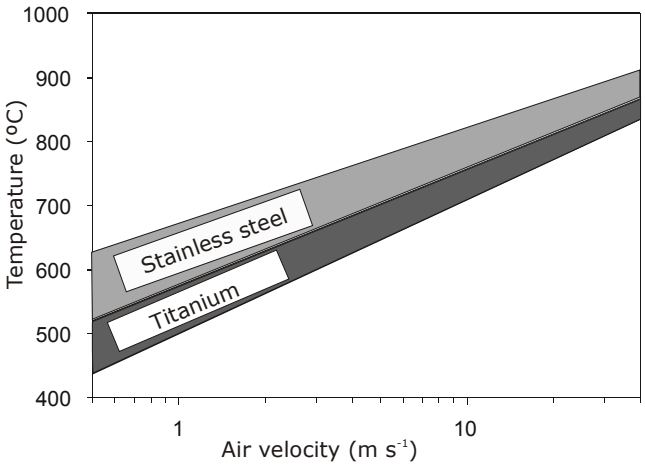

Figure 41 Myronuk's results for ignition of JP-4, JP-5 and MIL-H-5606 hydraulic fluids on hot engine surfaces

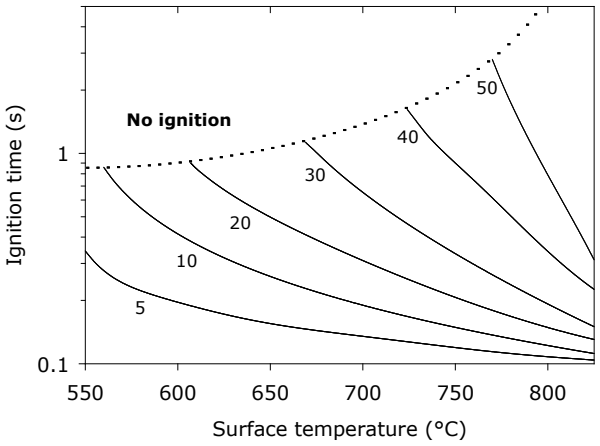

Figure 42 Myronuk's results for ignition of JP-4 sprays onto a hot engine surface, for various air flow rates (m s^{-1})

Similar tests were later performed by Clodfelter[144] using a realistic mockup of a jet engine. His results are shown in Figure 43. Unlike Myronuk, his results showed a clear difference between JP-4 and MIL-H-5606 ignitability. The flash point of JP-4 is –18ºC, versus +89ºC for MIL-H-5606 hydraulic fluid. However, the AIT of JP-4 is 240ºC, versus 227ºC for MIL-H-5606. It may be noted that these AIT values are very close, so if AIT values were controlling, the results should have been very similar. Instead, it is seen that the *lower* flash point liquid is much harder to ignite.

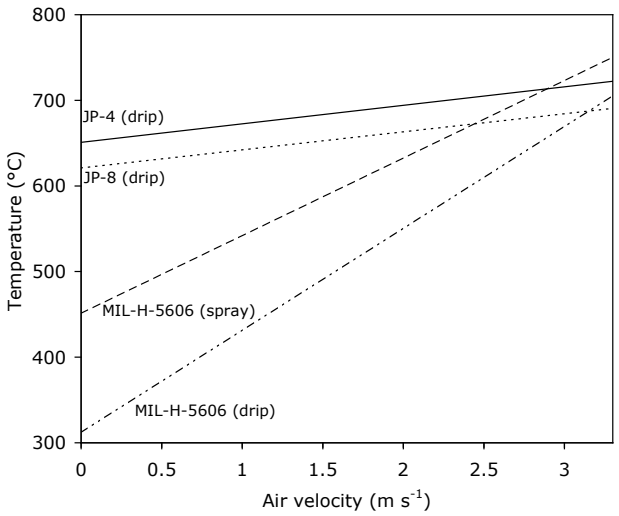

Figure 43 Clodfelter's results for ignition of drips and sprays onto a hot engine surface

Johnson et al.[145] explored the effect of *ambient pressure* on heated surface ignition temperatures. Using aviation fluids sprayed into a heated duct, they found a substantial pressure effect, with lower pressures giving higher ignition temperatures. Lowering the ambient pressure to 0.5 atm corresponded, roughly, to an increase of 250ºC in the hot surface ignition temperature for two hydraulic fluids.

The role of *time* was explored to a limited extent by Geyer and Moussa[146]. They used an engine nacelle simulator where fuel mists were applied for varying durations. Under some conditions, it was evident that fuel application needed to be fairly long (up to 1 min) for ignition to occur, but sufficient results were not obtained in order to derive quantitative relations.

It should not be much surprise to find that if a liquid is introduced into a fully enclosed space, then results similar to those obtained from AIT tests, rather than from hot-surface tests, will be obtained. Glendenning[147] demonstrated this by obtaining a 280ºC ignition temperature for aviation gasoline injected into the inside of a heated exhaust pipe.

While the above comprises a fairly long list of research studies, general guidance emerges only qualitatively. The reason why temperatures significantly higher than the autoignition temperature are necessary has to do with the distribution of fuel vapors in the vicinity of the hot surface. A location *in the gas* has to exist where

(a) the temperature is at or above the autoignition temperature;
(b) the fuel concentration is between the LFL and the UFL, as determined for that particular temperature; and
(c) the fuel/air mixture stays in a high temperature zone for a sufficient time.

Such a location will not exist until the surface is significantly hotter than the autoignition temperature. From these requirements, it can also be seen that if a partly- or fully-enclosed environment is involved, the needed temperature will drop, since there will no longer be a dropping temperature gradient with increasing distance away from the wall.

These considerations also make it clear that the temperature at which a hot-surface ignition can take place is not a constant of a substance, but is equally affected by the chemical nature of the substance and the environmental conditions. The latter include such details such as the amount of material dispersed and any imposed flow velocity. Experimental data indicate that there exists an inverse relation (Figure 44) between the flash point and the hot-surface ignition temperature, although, in view of the many variables governing the hot-surface ignition temperature, this relation is hardly quantitative.

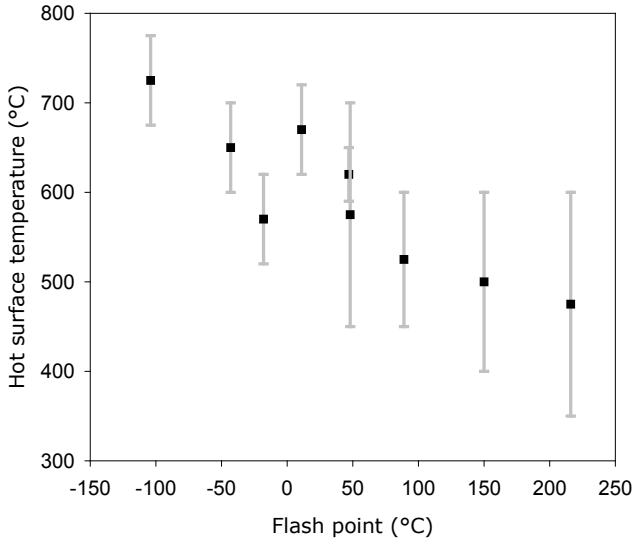

Figure 44 Relation between hot-surface ignition temperature and flash point

Most of the studies where velocity was varied indicate that an imposed velocity above a certain minimum value raises the surface temperature required for ignition. This is consistent with a minimum induction period interpretation, but is hard to evaluate quantitatively without elaborate experiments or complex computer modeling. Even early studies showed that results may be affected by the type of metal used for the heated surface, but no practical guidance has emerged on this point. Surface roughness plays a role in the evaporation process which is complicated and only partly understood. But Bennett[148] has reported on some preliminary research indicating that a surface with micro-cavities may be less prone to igniting some liquids.

The value of AIT is determined solely by the reactivity of the fuel. The value of the flash point is mostly a measure of the volatility of the fuel, although chemical reactivity plays a secondary role. The hot-surface ignition temperature can be viewed as being roughly equally affected by chemical reactivity and volatility. In the limit case, as the heated surface covers an ever-increasing fraction of the periphery of the volume under consideration, the value of the hot-surface ignition temperature must necessarily approach the AIT and volatility no longer plays a role. But this is normally not the type of hot-surface ignition problem that is of interest to the user. Parenthetically, the experimental studies considered in this Section suggest that such highly enclosed, heated geometries are rare, since most investigators (many of which created semi-enclosed environments) reported hot-surface ignition temperatures much higher than the AIT. If the space in question is roughly approximated as a cube and hot surfaces occupy more than one face of the cube, it is prudent to consider that the substance will ignite at the AIT. Otherwise, with the exception of substances whose droplets show a cool-flame ignition, the hot-surface ignition temperature it typically more than 200ºC greater than the AIT. The American Petroleum Institute concluded in its recommendations[149] that hot surfaces are liable to ignite fuel vapors only if the surface temperature exceeds the AIT by at least 200ºC in still air, and by even a larger amount if an appreciable velocity exists. This appears to be as reasonable a statement as can be made on the subject without getting into details on the specific geometry and materials and doing *ad hoc* testing.

There has been almost no theoretical work on the hot-surface problem, with the study by Vaivads et al.[150] being the sole one. Unfortunately, their model gave results which are the opposite of the experimental findings: their computations indicated that the lower-flash-point liquid would be more readily ignitable than one of a higher flash point.

POOLS

POOLS AT OR ABOVE THEIR FLASH POINT

"A pool will ignite if its temperature is above the flash point, and will not if below." This would appear to be a natural conclusion from the principles and results of flash point tests. But complications exist in real-scale pools that are not reflected in flash point testers. Where shall the pool be ignited? This questions was examined by Atkinson and Eklund[141], who studied the ignitability of jet fuels in two pool environments—an open one and a shrouded one. The pools were 250 mm diameter; three ignition sources were used—a small pilot flame, a 10 J spark, and a hot Nichrome wire.

Using the open-pool configuration, visual observations indicated that the vapor behaved differently for the two fuels. In the case of JP-4, a stagnant layer of fuel vapors formed about 25 mm high over the fuel surface, and a convective motion wafting the vapors upward was not seen. For the JP-5, which has a much lower vapor pressure, a stagnant layer did not form and a convective column was seen rising. This behavior in a quiescent environment determined the quanti-

tative results that were obtained. The results (Figure 45) show that for distances of ca. 25 mm above the pool, ignition occurs at about the nominal FP of the fuel. At progressively greater igniter heights, the pool has to be raised to temperatures considerably in excess of the FP. For JP-4, ignition with the spark was problematic, in that results were extremely erratic for heights in the range of 25 – 50 mm, and ignition was impossible at heights over 50 mm. The hot wire, as expected, was found to be a much less effective igniter than the spark. For JP-5, the results indicate that the most effective igniter was the hot wire, the least effective the spark, with the flame being intermediate. This ranking is hard to interpret and probably simply reflects data scatter.

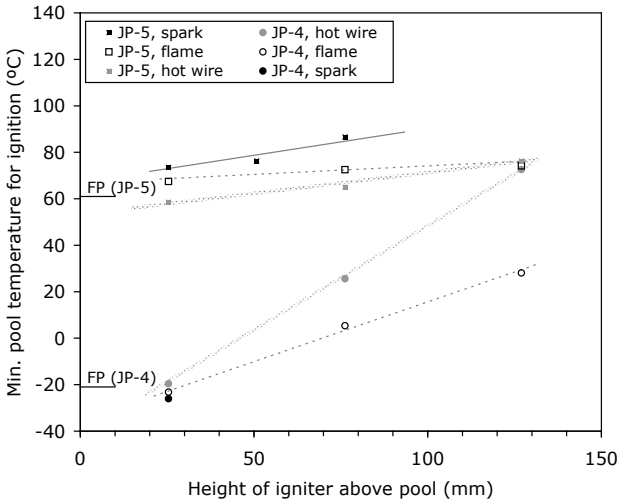

Figure 45 Effect of igniter height and igniter type on ignition of unshrouded pools

The authors then repeated the experiments, but with the pool surrounded by a 300 mm high shroud. Since in a large-size pool the vapors are likely to accumulate to a greater height than possible with a small, open pool, the shroud was considered to represent a sectional slice from a large pool. These results are shown in Figure 46. Similar trends with temperature were seen, but now reliable spark ignitions of JP-4 were possible up to the maximum height tried, 127 mm. In the shrouded pool tests, the effect of the ignition source was no longer anomalous, as it had been with the small, open pool—the flame source was consistently more effective than the spark, for both fuels.

Atkinson and Eklund also examined the effect of wind velocity on the ignitability of pools. The ignition sources were placed at the downstream edge of the pool, slightly above the pool surface. The results (Figure 47) show that modest wind velocities have a small effect, but the effect is to raise the temperature needed for ignition. Again, flame ignition sources provide some local preheating for the pool, so ignition may be possible at temperatures somewhat below the FP; the data on this point should not be considered rigorous, since jet fuels are mixtures, not pure chemicals, and

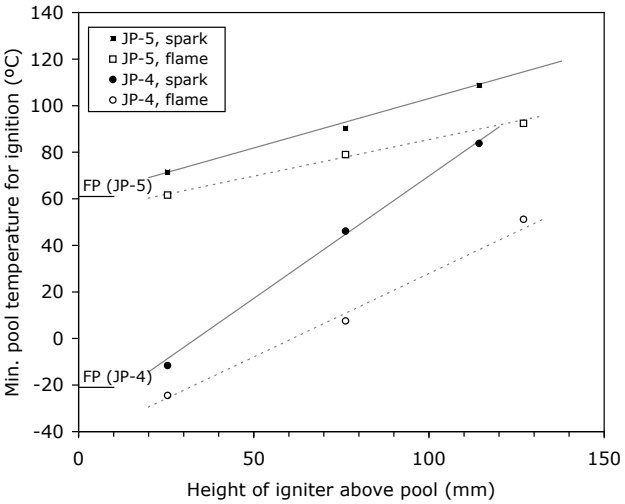

Figure 46 Effect of igniter height and igniter type on ignition of shrouded pools

actual flash points will change with progressive evaporation.

If a liquid pool has a temperature above its flash point, then in still air there is likely to be a large column above the surface where putting in a small spark or pilot will result in ignition. If there is a cross-wind, however, then the vapor rising from the surface forms a thin boundary layer, instead of a tall column. The fuel concentration is highest at the surface and monotonically decreases further out into the boundary layer. Ignition will occur only if the ignition source is placed at a location lower than the place at which the LFL is reached in the boundary layer. Murad et al.[151] applied boundary layer theory to compute the location of the LFL and found that this coincided closely to the maximum experimental height at which ignition could be achieved.

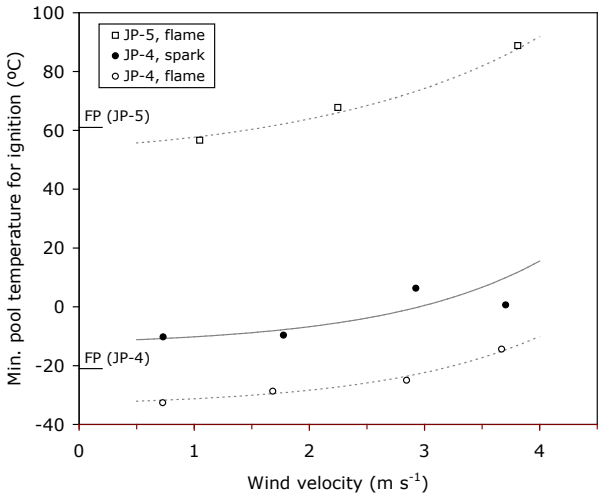

Figure 47 Effect of wind velocity on ignition of pools

POOLS BELOW THEIR FLASH POINT

Ignition of pools having a temperature less than their flash point presents a different situation. Assume for the moment that the flash point is a true material property and is not apparatus-dependent. Then clearly if the temperature of the liquid is below T_{FP} and a small igniter is placed above the surface, neither flashing nor ignition will occur. But what if a larger igniting flame is used and it is played on the surface to cause significant heating of the liquid? For modest heating, there still will be no ignition, but the explanation involves thermally-induced fluid motions. When a strong flame is used, the temperature of the fluid's surface is raised locally. However, the surface temperature remains at its lower original value a short distance away. This difference in temperatures sets up a convective current[152,153], whereby the heat is taken away from the region of the flame and distributed over a wide surface area of the liquid pool. Assuming that the area of the pool is greatly larger than the area being subject to direct flame heating, the rise in the surface temperature is negligible, and a flash does not occur. The flame or hot body, however, does not need to be massive for small pools (say, less than a few centimeters); for these, the effect of heat redistribution becomes limited due to small pool size.

Given the above physics, it is sometimes believed that liquids having a flash point significantly above the ambient temperature cannot be ignited. There are many ways in which this belief can be found to be false. The simplest way is by the use of a wick. An oil lamp would not burn if one attempts to light the vapors with a match. It burns readily when a wick is lighted, however. The physical principle involved is that of *constrained local heating*. The only reason that ignition does not occur in previous example is that the heated fluid elements can escape the heating zone. Thus, any mechanism which restrains fluid elements from escaping may lead to ignition. On a wick, surface tension provides the necessary force to hold in local fluid elements. Alan Roberts studied in detail the process of wick-supported flaming in his dissertation[154]; his results were summarized in a series of papers[155]. In burning pools of isoamyl alcohol, Roberts determined that the temperature of the surface of the wick was slightly above the boiling point of the liquid, indicating that the effective liquid level was slightly underneath the surface of the wick. The effect of the wick is highly localized. By using a tiny test flame, Roberts found that pool vapors were ignitable only for lateral distances no greater than 20 mm from the wick.

Other innovative ways exist whereby constrained local heating can occur. Glassman et al.[152] conducted experiments wherein they added a small amount of a thickening agent into kerosene pools. A polyisobutylene with a molar mass ~20,000 was used. The flash point of such a mixture was found to be no different from pure kerosene. However, they found that whereas a pure kerosene pool cannot be ignited from a small pilot flame, a thickened pool readily ignites. With the thickened fuel, the heated liquid is unable to move away from the source of the heat.

Incidents have been reported[156] where welding operations on 'empty' tanks holding residues of heavy oils caused ignition and explosion, even though these oils had flash points much above the prevailing temperature. There are several possibilities for this. (1) A thin coating of a high viscosity oil is unable to create convective currents when subjected to localized heating; thus such a layer might be viewed as "self-wicking." (2) Tank samples that were taken may not reflect the vapor available for ignition. The lighter fractions which would comprise the ignition problem may all have already been evaporated, so that sampling the liquid simply does not reflect on what is in the vapor phase. (3) Certain areas may release liquid or vapor after initial vapor-freeing of the tank[157]. It would seem simple to just use a combustible gas detector to determine the actual content of the atmosphere, but a study[158] showed that it is very easy to get erroneous readings with these detectors due to sampling problems. Other related issues are discussed under *Asphalt storage tanks* in Chapter 14.

The issue of ignition of *very thin* layers of liquids is not well quantified. Liquid layers thinner than about 0.8 – 2 mm may not ignite due to heat losses occurring to the bottom, possibly augmented by a liquid-film thermocapillary deformation effect which reduces the layer thickness locally[153,155].

Ignition of fuel in closed vessels

A common question concerning flammable liquids is: "For a vessel partially filled with a flammable liquid, what is the temperature range over which the vapors can form an ignitable mixture?" This question may be the most common for motor vehicle gasoline tanks, but can occur in a wide range of circumstances. The vapors in a gasoline tank will not ignite, due to the concentration of the vapors being above the UFL (except under very cold temperatures). An 'empty' gasoline tank will, however, have a lower vapor concentration; this can be within the flammable range. It may be surprising, but this fact was already known in 1877[159], way before the automobile era. For many types of tanks, it may be impractical to get them sufficiently empty. For example, extrapolations based on laboratory tests indicated that a tank of the Boeing 747 airplane would have to be emptied of all but about 4 – 8 L of fuel before assurance could be had that the LFL is not reached within it[160].

In discussions of the flammable range, it is often assumed that the liquid contents of a vessel are all at the same temperature. In tanks which are stirred through the motion of a vehicle, this is likely to be an excellent assumption. But in fixed tanks, especially ones which may be getting substantial heating from sunlight, temperature distributions may be substantially non-uniform. For large industrial tanks that are not fully sealed but are 'air-breathing,' Britton[161] states that

fuel vapor concentrations found escaping the breathing pipe are typically only 30 – 50% of the computed values, if computation is based on the average temperature of the liquid in the tank, but reasons for this deviation have not been studied.

A safety precaution must be emphasized: To fill a tank, at least initially, one has to start with an empty tank! Thus, even for a liquid with a very low UTL, one cannot assume the tank atmosphere will be above the UTL during the initial filling. It may be necessary that the tank first be filled with an inert gas, before introducing the liquid to it, if there is a possibility of ignition from electrostatic or other causes.

Apart from the question of stirring, there are three factors to consider in determining whether or not ignition occurs: (1) the energy of the spark; (2) the amount of fuel in the tank; and (3) the temperature. The amount of fuel is important since it determines the fuel vapor concentration that can be attained. Battista and coworkers[162] set up a device for creating a spark (of unspecified energy) inside a fuel tank which was 1/30 full of fuel. For methanol, they obtained ignition at 19ºC, but this was a very mild event, entirely contained within the tank. For a 85% methanol/13% gasoline/2% butane fuel ignition occurred at –34ºC, with unspecified consequences. For an 85% methanol/15% gasoline fuel, the ignition occurred at –25ºC, and was another mild event contained within the tank. For methanol containing 4% cetane improver, ignition was at 20ºC, but the ignition event resulted in burning fuel discharge and tank bulging. Both of these consequences, however, were also very mild.

The authors then investigated ignition using a small flame at the open neck of the filler. With gasoline in a steel fuel tank, the vapors did ignite and the tank expanded, vented, and the fuel was consumed. Using gasoline in a plastic fuel tank, the results were roughly similar. In neither case, judging by the description of the events, would it appear that the fires would have been threatening to individuals not intimately involved in fueling. For methanol, either with or without cetane improver additive, there was no ignition of fuel from the flame at the open filler neck. Using an 85% methanol/15% gasoline fuel, the results were ignition and burning roughly similar to gasoline, for both the steel and the plastic tanks.

In an interesting companion examination, Battista and coworkers fired explosive projectiles (nails fired from a Ramset explosive-actuated power tool) at steel and plastic fuel tanks. The fuels tested were gasoline, methanol, methanol with cetane improver, and an 85% methanol/15% gasoline fuel. In no case did ignition result due to penetration of the tank.

Battista and coworkers also extended their study in a more fundamental vein by conducting a series of experiments with the 85% methanol/15% gasoline fuel in the IEC spark test apparatus[163]. Figure 48 shows the combined effect of temperature, fuel amount, and ignition current. These results are under idealized laboratory circumstances (such as a stirred vapor space without stratification) and cannot be directly extrapolated to field experience. Nonetheless, they are valuable since the trends are delineated quantitatively.

EFFECT OF VAPOR/LIQUID VOLUME RATIO

When a liquid/vapor equilibrium exists in a part-filled, closed vessel the vapor pressure will be a constant value, irrespective of vapor/liquid volume ratio, if the liquid is a pure compound. If the liquid is a mixture, however, then the vapor/liquid volume ratio will affect the vapor pressure and, consequently, the flammability limits and the flash point. If the volume of the vapor space is very small, even the most volatile component will be able to exist in both liquid and vapor phases. But if the vapor space volume becomes large, then the most-volatile component may entirely evaporate from the liquid and not raise the fuel concentration in the vapor space to the same value which would be possible if there was a larger reservoir of liquid. Then, the temperature of the liquid will have to be raised to vaporize less volatile components, if ignition is to be possible. The standard ASTM Reid vapor pressure test uses a vapor/liquid volume ratio of 4:1. *True vapor pressure* is defined as the vapor pressure as the vapor/liquid volume ratio → 0. An illustration is given in Chapter 14 under *Aviation fuels* which shows how the vapor pressure rises as the vapor/liquid volume ratio drops. For gasoline, the true vapor pressure is about 7% higher than the Reid vapor pressure.

For this reason, closed-cup flash point test methods need to prescribe a fixed vapor/liquid volume ratio to give reproducible results. Actual end-use environments may have a different vapor/liquid volume ratio, however, thus the end-

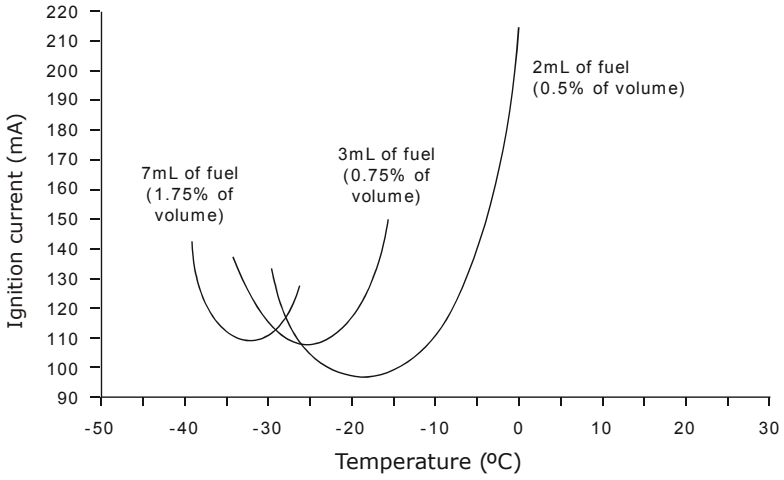

Figure 48 Combined effects of temperature, fuel amount and ignition current on the ignitability of a closed volume containing a motor fuel

use flash point may differ from the one determined in the standard test method. Carhart[172] compiled data for several JP-5 fuels at various ullage percentages and found a clear effect for certain batches and none for others. The variations can occur because specifications for JP-5 fuel control the composition of the fuel only within a broad range.

EFFECT OF SLOSH

The flammability of liquid in a closed container may change if the container is *shaken or sloshed*. Within a closed container that is at rest at a given temperature, a liquid/vapor equilibrium is established and the partial pressure developed by the vapor is simply the equilibrium vapor pressure of that particular substance at the given temperature. This vapor pressure is defined with respect to a flat liquid surface; with a curved liquid surface, as present at a droplet, the vapor pressure becomes higher[164]. Thermodynamically, this is due to a surface contribution to the Gibbs free energy, with convex surfaces raising vapor pressure and concave ones lower it. The vapor pressure at a droplet P_d is related to the vapor pressure at a flat surface P according to the relation:

$$\frac{P_d}{P} = \exp\left(\frac{2k(T_c - T - 6)}{rRT} \left[\frac{M}{\rho} \right]^{1/3} \right)$$

where T_c = critical temperature of the liquid (K), T = temperature (K), r = radius of droplet (m), R = universal gas constant (= 8.314 J mol^{-1} K^{-1}), M = molar mass (kg mol^{-1}), ρ = density of droplet (kg m^{-3}), and the constant k is approximately 2.1×10^{-7} J K^{-1}. The critical temperature of various liquids can be found in standard handbooks[3]. Since all of the remaining variables are fixed at a given temperature, the vapor pressure increases ~ exp (1/r), which means that if the droplets are small, there will be a significant vapor pressure increase. Since the vapor pressure of interest represents a dynamic equilibrium, it can be visualized that the reason why the vapor pressure is higher for small droplets is because it is harder for a vapor molecule to return to a small drop than to a large planar surface.

Ott[165] conducted slosh-tank experiments on various aviation fuels and found that by vigorous sloshing he could lower the LTL by about 33ºC, however the LTL under slosh conditions becomes somewhat poorly defined, that is, as the temperature is lowered, explosion pressures progressively fall, without there being a sharp explosion/no explosion demarcation. He also found experimentally that there was no detectable effect of slosh on the UTL.

Radiant ignition of liquids

Pools which are at a temperature above their flash point can be ignited by a spark, a small flame, and other localized sources of heat which do not provide any substantive heating to the body of liquid itself. But one way in which pools at an initial temperature below their flash point can ignite is if they are subject to radiant heating. Typically, this heat flux may originate from another nearby, but not contiguous burning object. In this section, we consider separately thick and thin layers. For thick layers, both the theory and the engineering treatment are nearly identical to the case of solid combustibles. For this reason, we refer the reader to the pertinent sections in Chapter 7 for a systematic presentation of the principles of radiant ignition. Thin spills of a combustible liquid upon a solid substrate present some unique issues, and its theoretical treatment is given below.

THICK LAYERS

Putorti et al.[166] tested layers of motor oil in the Cone Calorimeter for radiant ignition. Depths of 10, 15, and 42 mm were tested, but no significant effect of layer depth was found. The results are indicated in Figure 49. There was a very modest difference between the two grades tested and it is not clear if this difference would be reproducible. The results can be represented for SAE 30 oil as: $\dot{q}''_{cr}$ = 1.20 kW m^{-2}; B_{ig} = 315. For SAE 50: $\dot{q}''_{cr}$ = 1.21 kW m^{-2}; B_{ig} = 336. Similar tests were also conducted by Wu et al.[167] for pools of 6 – 10 mm depth and, again, no layer depth effect was found.

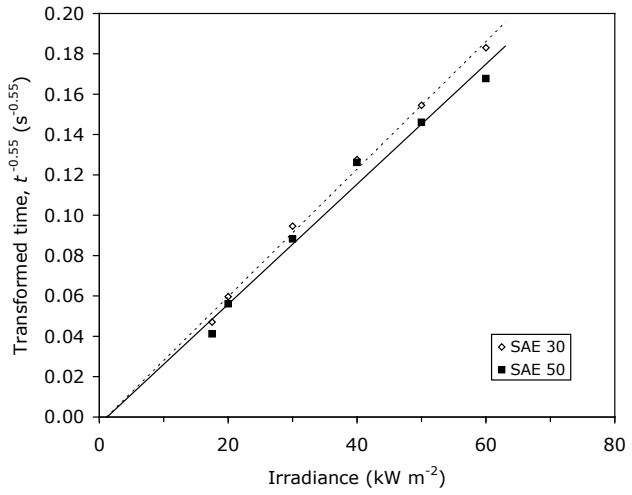

Figure 49 The piloted ignition of thick layers of motor oil

Wu and Torero[168] examined the radiant ignition of crude oil from the Alaska North Slope. Crude oil contains hydrocarbons spanning a wide variety of molar masses and the lighter fractions can be evaporated by prolonged open-air exposure or by heating. Their data are shown in Figure 50. It may be noted that the sample which was 12% evaporated shows a critical ignition flux of about 1 kW m^{-2}, while the 20% evaporated sample shows 4 kW m^{-2}. The non-evaporated and the 8% evaporated samples, however, show a different behavior: their critical flux is less than zero. The authors did not explore the minimum needed flux, but if the minimum flux is not too far from the critical flux, the results would suggest that the 0% and 8% evaporated specimens do not require any radiant heating and a simple spark should suffice to ignite them.

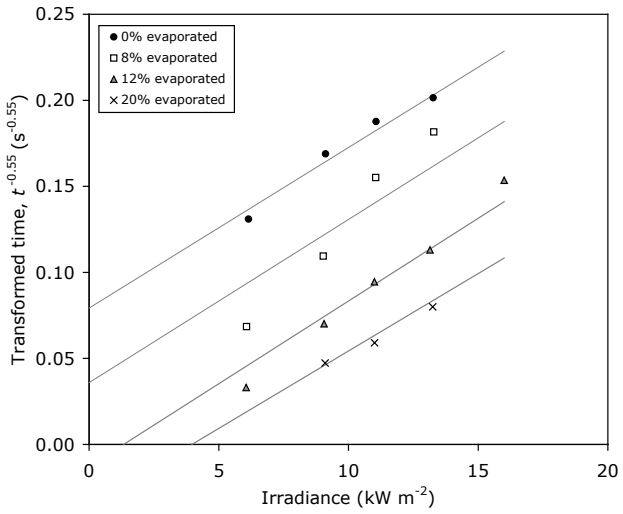

Figure 50 Piloted radiant ignition of Alaska North Slope crude oil

This interpretation is confirmed by the results shown in Figure 51. The ASTM D 56 closed-cup flash point is seen to linearly depend on the percent evaporated of the crude oil. Furthermore, if ambient temperature is around 23°C, then it is seen that samples of less than 9% evaporated fraction show a flash point of less than ambient temperature. Thus, *a negative value of critical flux suggests that the flash point is less than ambient temperature*. This relation should not be taken to be highly precise, however, since results from both radiant ignitability tests and flash point tests are dependent on apparatus details and are not absolute quantities. Wu and Torrero also demonstrated that oil layers as small as 6 mm behave as thermally thick materials, but did not explore ignition of thinner layers.

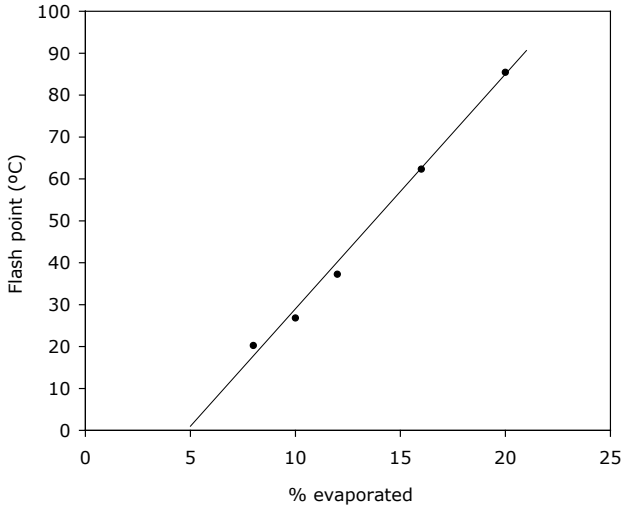

Figure 51 Relation between flash point and % evaporated for Alaska North Slope crude oil

Li et al. measured the ignitability of several liquids using both tungsten-lamp and CO_2 laser sources[169]. Their results are shown in Table 13. The laser results are atypical of other heating mechanisms, since the absorption of radiation occurs solely within a few molecular diameters of the surface. This causes unusual motions both in the vapor plume above the surface and in the liquid itself.

Table 13 Ignitability of liquids determined by Li et al.

Fuel	Flash point (°C)	Min. flux (kW m^{-2})	
		Lamp source	Laser source
kerosene	43	2.9	6700
light diesel	62	3.7	4600
heavy diesel	82	5.2	3200

THIN LAYERS

If a liquid is spilled on a surface, typically, on the floor, two possibilities can occur: (1) Its exposed surface area becomes limited by a 'diked' area, whether it is diked intentionally or not. (2) Either no means of diking exist, or the amount of liquid spilled is small enough that the size of the spill area will be governed by the amount spilled, the surface tension and viscosity properties of the fluid, and the roughness or porosity properties of the surface. In addition, if floors are sloped or warped, a pattern may be established which is centered on the low spots of the surface. Modak conducted an extensive experimental investigation of thin-spill ignitions[50]. He demonstrated that the thermophysical properties of a wide range of common oils (No. 2 fuel oil, SAE 30 motor oil, turbine oil, and fire-retardant hydraulic fuel) are indistinguishable, even though their flash points and fire are, of course different. This means that for a given irradiance and a given depth of spill, the surface temperature versus time relation was found to be identical for these oils. For smooth, non-absorptive surfaces, e.g., steel or epoxy-coated concrete, the depth of spill, computed as the (volume spilled)/(surface area formed) ratio, was found to be a constant value, independent of the amount spilled (Table 14). In the case of normal, uncoated concrete, however, for larger spills resulted in effectively greater depths being computed, due to in-depth absorption by the surface.

Table 14 Effective depth of spill for undiked spills on flat, non-absorptive surfaces

Oil type	Depth of spill (mm)
No. 2 fuel oil	0.22
turbine oil	0.34
SAE 30 motor oil	0.75
fire-retardant hydraulic fluid	0.84

Putorti et al.[170] studied gasoline spills on wood parquet, vinyl floor tiles, and carpeting. The effective depth of spill he found was 0.67 mm for a wood floor and 0.56 mm for vinyl tile. Carpeting did not exhibit a constant depth of spill. His results appear to be at variance to Modak's, since Modak found that depth of spill effectively decreased with viscosity, but gasoline is less viscous than fuel oil.

Modak also provides several different theoretical approximations to predicting the ignition time. Ignition is assumed to be reached at the moment that the fluid's surface temperature first attains the fire point temperature. The agreement between theory and experimental results was limited. However, in view of this, the simplest approximation appears to be a useful starting point. In this approximation, the thermal properties of the liquid are ignored, since a very thin layer does not appreciably change the heat balance of the substrate. Instead, the temperature-time curve of the liquid surface will be governed by the thermal inertia *of the substrate*. Liquids will still differ in their fire point temperatures. But since the thermal inertia of common substrates varies enormously, much more than do the fire points of common liquids, it is clear that ignition time is largely governed by the nature of the substrate, rather than by any property of the liquid itself.

Ignition of liquids by other means

A fundamentally different way of igniting liquid drops or aerosols is by shock waves. Miyasaka and Mizutani[171] conducted experiments igniting liquid droplets and sprays with shock waves. They studied sprays of a high volatility fuel (tetralin) and a low volatility one (cetane). Droplet diameter was ca. 80 μm. For tetralin, there was no effect of droplet injection rate, and the results were in all cases identical to tetralin vapor. Ignition was extremely fast, however, and was orders of magnitude faster than when ignited by other means. The ignition time t_{ig} (ms) was expressed as:

$$t_{ig} = 0.0005 \exp(5680 / T_2)$$

where T_2 (K) is the static temperature of the shock wave, determined from its velocity by use of the Rankine-Hugoniot relationship. For the low volatility fuel, similar exponential relationships could again be obtained, but these differed for each injection rate. The rapidity of ignition was attributed to the fact that the shock wave shatters the initial droplets to a 'micromist' where the diameters are only a few μm.

Tests for ignition properties of liquids

AUTOIGNITION TEMPERATURE

The AIT is a variable which is highly dependent on the test apparatus and the test protocol used. NFPA 32[5] provides the following general guidance in selecting and relying on ignition temperature tests: "Some of the variables known to affect ignition temperature are the percentage of the gas or vapor in the mixture, the shape and size of the test vessel, the rate and duration of heating, the kind and temperature of the ignition source, and catalytic or other effects of materials that may be present. As there are many differences in ignition temperature test methods, such as the size and shape of the test vessel, the material of construction of the test vessel, method and rate of heating, residence time, and method of flame detection, it is not surprising that reported ignition temperatures may differ for the same material."

Carhart[172] noted that AIT values tabulated for common substances in authoritative data compilations sometimes differ by 100ºC or more. One variable that has been studied at some length is the size of the test vessel. Figure 52 shows some data obtained by Setchkin[173] on the size effect using spherical flasks. The size effect should be similar to that found for gases and an orderly decrease of AIT with size is found, except for the largest size (15 L; V/A = 67 mm). This was an artifact of the experiments, since a thicker glass vessel had to be used, giving higher heat losses. Flasks on the order of 12 or 15 L are not practical for laboratory testing, so Setchkin recommended that a 1 L size (V/A = 27 mm) would be sufficient. According to thermal ignition theory (see Chapter 4), plots of $\ln\left(T_{ig}^2 / r\right)$ should give straight lines if plotted as a function of $1/T_{ig}$, where T_{ig} = ignition temperature (K), and r = radius (m). This is shown in Figure 53, where reasonably straight lines are seen, except for the smallest and largest sizes.

EARLY TEST METHODS

The early history of developing test equipment for characterizing the autoignition of liquids took place during the first three decades of the 20th century. It was largely motivated by the desire to develop suitable motor fuels for automobiles, aircraft, and other related applications. Thus, perhaps it is not surprising that the very first test method proposed in 1906[174] involved a compression cylinder. Effectively, this was a h ighly-simplified version of a one-cylinder internal combustion engine. Under assumptions of adiabatic compression, the temperature reached in the en-

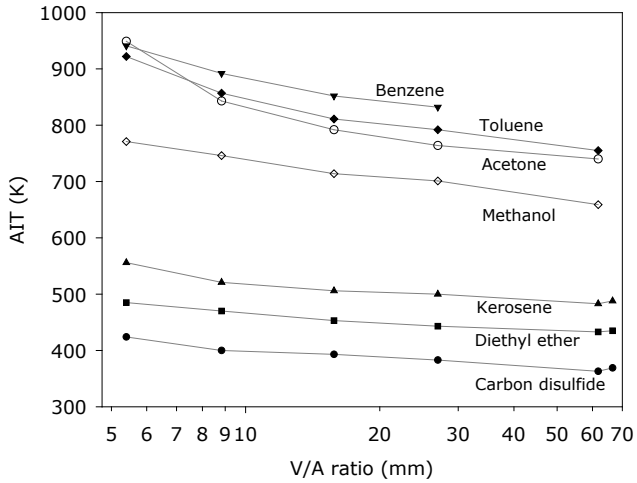

Figure 52 The effect of flask size on the AIT of liquids

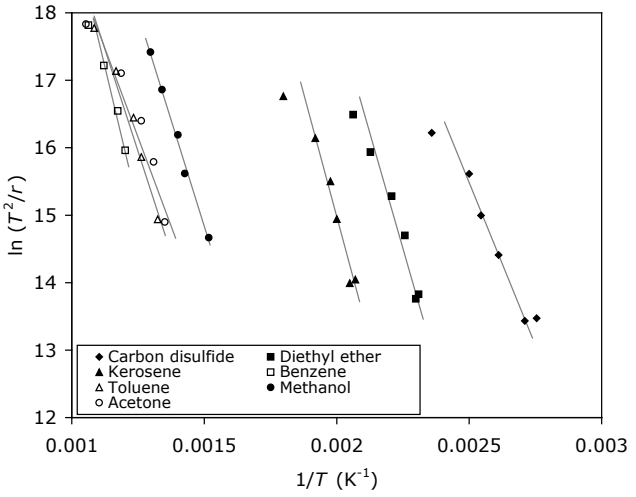

Figure 53 Setchkin's results plotted according to Semenov theory

gine can be computed from the pressure attained. This was certainly an indirect method and one especially problematic because no visual observation was possible.

Since in this Handbook the focus is on unwanted fires, test methods especially tailored for improving the design of internal combustion engines are not within the scope. It is interesting to note, however, that a large number of further adiabatic-compression ignition test methods were described in the literature subsequent to 1906. Mullins[175] reviewed these test methods comprehensively. In more recent decades, there has been a revival of interest in adiabatic compression tests for use within the aerospace industries, because of the possibility of evaluating substances at high pressures. However, values from adiabatic compression tests are systematically high when compared to tests performed in other types of apparatuses[173]. This is due to the basic pressure effect, compounded by non-uniformities in temperature that are a consequence of the rapid compression[176]. The basic compression-ignition principle is presented in Chapter 11, while additional use of test methods based on this principle is discussed in Chapter 4.

The majority of test methods which have been proposed for the purpose of determining an autoignition temperature of liquids are a form of heated-crucible test. The two most-used types of crucible tests have been the Moore test and the Jentzsch test. Moore's apparatus[177] is shown in Figure 54. An electrically heated block forms the crucible onto which a drop of liquid is released. Combustion air is supplied through a separate pipe and is wound for a number of turns through the heated block. This allows the incoming air to assume a temperature close to that of the crucible surface. A thermometer monitors the block temperature, while two cover plates are used to minimize the influence of room air currents. The liquid to be tested is held in a room-temperature dropper. This apparatus shown was Moore's 'improved' tester; his original design dates to 1917[178]. Moore's tester was not the earliest crucible method; two different German crucible test apparatuses were first described in 1913, but these were quickly supplanted by more evolved techniques. Many further elaborations along the same line of design as Moore's apparatus were seen during the subsequent years. The most important one of those was the first standard test method, ASTM D 286, described below. Apart from the general problems with test in this category, the Moore tester has been criticized[179] for giving too-high ignition temperatures on account of having too small a test chamber. The temperatures reported using the Moore tester are often hundreds of degrees higher than those obtained from a better test apparatus. For example, diethyl ether is reported[180] as 487ºC, compared to the 195ºC normally taken as its AIT today; or 520ºC for hexane, compared to 223ºC.

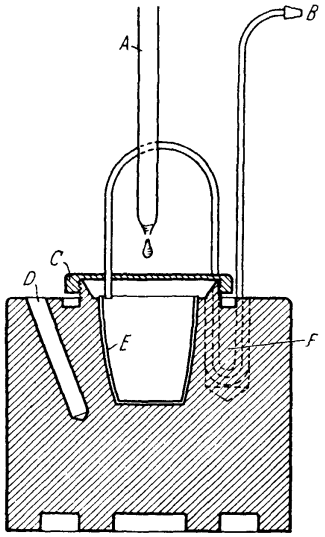

Figure 54 Moore's tester (**A** oil dropper; **B** oxygen feed tube; **C** cap; **D** pyrometer hole; **E** crucible; **F** thermal plug)

The second type of crucible test to achieve an early following was Jentzsch's method. In 1924 Jentzsch[181] designed a four-chamber tester, with one chamber holding a thermometer, while the other three are fed with oxygen and one of those receives a drop of specimen (Figure 55). Oxygen is metered in through a bubble counter. Jentzsch used the latter because he proposed a hazard rating scale which encompassed both the AIT and the amount of oxygen required by the specimen. For reasons not entirely clear, test results from Jentzsch's tester are broadly similar to values obtained in other test methods that use air, not oxygen. There were not many subsequent modifications of this apparatus as there were of the Moore tester, but the Jentzsch method continued to have wide and extensive use, even into the 1950s. At that time, the US Navy conducted some detailed studies of the apparatus and concluded that reproducibility is unacceptable with this test[182].

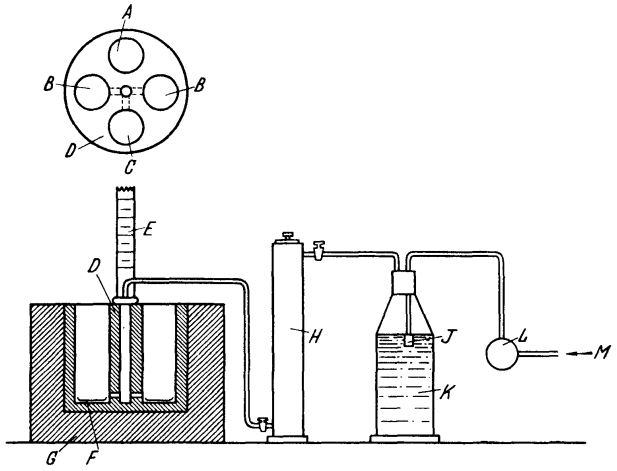

Figure 55 Jentzsch's tester (**A** thermometer well; **B** auxiliary chambers; **C** specimen chamber; **D** crucible; **E** thermometer; **F** vaporization dish; **G** furnace; **H** drier; **J** jet; **K** bubble counter; **L** adjusting valve; **M** oxygen supply)

Another category of autoignition testers differed from Moore's or Jentzsch's methods fundamentally because they did not pump in an oxidant stream into the crucible. The air was stagnant in a flask which was open to the atmosphere. Methods of this type were developed in the 1920s at Factory Mutual[179] and at Underwriters Laboratories[183]. A number of less-frequently used variants have also been reported in the literature. While the air flow was not capable of being varied in such methods, significant emphasis was placed on studying fuel-quantity effects. To that end, flasks of varying sizes and varying *flask materials* were used, and also varying amounts of fuel were introduced in an experiment. In the FM studies, glass and metal (copper, steel, chromium) flasks were compared. In some cases, the differences were small (<10 – 20°C). In other cases, differences on the order of 200°C were seen. This was true especially for alcohols. For example, isopropyl alcohol ignited at 456°C in a 125 cm^3 glass flask, but required 638 C in a 106 cm^3 chromium vessel and failed to ignite at up to the maximum temperature (649°C) that could be attained in a 106 cm^3 copper vessel. Hilado and Clark[184] surveyed available data and recommended that for consistency, tests should only be made in glass vessels. Glass is chosen due to its low reactivity and because, in most cases, it gives the lowest reported AIT values.

All of the above tests share the trait that substances are introduced at ambient pressure. A different scheme is to admit substances into an evacuated vessel. This type of an arrangement was found in some very early research done in 1880 by Mallard and Le Chatelier and later by Mason and Wheeler[185]. Several other researchers also used evacuated vessels, but no schemes of this kind have been proposed for standardized tests.

Certain substances decompose rapidly when exposed to heat. Thus, Frank and Blackham[186] pointed out that when testing ethers, a much larger amount of liquid must be used than for other organic compounds. Otherwise, rapid decomposition of the ether led to insufficient vapor concentration available for ignition. The form in which the liquid is delivered also has an effect. Most substances show similar AIT values when a few drops are dropped in, as compared to spraying the test substance into the chamber, but motor oils were found to exhibit significantly lower AIT values when sprayed in[187].

The range of reported data when experiments from various laboratories using various test apparatuses are considered can be enormous. For example, a comparison of values for benzene ignition in air reported by seven workers showed values of 370, 500, 520, 656, 700, 740, and 1062°C[183]. Larger differences yet may be involved when the substance (e.g., gasoline) is not a pure chemical.

Mullins[175] viewed that 'static' (i.e., no forced air flow) crucible methods, such as those of FM or UL, give poorer results than the Moore, Jentzsch, etc., crucible methods where air is pumped in. This is because he concluded that AIT values from the latter were more reproducible and were generally numerically lower. The exact opposite conclusion was arrived at by NACA[187]. They concluded that tests under zero-flow conditions gave the lowest results and a better correlation with chemical structure. NACA views proved to be more persuasive, since the later test methods (e.g., the ASTM methods) are zero-flow methods.

A number of other designs have been reported through the years. *Heated tube* methods have frequently been used in research studies on the AIT of gases and can be modified for fuels originally in liquid form. This is arguably the most accurate way of determining an AIT value, as discussed in Chapter 4. However, no standardized tests of this type have been put forth. A variety of *bomb methods* has seen significant usage in aviation-fuel research, where they are necessary if conditions other than at atmospheric pressure must be considered.

ASTM D 286

In the 1920s, the Bureau of Mines developed a test method based on a 125 cm^3 flask which is submersed in a bath of liquid solder. A gas burner heats the solder to a desired temperature. This method became standardized as ASTM D 286[188] (Figure 56). Results of a roundrobin using this method were published[189]. Gases can also be tested in the apparatus, by syringe injecting a suitable amount. Lewis[190] has discussed some problems associated with testing of gases, and it is clear that better methods are available for the purpose. The method has been criticized on several grounds[191]:

- the results are markedly affected by the size and shape of the cavity
- a fuel concentration gradient exists vertically in the cavity
- temperatures are non-uniform in the cavity
- because of the non-uniformity of fuel concentration, the minimum ignition temperature corresponds to unreasonably rich fuel vapor concentrations.

On a practical basis, the apparatus was criticized due to the fact that it lacked a way of making visual observations of ignition and also because it was difficult to keep clean[192]. A large compilation of results from a modified version of the test method (using a steel block, instead of liquid bath) has been published by the Bureau of Mines[193]. The test method was subsequently replaced by ASTM D 2155.

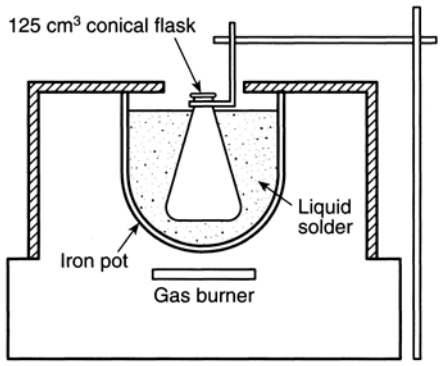

Figure 56 ASTM D 286 autoignition test (withdrawn)
(Copyright NFPA, used by permission)

ASTM D 2155

This test method was developed by the Bureau of Mines as its "I-8" apparatus and involves a heated 200 cm^3 glass Erlenmeyer flask[194]. The apparatus was more modern, with electric heaters being used to heat the flask. In the ASTM D 2155 apparatus (Figure 57), a small amount of the liquid is injected, and the flask is watched for 5 minutes for signs of a flash. If no flash occurs, the flask temperature is reported as being above the AIT. ASTM D 2155 has been withdrawn and superceded by ASTM E 659; however, the method remains an official US government test, used by the Mine Safety and Health Administration[195]. IEC 60079-4[196] is basically similar, except that a new flask must be used for each substance tested.

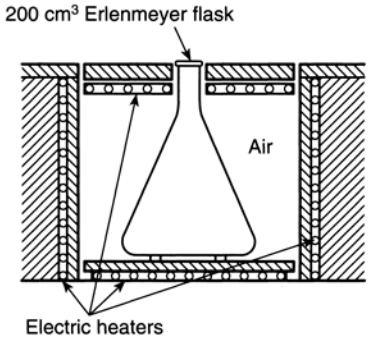

Figure 57 ASTM D 2155 autoignition test (withdrawn)
(Copyright NFPA, used by permission)

ASTM E 659

The ASTM E 659 test[197] (Figure 58) for autoignition of liquids is based on an apparatus developed by Setchkin[173] (Figure 59) at NBS (NIST) in 1954. A glass flask is surrounded by an electrically heated oven and is equipped with measuring thermocouples. To perform a test, an 0.1 mL sample of the liquid is injected with a syringe. The apparatus is observed for 10 min for signs of ignition by viewing in a fully darkened room. If no ignition occurs, another temperature is selected for the oven and the procedure is repeated. When the ignition temperature has been determined to within °3 C using 0.1 mL samples, both larger and smaller amounts are investigated to determine the overall lowest autoignition temperature. If cool flames are observed, these are reported separately as a 'cool-flame autoignition temperature.' Compared to Setchkin's original design, the ASTM version reduced the flask size from 1.0 to 0.5 L, removed the stopper, and provided a mirror for viewing of the inside of the flask. The apparatus itself is the simplest of the various 'autoignition' tests for liquids that have been proposed and contains nothing more than the heated flask and a viewing mirror; no forced air supply is used. It replaced older ASTM tests for autoignition of liquids, ASTM D 286 and ASTM D 2155 which were withdrawn. The method is also described as being suitable for readily-vaporized solids. While detailed studies have not been reported, it does not appear that the ASTM E 659 overcomes any of the fundamental shortcomings of the older tests.

Judging from the limited data of Johnson et al.[145], results obtained from the ASTM E 659 test are lower than from the ASTM D 2155, and the differences are greater for more volatile fuels, as shown in Table 15.

OTHER BUREAU OF MINES TESTS

For tests at low pressures and also for studying vessel size effects, the Bureau of Mines constructed a 4900 cm^3 heated steel vessel[198]. For studying motor engine fuels and related substances, the Bureau developed a bomb able to withstand explosion pressures, and thereby permit characterization of ignition times for a wide range of pressures[199]. The stainless steel bomb had an inside volume of 0.3 L.

FLASH POINT

A flash point tester is a simple device and needs only the following components:

(1) a small cup
(2) a device underneath the cup for heating it
(3) a thermometer
(4) a small flame that can be swung in and out, at a fixed distance above the liquid
(5) a lid (only for closed-cup tests)

The basic test procedure is also very simple. The test liquid is placed in a temperature-controlled cup and is allowed to reach equilibrium at a pressure of 1 atm and a given temperature. When equilibrium is reached, a small premixed flame is introduced into the air/fuel-vapor mixture above the liquid. If this vapor mixture flashes, then the vessel temperature is above the flash point; if not, then it is below. By trial and error, a temperature is determined which is the lowest at which the vapor does flash. This is reported as the flash point of the liquid. Despite this basic simplicity, development of flash point tests has had a very long and rich history. In this section, we review mostly the currently-used devices, with a brief historical look at early developments. A 1913 book[200] discusses some 48 apparatuses that were in use or were described in the literature. Fortunately, most of these are now obsolete but even the number of remaining ones might be considered excessive.

The testing of liquids for flash point properties became necessary in the 1860s, with the introduction of kerosene for kerosene lamps and for house heating. The use of a liquid fuel indoors is much more dangerous if the fuel vapors can ignite at ambient temperatures. These hazards of low flash point fuels became clear early, and during the 1860s the Abel closed-cup apparatus and the Tagliabue open and closed-cup testers came into use. The first UK Petroleum Act of 1862 attempted to restrict fuels having a flash point below 37.7ºC (100ºF), but did not specify a test method. In 1868 this was changed to specify an open-cup apparatus developed by Letheby and Attfield of the UK Home Office. The latter was found out not to be well-reproducible and Keates developed the first closed-cup apparatus, which was suggested for regulatory use in 1871, but never adopted. In 1875 Sir Frederick Abel was asked by the Home Office to help improve Keates' test. Abel's device was a rather strange closed-cup apparatus which used a water bath to maintain a fixed temperature, but interspersed an air space between the bath and the sample cup[201]. The heat to the unit was supplied by an alcohol lamp. A significant advance was the introduction of a controlled flame to replace the lighted string (!) previously used to test for flashing. In 1879 the UK recognized the use of the Abel flash point tester, and since the previous test was an open-cup unit, lowered the value to 22.7ºC (73ºF) on the grounds that this corresponded to a 37.7ºC reading of the open-cup method. Abel's test saw significant use in Germany, where it was early discovered that barometric readings have a substantial influence on the results. In high-altitude cities, values as much as 7°C lower were being determined. Despite this problem, it was noted that the Abel test was considered better than some 20 apparatuses previously invented in Germany. However, since high-altitude cities were not a concern in the UK, the problem was noted but not addressed[201]. In the US, regulation proceeded on a local or State basis, and 19th century fire safety literature contains significant pleas for mandating "100ºF kerosene" in order to reduce fire fatalities.

Barometric pressure has an effect on the flash point since, at any given temperature, it changes the fuel concentration. The fuel vapor pressure is only dependent on temperature (and not on total pressure). But changing the total pressure

changes the ratio (fuel vapor pressure)/(total pressure) and consequently changes the volume fraction of fuel in the atmosphere. To make a fully accurate correction would require knowing the vapor pressure of curve of the fuel in question, which is impractical. Consequently, ASTM E 502[202] recommends a universal correction which is deemed to be sufficiently accurate for physically reasonable variations in barometric pressure:

$$T_{fp}(corr.) = T_{fp}(meas.) + 0.25\,(101.3 - P)$$

where P = barometric pressure during test (kPa).

Prior to 1977, the US Dept. of Transportation regulated chemical hazards by using the Tagliabue (Tag) open-cup flash point tester and defining 'flammable' liquids as those having an open-cup flash point below 80ºF (26.7ºC). Since then, DOT, NFPA, and other US organization have agreed to use the Tag closed-cup test, with 'flammable' liquids being defined as those showing a closed-cup flash point below 100ºF (37.8ºC). This was based largely on demonstrations[74] that the Tag open-cup tester showed poor reproducibility, and the that reproducibility was better in the Tag closed-cup tester, and better yet in the Pensky-Martens tester.

Flash point measurements are occasionally applied to substances not in the liquid phase. NFPA 325 points out that: "Flash point applies mostly to flammable and combustible liquids, although certain solids, such as camphor and naphthalene, that slowly volatilize at ordinary room temperature, or certain liquids, such as benzene, that freeze at relatively high temperatures, will exhibit a flash point in the solid state."

ASTM defines 8 different flash point test methods. Their main traits are categorized in Table 16. Due to the proliferation of test methods, ASTM has a specific standard, ASTM E 502[202], which is devoted solely to giving the user general instructions on how to select and use a flash point test method. Note that the Abel test method, sometimes used in Europe, is not recognized by ASTM.

The Setaflash methods are intended as go/no-go tests at some temperature of interest for regulatory or specifications purposes. In that mode, they are very easy to use. They also avoid some of the inaccuracies associated with the rising-temperature methods. The latter have limitations[203] that can be serious, especially for mixtures (impure substances):

(1) each time the flame is dipped, some volatile components may escape. This can cause an improperly high reading to be registered.
(2) the vapor is not at the same temperature as the liquid, and this difference is exacerbated by the temperature ramping. This is especially a problem for high viscosity or low thermal conductivity liquids. The use of a stirrer is intended to overcome this problem, but it can lead to forming a mist in the chamber, which again will make results erroneous.

It has been stated[105] (but not proven) that for some petrochemical mixtures the flash point is dependent on the rate of heating and that slower heating may lead to a significantly lower T_{fp} being reported.

An extensive interlaboratory study of the reproducibility of closed-cup flash point methods was conducted in Europe[204]. The two primary methods studied were IP 303/74[205] (similar to ASTM D 3278 and D 3828) and IP 304/74[206] (similar to ASTM D 3941). These methods were selected because they are fixed-temperature methods. The investigators initially determined that all rising-temperature methods give apparatus-dependent results (primarily due to temperature non-uniformities in the apparatus and vessel size/shape differences), while results from fixed-temperature methods should be independent of the exact apparatus used. Thus, it was held that only fixed temperature (also called 'equilibrium') methods can be used to assign apparatus-independent values for flash points. Apparatuses normally used in a rising-temperature mode—such as Abel, Abel-Pensky, Pensky-Martens, and Tag—can also be used, provided they are operated with an adequate water bath and that this bath's temperature is only raised slowly. Standard IP 304 provides the instructions for doing exactly that. The results of the study indicated that there was no statistically significant difference between the various apparatuses, when operating in the IP 304-prescribed mode. Furthermore, it was found possible to determine flashpoints for a series of calibrating liquids to a reproducibility of ±0.5ºC (95% confidence interval). Finally, it was found that, when operated in a rising-temperature mode, the Abel apparatus gave results which were indistinguishable from equilibrium determinations; however, the Pensky-Martens test gave rising-temperature results which were significantly higher than when operated in an equilibrium mode.

ASTM D 56

The Tagliabue closed-cup test method, ASTM D 56[207], is the oldest flash point method listed by ASTM, having first been issued in 1918. It is the primary method called out by US Dept. of Transportation regulations. A test cup (Figure 60) holding 50 mL of sample is immersed in a liquid bath,

Table 16 Main features of ASTM flash point tests

Test	Name	Open/ Closed	Rising/fixed temp.	Stirred	Regulatory use
D 56	Tag, closed	C	R	N	DOT
D 92	Cleveland	O	R	N	others
D 93	Pensky-Martens	C	R	Y	DOT
D 1310	Tag, open	O	R	N	others
D 3278	Setaflash	C	F	N	DOT
D 3828	Setaflash	C	F	N	others
D 3934	Flash/no-flash	C	F	Y/N	others
D 3941	Equilibrium	C	slow rising	Y/N	DOT

which is typically a water/ethylene glycol mixture. The liquid bath is heated by a gas burner and is to warm up at a rate of 1°C per minute (for substances with T_{FP} < 60°C) or at 3°C per minute (for substances with $T_{FP} \geq 60$°C). At every 0.5 or 1°C interval, a small flame is briefly lowered down near the surface to test whether a flash occurs. The upper limit for the test method is 93°C. The lower limit is not specified, except for the note that values below 0°C may be unreliable.

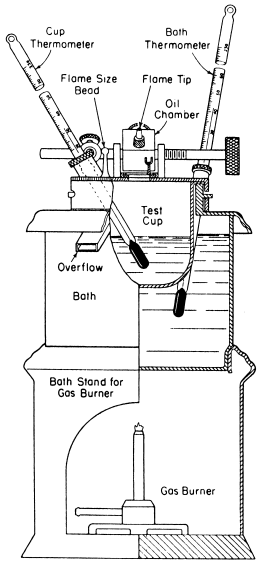

Figure 60 The Tagliabue closed-cup flash point tester
(Copyright ASTM International, used by permission)

ASTM D 92

The Cleveland open-cup test method, ASTM D 92[208], dates to 1921 and finds use in the petroleum industry for products, apart from fuel oils, having a T_{FP} between 79 C and 400 C. It uses a cup in which 70 mL of test liquid is held. There is no liquid bath, but temperature uniformity across the bottom of the cup is provided by a metal plate. Heating can be either by a gas burner or by an electric resistance heater. The heating, once a temperature close to the expected flash point is reached, is done at a rate of 5 – 6ºC per minute. The test method also provides for the reporting of the fire point, in addition to the flash point. The latter is defined as the lowest temperature at which flaming is sustained for at least 5 s. Its reproducibility was found to be the worst of all of the flash point testers[211].

ASTM D 93

The Pensky-Martens closed-cup tester, ASTM D 93[209], was first standardized in 1921 (Color Plates 8 and 9). It is limited to testing substances with a viscosity > 5.5 cSt at 40ºC. It has neither a liquid bath nor a heat sink plate, but relies on a stirrer inserted into the sample cup to ensure temperature uniformity. The Pensky-Martens test basically replaces the water bath of the Abel-Pensky test (not used in the US) with a heavy metal shell. The sample size is 75 mL. Due to absence of a water bath, high temperatures may be attained. The test method is usable for T_{FP} values from 40ºC to 370ºC. The sample is heated at a rate of 5 – 6 ºC per minute. Unlike other tests, there is a freedom to select the ignition source type, and both gas pilots and electric glow wires can be used. Burgoyne et al.[53] showed that a gas pilot used in the apparatus introduces significant aberrations both by localized heating of the liquid and by convection effects throughout the vapor space. Thus, they recommended use of electric spark ignition, but their recommendation was not adopted by ASTM.

The Pensky-Martens test was found to yield flash point values about 7 – 11ºC higher than the Tag Closed-cup tester[51]. Fire points reported in the Pensky-Martens test were found to be 8 – 13ºC higher than corresponding values in the Tag Closed-cup tester. In a research study where electric spark discharge was used at an optimized height[51], it was found that even the Tag Closed-cup fire point values were 1 – 10ºC higher than the 'true' values, while Pensky-Martens values were up to 18ºC higher than the 'true' values.

ASTM D 1310

The Tagliabue open cup test method, ASTM D 1310[210], was first issued in 1952. Flash points from –18ºC to 165ºC can be determined with this method. A water/ethylene glycol water bath is used, and the heat is provided by a gas burner. The sample is heated at a rate of 1°C per minute. Fire points may also be determined with this method, along with flash points. The fire point is defined the same as in ASTM D 92. Its reproducibility was found to be poor[74,211].

ASTM D 3278

While the preceding devices date to the early part of the 20th century, the Setaflash test, ASTM D 3278[212], was standardized in 1973 and reflects newer ideas in instrument design. The scheme was invented by T. Kidd at Esso Petroleum Co. and commercialized by Stanhope-Seat Ltd. Its development has been briefly reviewed by Wray[213]. It is a closed-cup test applicable for T_{FP} between 0°C and 110°C and viscosities less than 150 cSt at 25°C. A very small sample amount of 2 mL is injected with syringe into a preheated sample cup. The sample cup is part of a machined metal block which is directly heated by an electrical resistance heater. To examine higher or lower temperature values, a new specimen must be used. There is no stirring and no liquid bath. For temperatures below ambient, an auxiliary cooling block is used, which is packed with an acetone/dry ice mixture. A special procedure is given for testing organic peroxides. According to ASTM E 502, the Setaflash method is the preferred procedure for testing solid substances. Solids are dropped directly into the sample cup, instead of being injected into the filling orifice. This test method is very similar to ISO 3679[214] and ISO 3680[215] procedures.

ASTM D 3828

The ASTM D 3828 test method[216] is another version of the Setaflash test, developed by a different ASTM committee. It is specified over the temperature range of –20ºC to 300ºC. For temperatures over 100ºC, a 4 mL sample is used. At one time, ASTM also had a rising-temperature ('dynamic') Setaflash standard, ASTM D 3243[217]. Because of the small sample cup size in the apparatus, results from the dynamic procedure proved to be inaccurate, and the standard was withdrawn; it was officially superceded by ASTM D 3828.

ASTM D 3934

ASTM D 3934[218] evolved from studies in Germany that led to the German standard DIN 53213. It is an 'apparatus non-specific' closed-cup, go/no-go testing scheme which, in the ASTM standard, can use the sample cup of either the D 56 (Tag) or the D 93 (Pensky-Martens) test method. The liquid bath to be provided is not specified in detail. The test is intended for compliance verification, where a flash/no-flash result is to be obtained at a single test temperature. Temperatures in the range of 0ºC to 110ºC are encompassed. The method is roughly similar to ISO 1516[219] and is used by the paint and varnish industry. In the Pensky-Martens version, the sample stirrer is retained. A review of the inter-apparatus data correlation using this method has been published[220].

ASTM D 3941

For substances of low thermal conductivity, the rising-temperature Tag or Pensky-Martens tests may not give accurate results. A separate test standard, ASTM D 3941[221], has been developed which—like D 3934—allows the use of either the Tag or the Pensky-Martens sample cups and gives freedom in design of the liquid bath. Unlike D 3034, however, it provides a rising temperature program. The main difference between this standard and D 59 or D 93 is the slow rate of rise, being only 0.5ºC per minute. The method is similar but not identical to ISO 1523[222]; it is specified by the US Dept. of Transportation in regulations, in place of ISO 1523.

ABEL FLASH POINT TEST

The UK and some other countries still use the Abel flash point test. These are standardized by two IP (Institute of Petroleum) standards. IP 33[223] (also issued as BS 3442) is the official UK government test, according to the revised Act of 1928, while IP 170 describes a commercial standard that has been updated through the years. The device comprises a small, covered sample cup heated indirectly by an alcohol lamp. The lamp heats the water bath, but the sample cup is separated from the water bath by an air gap. The water bath is first heated to 54ºC (130ºF) and the source of heat is then removed. A specimen is first inserted at 16ºC (60ºF) and is then to be tested at every 1ºF rise in its temperature. The timing for opening the cover and applying the test flame is to be set by a metronome (possibly the only use ever made of a musician's instrument in fire testing). The peak test temperature is evidently somewhere below 54ºC, since reheating the bath is not allowed. A stirrer is provided for the specimen cup, but this is to be used for "viscous materials" only. A separate procedure is described for testing solid petroleum products.

The commercial IP 170 standard[224] provides a test range of –18ºC to 71ºC (0 to 160ºF). In the commercial procedure, the air space is also filled with water (or an antifreeze). All samples are stirred continuously by hand, not just viscous materials. Heat is continuously applied so as to raise the temperature of the sample at approximately 1ºC per minute.

TESTS FOR OTHER PROPERTIES

ASTM D 4206 TEST FOR SUSTAINED BURNING

The ASTM D 4206[225] apparatus is a small open cup which holds 2 mL of a test liquid and which is maintained at a temperature of 49°C by an electric heater. After the specimen is poured in, a small flame is applied for 15 s above the surface. The specimen fails if it sustains burning for more than 15 s after the removal of the pilot flame, or if it ignites from the pilot flame while it is still in its standby position, prior to having been moved into the test position. The test method is the ASTM equivalent of British standard BS 3900 Part A-11, which is used in the UK to regulate the flammability properties of kerosene.

HYDRAULIC FLUID SPRAYS

In many applications, hydraulic fluids are required to have low combustibility or a measure of resistance to ignition. For this purpose, a large variety of tests have been invented. Totten and Webster[226] reviewed 8 different methods. The methods in most current use are discussed below. The European Commission has issued a handbook—commonly called the 'Luxembourg report'—of test methods for fire-resistant hydraulic fluids[227]. Not all of the methods are for fire, since mechanical properties, toxicity, etc. are also encompassed.

ISO 15029

The method[228] provides three separate tests, a hollow cone nozzle method (ISO 15029-1), a 'small-scale' test (ISO 15029-2) and a large-scale test (ISO 15029-3). The hollow cone nozzle test was developed by the Coal Board of the UK. It is a bench-scale test where the test fluid, heated to various temperatures is sprayed from an 80 hollow-cone nozzle at a pressure of 7 MPa. The spray is ignited with an oxy-acetylene flame which is applied until ignition occurs. Upon ignition, the exposing flame is removed. The test variable reported is the time that it takes for extinction of the flame of the test fluid to occur. This method is little-used, with the Part 2 or Part 3 tests being viewed as more current test strategies.

The ISO 15029-2 test apparatus[229,230] resembles a wind tunnel, about 2 m long and 0.5 m high. It is called the 'Buxton test,' in reference to the town in the UK where the developing HSE laboratories are sited. An atomizer sprays the test fluid horizontally into the flowing air stream. Downstream of the atomizer is a propane burner which does or does not ignite the mixture. Two different propane flow rates are provided (approx. 3 and 10 kW), in order to better discriminate among fluids. The results are reported in terms on an 'ignitability index' RI, which is a complex expression involving various temperature measurements within the test apparatus. Smoke is also measured at the exhaust end and a separate rating is assigned for it. The product is rated into grades A – H, depending on its RI and its smoke measurement.

The large-scale ISO 15029-3 method was derived from an earlier Nordtest test[231]. It uses an arrangement involving a partially-enclosed room, where a nozzle sprays the test fluid into the air at an angle of 60º up from horizontal. Four different nozzle pressures are used: 50, 100, 150, and 250 atm. A propane igniting burner is located nearby, and products of combustion are collected in a large 3 × 3 m hood. The propane burner is used in three sizes, 10, 25 and 100 mm diameters, with the HRR values being 10, 100, and 200 kW, respectively. The results are reported in terms of combustion efficiency, with 0 indicating no ignition, and values greatly less than 1.0 indicating a sporadically igniting fluid. The reference heat of combustion has to first be determined using an oxygen bomb calorimeter. A report has been published giving guidance and example data[232].

Factory Mutual tests

FM uses an Approval Standard[233] that has two tests: (1) a hot surface test; and (2) a spray propagation test. In the hot surface test, a steel channel is place at 30º up from vertical, and its underneath surface is heated by propane burners to give a surface temperature of 704ºC. The heating is then turned off, and the test fluid is sprayed for 60 s onto the channel from a nozzle. If ignition occurs, the nozzle is turned away, and the flame must not follow the movement of the nozzle, for the fluid to pass. In the spray propagation test, a high-pressure spray is directed horizontally into open air. A propane torch is introduced at 0.15 and 0.46 m away from the nozzle. The flame must not persist for more than 6 s after removal of the torch.

MSHA spray test

The official test[234] specified for hydraulic fluids by the US Mine Safety and Health Administration is a spray test where fluid at 10.2 atm and 66ºC is discharged from a 90º cone angle nozzle. Three different ignition devices are used: (1) burning cotton waste in a metal trough; (2) an electric arc; and (c) a hand-held propane plumber's torch. The three hand-held sources are to be moved along the spray pattern in an undefined manner. To pass, the fluid must not burn for more than 6 s after withdrawal of the ignition source, when the ignition source is held for 60 s at any location farther than 0.46 m from the nozzle. Loftus[235,236] has discussed this test in detail, along with some other tests used by MSHA.

Chapter 7. Ignition of common solids

Highlights and summary of practical guidance **237**
Types of ignition **238**
General principles of flaming ignition **238**
Qualitative features *238*
The ignition problem for solids *239*
Research into ignition of solids **241**
Ignition temperature as ignition criterion *243*
Mass loss rate as ignition criterion *246*
HRR as an ignition criterion *248*
Other criteria for ignition *249*
Ignition from radiant heating **250**
Gas phase events *250*
Cool flames *250*
Comprehensive theories *251*
Atreya's model 254
Engineering treatments for thermally thick solids *256*
Development of approximate solutions 257
Janssens' procedure 260
Quintiere's procedure 262
Tewarson's procedure 264
Other data treatment procedures 264
Relation between minimum and critical fluxes 265
Engineering treatments for thermally thin solids *265*
Condition 1—back face insulated 266
Condition 2—back face cooled 267
Condition 3—back face also heated 268
Other issues for thin slabs 268
Illustrative data *268*
Composite materials *269*
Criteria for distinguishing thermally thick versus thin materials *271*
General and intermediate-thickness materials *272*
Energy needed for ignition *274*
Laser ignition *275*
Ignition from convective heating or immersion in a hot environment **277**
Ignition theories for convective heating *280*
Lumped-capacitance model 280
Thermally-thick solid—constant heat flux 280
Thermally-thick solid—constant convective transfer coefficient 280
Thermally-thick solid—boundary layer solution 281
Ignition theories for submersion in hot environments *281*
Theoretical solutions for other problem conditions **281**
Thermally-thick inert solid with fixed net heat flux *281*
Thermally-thick inert solid with fixed heat flux and convective cooling *282*
Thermally-thick reactive solid with fixed heat flux *282*

Finite-thickness inert plate with fixed heat flux 283
Finite-thickness reactive plate 283
Finite-thickness polymer undergoing charring 283
Thermally-thick reactive solid held at a fixed face temperature indefinitely 284
Thermally-thick reactive solid held at a fixed face temperature for a finite time 284
Thermally-thick reactive solid receiving fixed radiant heat flux only 284
Solid receiving a brief, high-intensity pulse of radiation 285
Porous solids 285
Diathermanous solids 285
Miscellaneous geometries 285
Depletion of reactants not ignored 285
Ignition from localized sources **286**
Small flames 286
Small-diameter, high-intensity heat sources 287
Hot bodies 287
Ignition from large flames **289**
Duration of ignited burning **290**
Flashing vs. sustained flaming 290
Sustained flaming after initial ignition 290
Variables affecting ignition of solids **292**
Type of pilot (or lack thereof) 292
Orientation 294
Exposed area size 295
Air flow rate 297
Oxygen concentration 299
Piloted ignition 299
Autoignition 299
Chemical composition of diluents 300
Total pressure 300
Moisture and relative humidity 302
Initial temperature of specimen 304
Acceleration of gravity 304
Surface absorptivity, material transparency, surface coatings, and spectral characteristics of the radiant source 304
Polymer structure 308
Porosity 308
Fire retardants 308
Movement of the surface 309
Surface roughness 310
Ignitability of aged, degraded, or charred materials 310
Wetting by water 310
Type of apparatus 311
Mass of sample 311
Long-term radiant exposures 311
Arcing across a carbonized path **312**
Glowing ignition **315**
Smoldering ignition **315**

Highlights and summary of practical guidance

Solids can ignite due to external heating, or self-heating (self-heating is discussed in Chapter 9). In some cases, both external heating and self-heating are involved. Despite many limitations, it is often reasonable to use the approximation that a solid ignites due to external heating when its exposed surface reaches a fixed ignition temperature. A quasi-constant ignition temperature is a usable concept only for external heat sources which cause a substance to be ignited in a flaming mode. There is no constant 'handbook' temperature which can characterize the process of smoldering ignition, nor the process of self-heating. The concept of ignition temperature (where applicable) is often valuable because it may allow the deduction that if an external heat source was not as hot as the ignition temperature of the material, the material could not have ignited from that source.

A solid may ignite from self-heating even if it is surrounded by an environment that is at a low ambient temperature, e.g., 20ºC. Almost all organic substances have a potential to self-heat. Self-heating is important, however, only when the mass of the substance is large and the available time is long, e.g., days to years. For ignition times on the order of minutes, only external heating effects will normally need to be considered. Exceptions exist for extremely reactive self-heating materials, such as linseed-oil covered rags, which can ignite in small quantities and in a time frame of only a few hours. For substances subjected to external heating, but at a low heat flux and for a moderately long time (hours), it may also occasionally be necessary to take into account self-heating effects. For most substances, self-heating is caused by oxidation rather than decomposition, thus self-heating is less common among non-porous materials.

Pre-charring most solids at fluxes insufficient to cause ignition, if it has any effect at all, usually makes the substance more difficult to ignite when larger heat fluxes are subsequently applied. This is because readily ignitable volatiles are driven off in the initial heating process.

For most solids, ignition due to external heating occurs in the gas phase, that is, volatiles are driven off which then ignite and burn in the surrounding atmosphere (this is not true for metals and other elements, and these are separately discussed in Chapter 8). Self-heating involves reactions occurring in the solid phase. Thus, a self-heating-caused ignition manifests itself as a smoldering or glowing; this can transition to flaming when the reaction front reaches an open surface. Substances which are self-heating, but have negligible heat flux imposed from the outside show ignition first in the center, because this is where the least heat losses are occurring. If they are cut apart before going to flaming, a charred core is found, surrounded by less-damaged material.

Apart from some specialized mechanisms (ohmic heating, arc tracking, etc.) external heating of solids involves one or a combination of the three classical heat transfer mechanisms:

- conduction
- convection
- radiation.

Heating by radiation is considered to be the most important of these and is the dominant one in flames and in situations where a non-contiguous hot body provides the heating. Heating by conduction is the primary mechanism when a hot body comes into direct contact with an ignitable material. There is a vast body of literature on radiative-mode ignition of solids and the bulk of this Chapter is devoted to this topic. Research on conduction or convection modes of ignition has been extremely limited.

The concept of an ignition temperature is useful in understanding why, using a small flame, it is hardest to ignite a flat surface, easier to ignite an edge, and easiest to ignite a corner. This is because in a corner the heat can flow into the body along three directions, so as to raise its temperature to a given value the quickest.

Reported ignition temperatures (and other ignition properties) of plastics are often vary over a wide range, since common commercially-useful plastics are rarely of high purity. PVC is perhaps the most extreme example, since the pure polymer—which has very good resistance to ignition and burning—is a rigid, brittle material of limited uses. Practical PVC formulations include numerous additives; to make flexible PVC products, large amounts of plasticizers have to be added. Unless halogenated, these additives are more readily ignitable than pure PVC, and flexible PVC formulations reflect this fact.

Hot objects—embers, welding slag, flying brands, etc.—can often be exceptionally effective as ignition sources, even when they are quite small. This is true regardless of whether they are flaming or merely incandescent. But research on ignition from hot objects is scant, although some indicative data is available (see Chapter 14 for specific substances).

Materials which char when subjected to heat are likely to be able to smolder under some circumstances. Smoldering is a complicated phenomenon, yet research in this area has been quite limited. Consequently, very little guidance is available on the quantitative aspects of smoldering. Under the right circumstances, wood products and almost any material of botanical origin can smolder. A few inorganic materials also have the ability to smolder. Smoldering can be started by a variety of ways, including glowing bodies, flames (with flaming then being extinguished but smoldering continuing), or without any external ignition source,

simply by assembling a large enough pile of a self-heating material. Smoldering can also be started by an already-smoldering object, e.g., by inserting a burning cigarette into a pile of smolderable material.

The assumptions are often made that common solids will not be ignited from (1) electric circuits where the current, voltage, or power are below certain values; and (2) by hot objects having less than a certain amount of stored thermal energy. Unfortunately, there is very little research on #1, so that it is not possible to draw useful conclusions. But research on Christmas tree lights (see Chapter 14) indicates that as little as 1.25 W can ignite paper. Assumption #2 is incorrect, both from theoretical principles and according to laboratory measurements: stored energy is not the sole controlling variable of the problem. This is discussed in detail in Chapter 14 under *Forest materials, vegetation, and hay*.

Types of ignition

Ignition of solids can basically be of four types:

- Ignition of the fuel vapors driven off the solid. This is the most common form of ignition and is manifested as flaming. Most of the solids in this category produce flammable vapors by *pyrolyzing*, that is, chemically degrading due to the action of heat[*]. The degraded substance is no longer of the same chemical identity as the virgin substance. A few low molecular-mass solids liquefy and vaporize without pyrolyzing, that is, the substance vaporized is chemically identical to the virgin substance. Naphthalene is an example.
- Smoldering ignition. When a porous or granular substance undergoes self-heating, ignition is commonly manifested first as smoldering. However, smoldering ignition also may be caused by external heating, e.g., a glowing cigarette falling down on a sofa.
- Direct ignition of the surface of a solid. Many metals and a few other substances are examples. A flammable vapor is not released which could then be subject to ignition, instead, the oxidation takes place directly at the solid's surface. Ignition of metals is considered in Chapter 8. Under certain conditions, cellulosic materials (e.g., wood) can ignite in this manner, which is generally called glowing ignition.
- Ignition by a chemical reaction (e.g. thermal decomposition) that occurs directly in the solid phase. Reactive substances, explosives, and pyrotechnics fall into this category. These are considered in Chapter 10. The burning of gases is either not involved at all with these substances, or occurs only to a limited extent after the initial solid-state reaction has started.

[*] Some chemists use a definition whereby pyrolysis is taken to be the degradation due to the action of heat *in the absence of oxygen*. In fire science, however, the term is used to mean degradation due to the action of heat in any atmosphere, including ones that do contain oxygen; this latter definition is used throughout this book.

Pyrolysis can be explained as follows. The molecules comprising most combustible solids are very large, commonly involving thousands of atoms. As such, these molecules are not able to be directly oxidized, at least not in an oxidation rapid enough to be called combustion. So ignition takes place as a 2-step process. Upon initial exposure to heat, the large molecules break apart and release some small fragments. Since the fragments are small and since heating has raised the system temperature, the fragments largely emerge as gas molecules. These now have the potential to ignite in the air above the solid's surface under the right conditions. The nature of the residue remaining when the fragments leave depends on the substance involved. For some substances (e.g., wood) the residue is a solid carbonaceous matrix called a char. But for others (e.g., polypropylene) the residue is essentially a liquid. There are also substances (e.g., PVC) which can leave either a char or a liquid-like material, depending on details of the heat exposure.

In addition to systematic effects due to the of the fuel, there can be three basic physical arrangements:

(1) a single, isolated mass, which may range from a microscopic particle to a huge object
(2) a pile or layer of small particles
(3) a dust cloud.

Dust clouds of solid particles share more characteristics with gases than with solids, and are treated in Chapter 5. Piles or layers of pyrolyzing or otherwise exothermically reacting granular or powdered material are treated in Chapter 9. Thus, in this Chapter only the ignition of a single item of a solid fuel is considered. Furthermore, there is very little information on the ignition of single particles if they are of tiny size; most of the available information concerns metals and other elements and this topic is treated in Chapter 8.

General principles of flaming ignition

QUALITATIVE FEATURES

Before either theory or engineering data are examined, it is worthwhile to consider some general features of the problem of the flaming ignition of solids. First of all, since flames are a gas-phase phenomenon, for a solid to be capable of a flaming ignition it must respond to heat by breaking down and releasing combustible vapors. This is the pyrolysis process discussed in the previous Section. For a pyrolyzing solid to ignite in a flaming mode, the same three conditions must be satisfied as for liquids:

1. the substance must be sufficiently heated so that an adequate concentration of *pyrolysate* (the pyrolyzed vapors) exists at some location away from the surface
2. an adequate concentration of an oxidizer (typically, air) must be mixed in with the fuel vapors so that a flammable fuel/oxidizer gas mixture exists somewhere above the surface
3. either the temperature of the pyrolysate/air mixture must become high enough (for autoignition to occur) or

else a sufficient external energy source such as a pilot flame or a spark must be introduced (for piloted ignition to occur).

There are several fundamental differences between ignition of solids and liquids, apart from their general similarities. If the ignitable liquid is a pure substance (not a mixture, such a gasoline) then in most cases it will produce a vapor which has the identical chemical composition to the liquid. In thermodynamic terms, the vaporization of such a liquid is *reversible*; that is, if the vapors are cooled, they will condense into the original substance. In the case of a solid, the process of heating up the solid is normally destructive, or *irreversible*. If the vapors are cooled down, the original solid is not regained. The term 'pyrolysis' denotes that heating is accompanied by irreversible chemical changes.

The response of a liquid to heat sets up convective currents inside the liquid; these influence the ignition behavior. Such convective currents do not occur in a solid, although pyrolysis manifests itself by the production of vapors from the solid. Some solids form a film of liquid at the surface when exposed to heat. Plastics such as polyethylene are an example. Other solids do not form a layer of liquid, but instead exhibit a flow of gases through a porous matrix which becomes less dense with prolonged exposure of heat. Wood is an example of such a substance.

The ignition may be *autoignition* or *piloted* ignition. The term 'forced ignition' is sometimes used as a synonym for piloted ignition. The use of the term autoignition for solids is rather different than for gases. For a gas, autoignition occurs when the entire substance is raised in temperature to a point that flames appear. For a pyrolyzing solid, however, what becomes raised in temperature sufficiently to ignite is not the solid itself, but the gas that has been pyrolyzed from it. The term 'autoignition temperature' is applied either to the minimum surface temperature of the solid for which the gas-phase flaming event occurs or to the minimum temperature of the furnace needed for ignition to occur. The latter definition is used when testing small samples in a furnace, but the two temperatures are not generally identical.

Ignition of solids may be *transient* or *sustained*. If the ignition is transient, then removing the source of external heating causes combustion to cease. If ignition is sustained, then combustion continues until a substantial fraction of fuel is exhausted, even if the external heat source is removed. Transient ignition (or flashing) can occur in a slightly different context, whereby even if the external heat source is not removed, only a brief period of combustion occurs, and most of the material in unconsumed. While these distinctions would appear to be substantively fundamental, in actual testing of materials they do not play a major role. Surprisingly little is known about the behavior upon removal of the heat source, and even most test methods do not quantify this property. As for brief transient or flashing events, these are observed and recorded, but rarely form any basis for judging of product performance. The length of time that divides flashing or transient flaming from sustained flaming is a matter of definition. In standard test methods for solid substances, a value of 4 to 10 s is typically defined as the minimum time necessary for sustained ignition.

Figure 1 illustrates flashing and sustained flaming ignition during piloted-ignition testing of PMMA. Not all substances show flashing prior to sustained flaming. The terms 'flash point' and 'fire point' can also be applied to solids. In this PMMA example, the flash point is 287ºC while the fire point is 306ºC. Note that, due to flashing, the temperature actually being registered by a thermocouple located at the surface of the sample is 312ºC at the time of ignition. This reading is influenced by the presence of the flashing, and so T_{ig} is assigned the extrapolated smooth-rise value, in other words, the temperature rise solely due to the external heater[1]. The fact that momentary increases in surface temperature due to flashing must not be considered in determining the value of T_{ig} can also be learned from the fact that, at several of the flashes preceding sustained-flaming ignition, the instantaneous surface temperature notably exceeded 306ºC, yet sustained flaming did not occur. A similar graph has been shown by Atreya for red oak[49]. He notes that of over 100 wood samples tested, only one showed flashing prior to sustained flaming. Details of the autoignition phenomenon are generally understood much less well, since testing and research in recent years has focused largely on the piloted ignition problem.

THE IGNITION PROBLEM FOR SOLIDS

For ignition of solids, the practical problem is usually the following: "For a given thermal attack, determine whether ignition will occur. If it does occur, determine how long it will take." This immediately suggests the areas which must

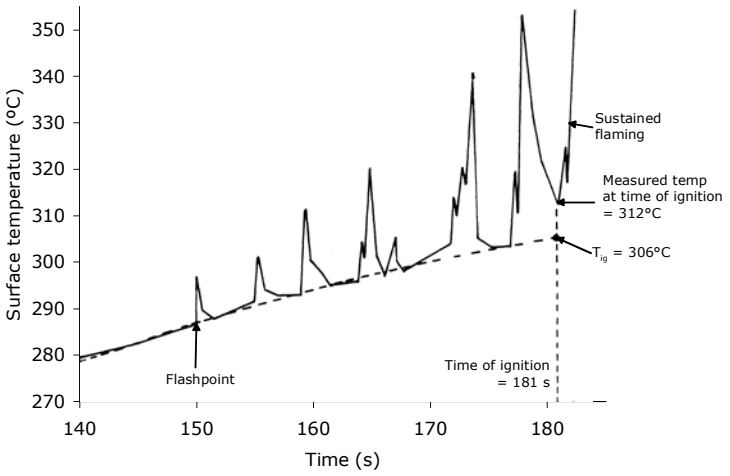

Figure 1 Flashing and sustained flaming ignition of PMMA exposed to radiant heat flux of 20 kW m^{-2} (Thomson[2])

be quantified:

- the thermal attack
- the heating up and pyrolysis of the solid
- the association of the observation of flames with a quantifiable variable.

Ignition of solid substances has been of interest even prior to the 20th century. In most early works, only a very crude notion of the thermal attack existed. It was not until the work of Brown[3] in the 1930s that it became clear to most researchers that, at ignition, the temperature of the substance and the temperature of the test furnace are not necessarily identical. Eventually, as a consequence of defense-related research in the early 1950s, incident heat flux came to be recognized as the primary engineering variable. It was realized that the temperature of the existing fire, test-device heater, etc., was *not* a sufficient description of the thermal attack upon the substance. Two different sources could have identical temperatures, yet cause very different responses of the ignitable substance. The science of heat transfer, of course, had been fairly well developed by the 1950s, but it was not previously used to quantify exposures to ignitable substances. There are known to be three primary mechanisms for transporting heat: conduction, convection, and radiation. Conduction heat transfer is important in certain ignition problems, e.g., firebrands. These problems will be considered later, and in the first part of this Chapter it will be assumed that there is an air space between the heating source and the ignitable substance. Thus, two means of transferring heat from the source to the target will need to be considered—convection and radiation.

The heating up of the solid, once the external thermal attack has been quantitatively and correctly specified, is the heart of ignition theory. Most common combustibles—wood is an excellent example—exhibit a highly complex chemistry of thermal degradation of the solid material. Thus, it is necessary to focus on theories which either lend themselves to a closed-form solution, or which can act as a framework for presenting and analyzing empirical data. More fundamentally ambitious theories have been formulated, but they are currently not able to act as practical tools for solving ignition problems. Consequently, as we shall see below, 'theory' of the ignition of solids normally connotes an engineering data-correlation approach, elevated by the introduction of a limited number of physics principles.

In this Chapter, we will see that—thus far—only theories based on simple heat transfer considerations have led to engineering relationships that can be usefully applied towards practical problem solving. This limitation is not satisfying, since it means that the ignition temperature must be introduced as an *ad hoc* hypothesis. We will also briefly consider theories which do bring in chemistry. The simplest way to do this is to introduce a chemical reaction only into the solid phase. This approach has received a fair amount of usage in the rocket propulsion community. Somewhat surprisingly, it appears that these theories can sometimes predict the correct data trends even for pyrolyzing solids, not just for propellants that ignite directly in the condensed phase. However, even such simplest-possible treatment of chemistry requires more input data than are obtainable in the course of normal testing.

To identify the moment that flames will first occur on the basis of fundamental science requires, in addition to modeling the solid, to model the complex fluid mechanical environment, along with the chemistry, in the gas phase. As was seen in Chapter 4, a comprehensive theory of the ignition of gases must solve hundreds of chemical reactions occurring simultaneously. In principle, this can be accomplished by advanced, 3-dimensional, numerical thermo-fluid-chemical modeling of the gas-phase environment above the ignitable substance. These calculations are currently difficult and lengthy, and it is likely to be a number of years before they might become a routine tool for solving ignition problems.

As we shall see in this Chapter, the research that has been successfully applied to problem-solving has generally had two components: (a) development of mathematical techniques for making the heat transfer problem tractable; (b) development of criteria for ignition, since the simple theories do not 'know' when ignition occurs. To accomplish the latter, it becomes necessary to associate the ignition event with some quantifiable feature of the solid's thermal response. This is not easy to do in a reliable way. Two main stratagems have developed: (1) identification of a certain face temperature of the substance with the ignition event; or (2) identification of the ignition event with a critical rate of mass loss of the substance. Both of these approaches will be considered below. Perhaps the most useful is a third stratagem which has only emerged recently. This stratagem takes a 'black box' approach to the heating of the substance and does not attempt to represent the physics in any direct way. Instead, it calculates the ignition time (or absence of ignition) solely from the input data, i.e., an experimental record of heat fluxes versus ignition times. In addition to these main types of criteria, a number of others have been proposed and have found utility in certain limited applications. We will also consider some of those in brief.

The ignition temperatures of common solids differ less among categories of materials than is sometimes presumed, although sizable differences can be found both due to details of the material's formulation and due to the testing method used. Table 1 shows data compiled from Chapter 15. Only polymers without FR additives have been considered; halogenated plastics, because of their innate FR characteristics, have been grouped separately. Within any of the categories, ignition temperatures typically vary by ±100ºC or less. Not surprisingly, thermosetting plastics typically have higher ignition temperatures. The values for the halogenated plastics group are skewed by the fact that most of the available data are for ordinary PVC, which is less re-

sistant to thermal attack than are some more advanced materials in this family.

Table 1 Ignition temperatures of various plastics grouped by category

Category of solid	Ignition temp. (ºC)	
	Piloted	Auto
thermoplastics	369 ± 73	457 ± 63
thermosetting plastics	441 ± 100	514 ± 92
elastomers	318 ± 42	353 ± 56
halogenated plastics	382 ± 70	469 ± 79

Research into ignition of solids

The current state of the art of ignition of solids from external heating is not necessarily easy to present succinctly or straightforwardly. For the last hundred years, understanding of the phenomenon was gained in spurts and jumps, part of which were empirical and experimental, while the other portion consisted of mathematical theories. To gain a reasonable understanding of the progress of these ideas, it is appropriate to start with a brief historical survey of research into ignition of solids.

One of the earliest systematic studies on the ignition of solids was by Bixel and Moore in 1910[4], who used a small crucible submersed in a constant-temperature bath to examine autoignition of woods and cellulosic materials. Their results are shown in Table 2. The specimens were small and were exposed for up to 6 hours. Bixel and Moore implicitly assumed that the temperature at which ignition occurs is going to be a characteristic value for the tested substance. This assumption had already been made by researchers in the 19th century, but it is by no means a trivial truism (nor is it always true!).

Table 2 Autoignition temperatures determined by Bixel and Moore

Material	Avg. AIT (ºC)
charcoal (moist)	159
charcoal (dry)	216
paper	224
Georgia pine	203
maple	232
cypress	241
chestnut	254
oak	257

The conditions needed for piloted ignition were examined in 1915 by R. E. Prince at the Forest Products Laboratory in Madison, WI, as part of an already ongoing program to develop fire-retardant treatments for wood[5]. For this work, two different test apparatuses were developed. Most of the studies were done in the first apparatus, which was an electrically heated vertical hollow cylinder. Specimens 31.8 × 31.8 × 101.6 mm were suspended in the center of this furnace. The furnace walls were set to various temperatures in the range 175 – 470ºC and the time to ignition recorded. Ignition was with a gas pilot, located at the top of the furnace, a substantial distance above the specimen. Some oven-dried specimens ignited in as short a time as 15 min at 175ºC, but minimum temperatures for ignition were not sought. Neither the heat flux to the specimen, nor the temperature of the specimen itself were studied. The test apparatus itself, with modest modifications, later became the Setchkin furnace, used in ASTM D 1929 and ASTM E 136 tests. Prince also developed a second ignitability test apparatus. The latter was a small electric radiant panel and was used only for testing wood shingles and siding. In the latter studies, Prince was the first experimentalist to focus on the question not only if flaming ignition will occur, but whether flaming will continue if the radiant source is removed. Experimentally, he pulled away the specimen from the radiant panel after 1, 6, or 12 min had elapsed after ignition, and then timed the 'afterflame' duration. Thomas et al.[6] reanalyzed Prince's results and concluded that their data indicated an average ignition temperature of wood of 210ºC. This is somewhat higher than average oven temperature, and the modest increment comes from self-heating of the solid.

The dissertation of Clement Brown[3] was the next significant step in quantifying the ignition of solids. As a starting point, Brown made a very extensive study of 19th and early 20th century literature on ignition problems and his dissertation is a valuable resource for exploring the early scientific history of ignition research. Even though basic fundamentals of heat transfer were already known in 1934, it is clear from Brown's study that researchers of that era were not yet ready to apply them to the study of the ignition problem—the ignition temperature was being treated as a hypothetical 'chemical property,' without any attempts to quantify the transport of heat into the substance, and without an understanding of the mechanisms responsible for raising the temperature of the substance. Even the distinction between external and self-heating was not being appreciated at the time, and test methods for both were being intermingled. Brown's actual test apparatus was roughly similar to Prince's, but he introduced a forced air stream into the furnace cavity and did not use a pilot. Brown used tiny samples (1 to 5 g) and observed mainly the onset of exothermicity. Thus, his study, if anything, more resembled current-day DTA studies rather than ignition tests. Brown's main contribution was the identification of the importance of the specimen-face temperature, as distinguished from the furnace temperature. Generally, he found autoignition temperatures of 220 – 250ºC for woods and other cellulosic materials tested. A few substances were lower, such as tobacco and hay at 172ºC, newsprint at 184ºC and jute at 192ºC.

The earliest ignition studies to adopt some engineering principles were those of British mathematicians Bamford et al.[7] Their first experiments used flames for exposing inter-

mediate-thickness wood panels on both faces, and their results specifically pertinent to intermediate-thickness materials are discussed later in this Chapter. Bamford et al. were the first to propose that the heat conduction equation be used as the primary basis for analyzing ignition. The heat-conduction based theory required knowing the heat flux from the flames, however, they lacked means for measuring it, and were forced to resort to a dubious estimate. Their theory included a heat generation term and they assigned Arrhenius-kinetics constants to it using a rationale which they did not describe, most likely curve-fitting to the experimental results. From this model, they also calculated the mass loss rates as a function of time, and correlated these computed results to the observations of ignition. This led to a postulated criterion that piloted ignition occurs when the mass flux of pyrolysates emerging from the surface (i.e., the mass loss rate of the specimen) first reaches the value $\dot{m}'' = 2.5$ g m^{-2} s^{-1}. Later work by Weatherford and Sheppard[8] indicated that there were errors in the numerical solutions of Bamford et al.; however they were able to demonstrate that, under most conditions, a constant mass-loss-rate criterion for ignition implies a constant face temperature at ignition, and *vice versa*.

Bamford et al. then went on to conduct a second series of experiments, wherein 50 mm thick wood panels were subjected to radiant heating from an electric heater and ignited with an impinging gas pilot. Under such conditions, they reported that wood panels showed a minimum heat flux necessary for ignition of about 2 kW m^{-2} (in light of later work, this value appears to be significantly too low). They also found that with low irradiances, specimens only burned 2 – 6 min, and then flaming stopped, with most of the material remaining unburned. For the specimens to burn up fairly completely, a minimum irradiance of ca. 46 kW m^{-2} was needed.

Heat-conduction theory was next used by Fons[9] in 1950 who studied the ignition of ponderosa pine cylinders. Because accurate surface temperature measurement with thermocouples tends to be very difficult, Fons used interior thermocouples, then computed the surface temperature by using the heat-conduction equation (solving the 'inverse problem'). By this computation, he determined the autoignition temperature of wood to be 343ºC.

Buschman[10] examined the piloted ignition of various wood specimens exposed to a radiant panel. Over the heat flux range of 14 – 37 kW m^{-2}, he found that the computed surface temperature at ignition (Table 3) did not vary with the exposure time or the heat flux. Buschman computed the surface temperature using an inert-solid heat transfer model, but did not actually measure it.

In 1965, Martin[11] attempted to summarize a large volume of ignition studies on sheets of cellulose that were done for the U.S. Department of Defense. He identified three radiant heating regimes: (1) for very low heat fluxes, convective effects are important. In addition, the heat wave is able to reach the back face of the specimen before ignition occurs, thus, the material's thickness is an important variable. (2) For intermediate heat flux levels, sufficiently-thick specimens can ignite before significant back-face heating has taken place. This regime is governed by heat flow expressions pertinent to a thick solid. (3) At very high heat fluxes, ablation (i.e., a mass loss rate so large that the front face recedes rapidly) governs. In this regime, transient ignition is easy to achieve, but sustained flaming may not occur, because a very thin layer of material has been quickly heated to a high temperature. This layer may burn off without transmitting enough heat into the body of the material for combustion to continue. Martin's results for cellulose are shown in Chapter 14, and he effectively considered the ignition problem solved, since he was able to summarize all of his data into a 'universal' graph. It was not possible to use his graph for predictive purposes, however, so more suitably closed-form solutions still needed to be evolved.

Table 3 Surface temperatures for piloted ignition of woods, as computed by Buschman

Wood	Ignition temp. (ºC)
hardboard, tempered	298
maple	343
red oak	348
spruce	376
poplar	389
balsa	391

Shortly after Bamford's study, around 1950 the Fire Research Station in England began an extensive research program on ignition of wood and related materials, which continued into the 1960s. Lawson and Simms[12] were able to measure heat fluxes and produced extensive heat flux vs. ignition time plots for various woods. They also were the first to develop mathematical techniques that would allow predictions of ignition to be made from available test data. Their work in this regards forms the introduction to modern data-correlation methods, discussed below.

The gas-phase problem is moderately decoupled from the response of the solid to radiation. However, several researchers noted that, in certain specialized heating regimes, pyrolysates emitted by the solid cause significant radiative effects. Gardon[13] studied the autoignition of wood under quite high heat fluxes (120 – 200 kW m^{-2}) obtained from concentrating solar radiation using mirrors. He concluded that "the cloud of smoke" that rapidly forms in front of the surface significantly attenuates the radiation. Later, Kashiwagi, in studying the ignition of PMMA and wood using a CO_2 laser (which radiates at a 10.6 μm wavelength) found that extremely high attenuation of the beam could occur due to absorption by the pyrolysates forming in front of the specimen[14], with the radiation fraction reaching the specimen surface being as low as 20% in some cases. The

effect, evidently, can be serious for high-intensity radiation or for laser radiation. There have not been many studies directly examining the effect for non-laser sources in the more important sub-100 kW m^{-2} flux range. Kashiwagi[15] also examined the radiation fraction transmitted through the pyrolysates of PMMA and wood using a 700ºC black body heater and found it dropped below 70%. However, indirect evidence from other sources (for example, the modest effects of orientation, and successful validation studies for models that omit this phenomenon) suggests that the effect is typically not large.

IGNITION TEMPERATURE AS IGNITION CRITERION

The concept that a solid substance should have a unique ignition temperature has been a widespread, tacit assumption ever since scientific study of ignition began. As shall be seen later, this is hardly self-evident and, at best, is an approximation to reality. To make matters more complex, it must be realized that there have been two different meanings assigned to the term *ignition temperature*:

(1) the minimum temperature that the air must be heated to, in order that a specimen placed in the heated air environment would ignite;
(2) the surface temperature of the specimen just prior to the point of ignition.

Definition #1 was the prevalent one until about the last 3 decades. This is also the concept of ignition temperature invoked in the popular ASTM D 1929 ignition test. Definition #2 is generally more useful, both because it is more likely to be relatively constant for a material, and also because definition #1 is not applicable to the common situation, both in real fires and in more modern ignition tests, where the surface of a specimen is heated only by radiation, while convective heat transfer is small and is in the opposite sense (cooling). Use of definition #2 requires an accurate measurement of the surface temperature; this is much harder to do than is measuring the temperature of a test furnace, consequently, only when the importance of this measurement was finally realized, did researchers strive to develop the measurement technology.

To persons not well versed in fire science, it often seems that materials should be simply categorized by their ignition temperature. There are a number of limitations to this approach:

- It does not take into account how fast substances ignite.
- Accurate measurements of ignition temperature #2 (specimen face) are quite difficult to make; values of ignition temperature #1 (furnace) are of uncertain relevance for many applications.
- A great majority of combustible solids have fairly similar ignition temperatures, yet present diverse ignitability hazards; this is largely due to the fact that materials tend to differ widely in their thermal inertia, and the latter variable establishes the time scale of the problem. (Thermal inertia is the product of the solid's thermal conductivity × density × heat capacity and is discussed in detail later in this Chapter).

The concept of a 'handbook' ignition temperature is not without merit, however. In some cases, where time to ignition does not need to be computed, this concept may be sufficient to rule out certain fire causes. If an object ignites from *external* heating, and all temperatures in its environment are lower than a tabulated T_{ig}, then clearly we do not expect the object to be able to ignite. Conversely, if the surrounding temperatures are greatly higher, an ignition might be expected. It is very important not to apply this simple, sometimes-useful idea to *internal* heating. A number of substances are prone to self-heating, or spontaneous combustion. This topic is discussed in Chapter 9. For such substances, if the pile of material is large enough, ignition can occur even with no other source of heat apart from an ambient-temperature atmosphere surrounding the material. *It is in no way logical to assign an 'ignition temperature' to a self-heating substance.* As the size of the pile increases, the environment temperature needed to cause spontaneous combustion decreases. Thus, for a self-heating substance, a graph of size vs. environment temperature required for ignition can be made, but no single value can be assigned. Furthermore, it must be understood that substances prone to self-heating may also be ignited by external ignition. For example, if a pile of linseed-oil soaked rags is placed in front of a radiant heater, it may ignite in a few minutes, due to external heating, rather than in hours, which it would take if the pile were simply left in a 20ºC room. In such a case, the ignition of the pile should be treated by the methods of this Chapter, rather than Chapter 9. Many substances can be driven to ignition by a combination of self-heating, plus some localized heating. Such problems are difficult, but the time scale can be used for reasonable guidance: if ignition occurs in about 1 hour, or less, self-heating can probably be ignored. Conversely, if it takes days, weeks, or years to reach ignition, the problem is dominated by the self-heating aspects. To emphasize: if self-heating is involved, ignition can take place even though the highest temperature of any objects nearby the target substance is much less than the object's 'handbook' T_{ig}.

In the above discussion we have learned that an object may still ignite, even if it is exposed to temperatures well below a 'handbook ignition temperature.' On the other hand, an object may not ignite even if it is exposed to temperatures well above the 'tabulated ignition temperature.' A number of circumstances need to be considered.

- The temperatures usually discussed are the temperatures of hot objects near the material in question. But the surface of the material in question may never come up to a temperature even close to that value. One common situation is for thermoplastic materials, many of which can recede when subjected to heat. If the heat

source is localized, the material may fail to ignite simply by receding.

- A finite time is required for a material's face to rise to a certain temperature when heated. If the hot object is only exposing the target object for a short time, ignition may not occur.
- A tiny amount of material may ignite, but ignition may not be sustained. This occurs when 'flashing' instead of 'sustained flaming' happens. It may also happen that a chunk of the material ignites and falls away burning, while the rest of the material fails to burn because it is now too far away from the heat source.
- Finally, tabulated values may not be representative of the specific material in question. This is especially true for man-made polymers, since, in many of those, the primary ingredient may comprise only half or less of the total mass, the remainder being comprised of various additives.

A practical issue to consider is that ignition temperatures for common combustible solids vary only over a rather limited range of about 300ºC to 500ºC. By contrast, thermal inertia values of common combustibles vary by about a factor of 100 (see Chapter 15). This means that differences in time to ignition of different materials is likely to be determined by their relative values of thermal inertia, not of their ignition temperature. The role of thermal inertia is explored in the succeeding sections of this Chapter. Finally, it has been pointed out that while most researchers assign comfortably small error bars to their own results, comparing ignition temperatures obtained by different researchers often leads to major disagreements[16].

Whether or not T_{ig} is a sensible concept for characterizing materials has to be examined on the basis of experimental evidence. While this is often an oversimplification, for convenience, combustible solids can roughly be considered to be of two types: (1) those that melt when subjected to high temperatures; and (2) those that char. Most of the 'commodity' plastics, that is, excluding expensive 'engineering' plastics, are melting substances. For those, constancy of T_{ig} appears to be well-justified experimentally. One must ask: Constancy with respect to what? The effects of a wide variety of factors on the ignition of solids is considered in detail later in this Chapter, but clearly there should be constancy with respect to heating rate. This is best examined in tests where a specimen is heated by a radiant heater, and typical results obtained by Thomson[2] are shown in Figure 2. Four of the 5 polymers show a T_{ig} which is invariant with heat flux. For PMMA, however, T_{ig} is reasonably fitted by a horizontal line only in the mid-range of the heat fluxes; essentially the same results with PMMA were obtained in a different apparatus by Cordova et al.[17]

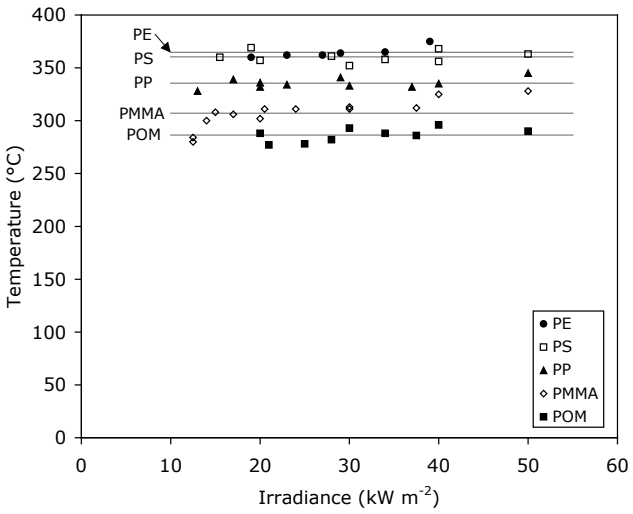

Figure 2 Ignition temperatures of several common plastics, as a function of irradiance

Kokkala[18] attempted to study the ignition of a PMMA ceiling in a somewhat real-life situation by impinging 3 – 10 kW burner flames upon it. He found T_{ig} = 380 – 410ºC, which is significantly higher than reported in most other studies; the higher values are probably attributable to a significant (but not measured) velocity induced by the burner. A minimum heat flux of 20 – 30 kW m^{-2} was needed for the PMMA to ignite; this is, again, much higher than found in radiant heating tests. Not enough results are available from flame-heating tests, however, to generalize these types of observations.

Some rather different results are found for charring materials. Most natural materials, e.g., agricultural products, are charring materials, but only wood has been studied in sufficient detail to draw systematic conclusions. Wood is dis-

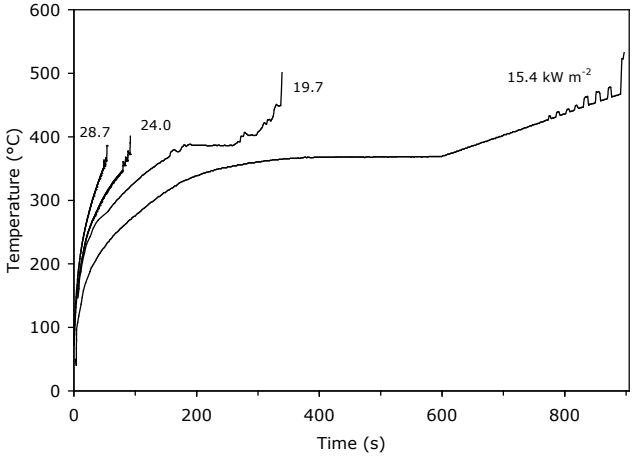

Figure 3 The surface temperature of Mahogany samples exposed to various heat fluxes

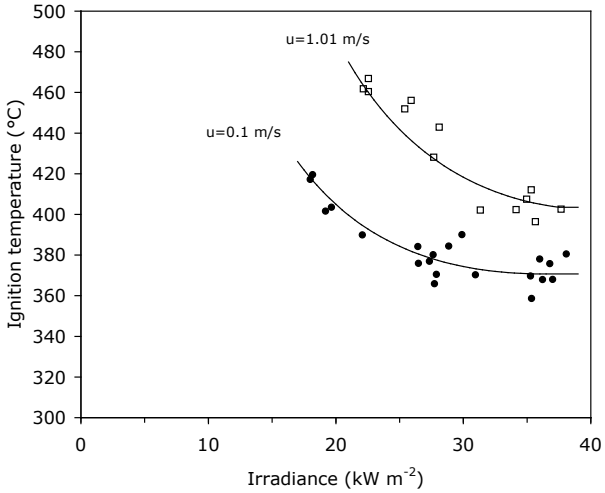

Figure 4 Effect of heat flux and air velocity on T_{ig}: results of Atreya and Abu-Zaid

cussed at length in Chapter 14, but here we present some example experimental data. Li and Drysdale[19] used a careful measurement technique to study the piloted ignition temperature of several wood species. Their results (Figure 3 and Table 4) showed some high T_{ig} values at low fluxes, then a lower, relatively constant, value at larger fluxes. Decreasing T_{ig} values with increasing heat flux were also found by Abu-Zaid[67] for red oak and by Atreya[62] for 8 different species of wood. A joint paper by these two authors[20] gave the results shown in Figure 4. The authors' test environment was a wind tunnel and it is evident that air velocity has quite a sizable effect on the results, with the irradiance effect also being apparently a bit smaller at the lower velocity. Moghtaderi et al.[21] measured the ignition temperature for Monterey pine as a function of both heat flux and moisture. Their results, shown in Figure 5, indicate similar trends. The analysis of a large number of other results for wood, given in Chapter 14, suggests that, as seen in the data of Li and Drysdale, there are two heat-flux regimes and T_{ig} is constant in the higher heat-flux regime, but varies with flux at low heat flux values.

Table 4 Piloted ignition temperatures of various woods

Wood species	Heat flux (kW m^{-2})	T_{ig} (°C)	Plateau temp. (°C)	t_{ig} (s)
Western red cedar (280 kg m^{-3})	15.4	450	366	583
	19.7	431	379	216
	24.0	365	—	57
	28.7	346	—	30
	31.7	354	—	23
obeche (350 kg m^{-3})	15.4	497	359	684
	19.7	442	361	176
	24.0	364	—	60
	28.7	344	—	39
	31.7	340	—	29
white pine (360 kg m^{-3})	15.4	446	354	1094
	19.7	411	380	257
	24.0	397	—	95
	28.7	387	—	48
	31.7	375	—	32

	28.7	360	—	60
	31.7	353	—	38

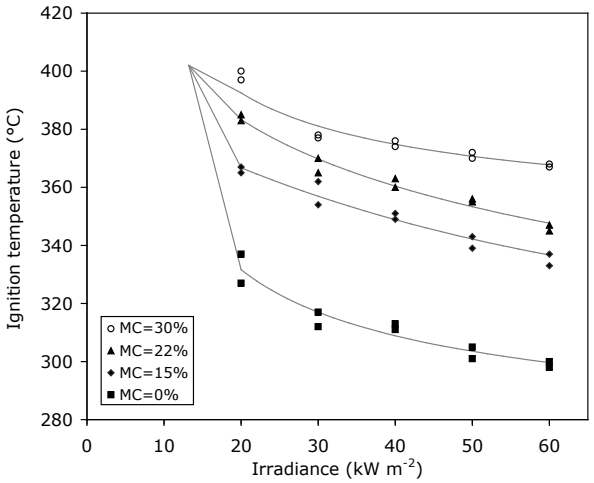

Figure 5 Ignition temperature of Monterey pine, as a function of irradiance and moisture content

These studies on wood materials indicate a number of complications, but foremost is the effect of glowing ignition. For irradiances below a certain value, such charring materials initially ignite in a glowing mode, and they may possibly subsequently transition to flaming. Any substances that ignite in a glowing mode do not show a constant T_{ig}, and details are discussed later in this Chapter. Another factor is self-heating. The effects of self-heating for wood, as for most other materials, are small or negligible if exposed to high external fluxes for a short time. In the opposite situation, heating by a low heat flux for an extended period of time, the surface temperature will rise due to a bulk self-heating effect, apart from what happens at the surface itself. Wood and agricultural materials furthermore are hygroscopic, that is, they have a tendency to take up moisture. Increasing the MC causes a notable increase in T_{ig}, provided the imposed flux exceeds a certain minimum value. For irradiances just barely sufficient to ignite the material, clearly MC cannot have any effect since ignition will not take place until the specimen is thoroughly desiccated.

The above experimental findings suggest that assuming that T_{ig} is a constant which is characteristic of a material is reasonable assumption for melting materials and is also a useful—albeit imperfect—concept for charring materials, so long as glowing-initiated ignitions are not considered.

Nonetheless, there are difficulties with the notion of a constant T_{ig}:

(1) The surface temperature is exceedingly difficult to measure accurately. Very tiny, fragile thermocouples (around 0.05 mm) are needed to avoid gross errors. But even so, errors arise. The foremost is that it is hard to keep a thermocouple fixed to the exact face of a specimen as it is heating up. Most materials tend to shrink, swell, melt, bubble, crack, or otherwise deform prior to ignition; a thermocouple which was accurately located at the start of the exposure may end up elsewhere, or broken, by the time that ignition is reached.
(2) Optical measurements of surface temperature are sometimes made. These avoid certain errors, but are subject to errors of their own—for example, a value of emissivity may need to be specified for the surface, but this can be both temperature-dependent and poorly known.
(3) Some external variables do have an effect on the ignition temperature.
(4) For some materials, if prolonged heating under heat fluxes somewhat lower than those needed to cause ignition is followed by increased heating so that T_{ig} is reached and surpassed, ignition may not occur.

In addition, it must be remembered, as illustrated above for the case of thermoplastics, that T_{ig} values for a large majority of combustible solids are clustered closely together, making this variable not too useful for distinguishing among materials.

For *thin materials*, the concept of a surface temperature is not particularly meaningful, since there is, by definition, negligible difference between the internal temperature and the surface temperature. For most analyses with thin materials, consequently, calculations are based on the specimen's mean temperature. Thus, it has been proposed that for thin materials the mean temperature can serve as the criterion of ignition. In experimental measurements, the surface temperature* at ignition for thin materials is found to be much higher than for the same substance in thick layers; for example, a value of 600ºC has been quoted for cellulose[27].

MASS LOSS RATE AS IGNITION CRITERION

Subsequent to Bamford et al., a number of other investigators explored the values of mass loss rate at the flash point or at sustained flaming under piloted ignition conditions. Melinek[26] developed a simple numerical model of the ignition process, where the mass loss rate of the specimen is treated as a first-order Arrhenius reaction, that is:

$$\dot{m}'''(t) = \left(\rho(t) - \rho_c\right) A \exp\left(\frac{-E}{RT}\right)$$

where $\dot{m}'''$ = volumetric mass loss rate (g m^{-3} s^{-1}), and ρ_c = the density of the char that remains after all volatiles have left. By solving the temperature equation and integrating the mass loss rate term with respect to specimen depth he was able to get an expression for $\dot{m}''(t)$, the mass loss rate per unit surface area (g m^{-2} s^{-1}). Typical results are shown in Figure 6. Because of the exponential dependence on temperature, until quite close to ignition time there are essentially zero pyrolysates generated. The curve reaches a peak and then decays; the decay is due to exhaustion of reactants. The shape of the curve explains why a specimen receiving only marginally sufficient flux for ignition might not sustain burning after a short initial period.

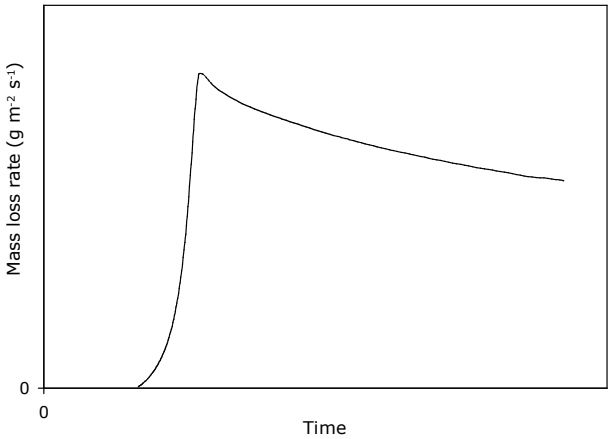

Figure 6 Mass loss rate curve of wood, as computed by Melinek

Kanury[28] attempted to evolve a single, theoretical expression for the needed $\dot{m}''$, but Thomson[2] found that there was an error in his reasoning (he assumed that the gas plume above the specimen reaches the flame temperature prior to ignition).

Table 5 Minimum mass loss rate for piloted ignition, as obtained by various investigators

Material	At flash point (g m^{-2} s^{-1})	At ignition (g m^{-2} s^{-1})
Non-oxygenated materials		
decane (liquid)		0.6[29]
polyethylene		1.3[29], 1.9[22]
polypropylene	0.6[29]	1.2[29], 2.2[22]
polypropylene, FR		3.1[29]
polystyrene	0.55[29]	0.4[23], 1.0[29], 3.0[22]
polystyrene, FR		5.0[29]
Oxygenated materials		
ethylene/vinyl acetate copolymer (EVA)		1.3[24]
PMMA	1.0[29]	0.7[23], 1.9[29], 3.2[22]
PMMA, FR	1.8[29]	4.0[29]
polyoxymethylene	0.85[29]	1.8[29], 3.9[22]
wood		1.5[25],1.8[1], 2.2[29], 2.5[7], 5.1[26]

* It is dubious that, in experimental thermocouple measurements with thin samples, the surface temperature can be differentiated from the mean temperature.

While not much progress has been made towards a workable theoretical basis for the minimum mass flux, a number of experimental results are available. Drysdale and Thomson[29] conducted what is arguably the most carefully prepared set of experiments for the purpose of obtaining minimum values of mass loss rate. Their values, along with those of several other investigators, are shown in Table 5. Tewarson et al.[30] also reported on the mass loss rate needed for piloted ignition for a series of electric cable specimens. The values are not shown in the Table, but ranged from 2.6 to 4.8 g m^{-2} s^{-1}.

It is clear that accurately measuring low values of mass loss rate is difficult and that the data are to some extent apparatus-dependent. Furthermore, it can be concluded that, for any given substance, lower reported values are more likely to be accurate than are higher ones. For example, Deepak and Drysdale[31] obtained a value of 4 – 5 g m^{-2} s^{-1} for PMMA. Upon further development of the experimental rig at the same facility, Drysdale and Thomson[29] found a value of 1.9 g m^{-2} s^{-1}. With this in mind, certain trends emerge:

(1) Non-oxygenated, non-FR solids show flashing when a mass loss rate of around 0.6 g m^{-2} s^{-1} is reached.
(2) Oxygenated, non-FR solids show flashing when a mass loss rate of around 1.0 g m^{-2} s^{-1} is reached.
(3) Non-oxygenated, non-FR solids show piloted ignition when a mass loss rate of around 1.2 g m^{-2} s^{-1} is reached.
(4) Oxygenated, non-FR solids show piloted ignition when a mass loss rate of around 2.0 g m^{-2} s^{-1} is reached.
(5) The ratio of the mass loss rate at ignition (sustained flaming; fire point) to that at flashing (flash point) is about 2:1.
(6) FR materials require about double the mass loss rate than do comparable non-FR materials for flashing or for ignition.

As several theories have suggested, there should be a relation between ignition temperature and $\dot{m}''$ at ignition. Due to the wide scatter of data obtained by different researchers, it is possible to look for trends only by focusing on a single study. Since the best data available are from Drysdale and Thomson, Figure 7 shows the trends from their results. Clearly, oxygenated and non-oxygenated fuels fall along separate trend lines. Polystyrene is seen to be an outlier, but decane follows well the trend of the non-oxygenated polymers. Due to paucity of data, the lines drawn in Figure 7 must be viewed only as indicating qualitative trends.

For a *thermally-thin* solid, some explicit calculations can be made, since, by definition, a thermally-thin solid is all at one temperature. If single-step, zero-order Arrhenius kinetics is assumed, then

$$\dot{m} = -A\,m(0)\exp(-E/RT)$$

where A = pre-exponential constant (s^{-1}), $m(0)$ = initial mass (kg), and E = activation energy (kJ mol^{-1}). But

$$m(0) = \rho(0)LS$$

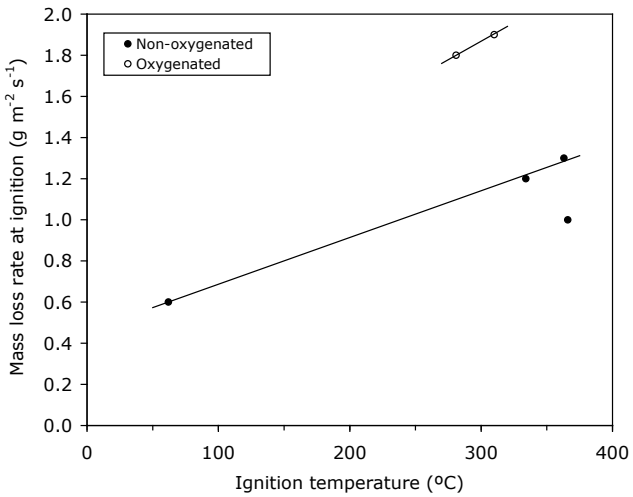

Figure 7 The relation between ignition temperature and mass loss rate criterion

where $\rho(0)$ = initial density (kg m^{-3}), L = thickness (m), and S = surface area (m^2). Then,

$$\dot{m}'' = A\rho(0)L\exp(-E/RT)$$

where any decrease in ρ or L prior to ignition has been ignored. Since A, E, and ρ are fixed, this implies that for the thin material there cannot be a fixed relationship between $\dot{m}''$ and T_{ig} as the thickness L is varied.

The above treatment assumed that $\dot{m}''$ is a constant for a given material and is independent of test conditions. Unfortunately, this is not exactly true. Rasbash et al.[32] examined the effects of certain variables on the $\dot{m}''$ for PMMA tested in the horizontal orientation. The instrumentation used at the University of Edinburgh was of much lower accuracy than subsequently evolved by Thomson, thus the data

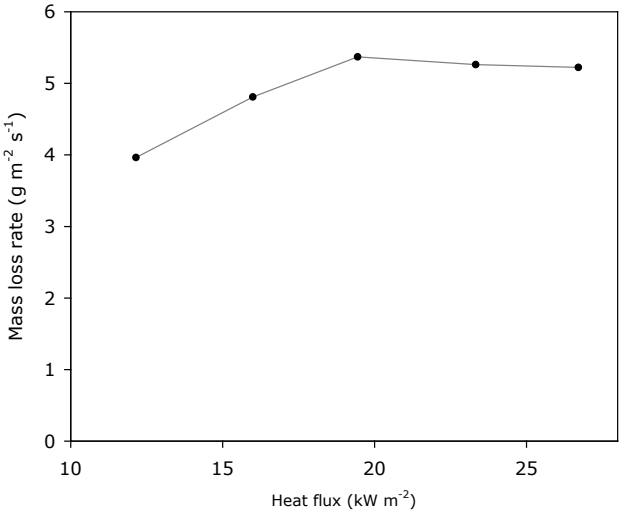

Figure 8 Effect of heat flux on MLR needed for ignition of PMMA

should be viewed as only rough indications. Figure 8 shows a modest drop in $\dot{m}''$ as the flux approaches the minimum value needed for ignition. The air flow rate according to Figure 9 is optimum at intermediate values. The reason for this has not been fully explained, but the same phenomenon is illustrated in Figure 56. Figure 10 indicates that as oxygen concentration is brought down to a critical value, the needed $\dot{m}''$ rises rapidly. The bump at 40% is most likely experimental error.

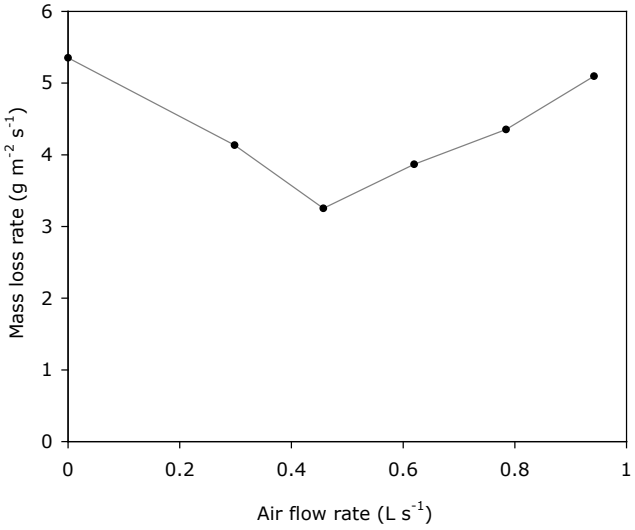

Figure 9 Effect of air flow rate on MLR needed for ignition of PMMA

Little information is available on the mass loss rate needed for autoignition. Melinek[26] observed that for one series of tests on wood, $\dot{m}''$ was 50% higher under autoignition conditions, compared to the piloted ignition value.

HRR AS AN IGNITION CRITERION

As discussed in detail in Chapter 4, flames cannot be sustained for arbitrarily low flame temperatures. Instead, a flame temperature associated with the LFL can be determined, and its value is relatively high. On this basis, a heat release rate (HRR) criterion becomes reasonable to consider. A volume of gases in front of the specimen must be brought up to, and maintained, at this flame temperature for initial combustion (ignition) to occur and then to be sustained. A heat balance on this volume implies that it is the product of the mass loss rate times the heat of combustion (in other words, the HRR) of the evolved pyrolysates that is governing.

Actual values of HRR at ignition can be computed using Thomson's results presented in the preceding Section and values of heat of combustion. Table 6 shows the results obtained; the lowest reported mass loss rate value was used for each material. FR materials could not be evaluated

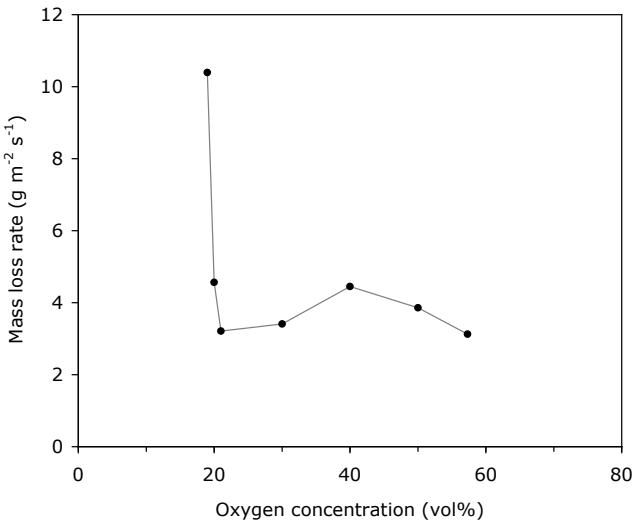

Figure 10 Effect of oxygen concentration of MLR needed for ignition of PMMA

since heats of combustion for the specimens used were unknown. There is quite a lot of data scatter and measurements of low mass loss rates are difficult to make. However, the results of Table 6 generally lie between the two published recommendations: 25 kW m^{-2} (by Hansen[33]) and 50 kW m^{-2} (by Kokkala and Baroudi[34]), irrespective of whether the fuel is oxygenated or not. For a mass loss rate criterion, a substantially higher value was found for oxygenated materials than for non-oxygenated. But the oxygenated materials have correspondingly lower heats of combustion (since they are 'pre-oxidized') and thus it appears that a single value of HRR can serve as an ignition criterion, irrespective of whether the fuel is oxygenated or not. It is unlikely that FR materials will fall in line with this same value, since flame retardants that are chemically reactive in the gas phase are expected to show a higher temperature at the LFL.

A quantitative prediction based on HRR was attempted by Alpert and Khan[35]. They argued that the ignition criterion should be:

Table 6 HRR as a criterion for piloted ignition

Material	MLR at ignition (g m^{-2} s^{-1})	Heat of combustion (MJ kg^{-1})	HRR at ignition (kW m^{-2})
Non-oxygenated materials			
decane (liquid)	0.6	44.2	26.5
polyethylene	1.3	43.2	56.2
polypropylene	1.2	43.2	51.4
polystyrene	1.0	39.7	39.7
Oxygenated materials			
PMMA	1.9	24.9	47.3
polyoxymethylene	1.8	15.7	28.3
wood	1.8	18.5	33.3

$$\dot{q}'' = 54\sqrt{D}$$

where D = fuel base diameter (m). Since the effective diameter of the Cone Calorimeter samples used by Thomson was 0.113 m, this would suggest that the critical HRR = 18.1 kW m^{-2}. However, Alpert and Khan did not provide any data of their own to validate their hypothesis and Thomson's data are not close to 18.1 kW m^{-2}.

OTHER CRITERIA FOR IGNITION

For experimental measurement of ignition, normally observation of flame (or, possibly, glow or explosion) should be sufficient. Yet, much of early experimental work on ignition was done using criteria other than observation of flame. Brown[3] adopted the definition: "The temperature at which the rate of generation of heat becomes greater than its dissipation under certain fixed conditions." This definition—with slight modifications—could form a viable definition of the critical temperature for self-heating; for flaming ignition of externally-heated solids, however, it makes little sense. In practice, Brown used specimens tiny enough that a single thermocouple inserted into the center of the specimens could be taken to represent the entire specimen's temperature. He inserted the specimen into an oven where the temperature rose at a programmed rate. He then plotted the difference between the furnace and the specimen thermocouple readings. The first instance that this signal started to deviate from a straight line was declared to be the ignition temperature. Occurrence of visible flaming was never recorded. Brown did record the crossing-point temperatures, i.e., the temperature at which the thermocouple traces for the furnace and for the sample thermocouples crossed over. This value was generally 30 – 50ºC higher than that which he recorded as T_{ig}, but in some instances the difference reached 100ºC.

Using a philosophy and procedures rather similar to Brown's, Graf[36] used a criterion that "the rate of heating in the substance exceeds the rate of heating induced by the external source of heat and has visible combustion in the form of a glow or flame as an end result." In his experiments, he inserted minuscule specimens into an oven which had a programmed rate of rise of temperature. His actual procedure was a bit unclear, but it appears that he looked, at a location very close to the specimen, for the first time where the slope of the temperature started to rise at a more rapid rate than the oven temperature was rising.

In his study, Brown also surveyed much older literature. His survey indicates that methods similar to his were predominant in that time period. Very few examples were cited of investigators actually using observation of flame as the ignition criterion. In the current era, criteria very similar to Brown's are still being used when thermal analysis instruments are used for determining ignition. No study exists that would document a relation between these 'pseudo-ignition' temperatures recorded for minuscule specimens and real ignition temperatures on materials of end-use size or configuration. The reason why early experimentalists favored these techniques appears to be expediency—tests could be run in an automatic fashion, rapidly and without needing to have an observer present. Despite the inappropriateness of 'non-observational' criteria in experimental work, a large, systematic error cannot be ascribed to such criteria, at least as found in Babrauskas' survey[37] on the ignition of wood.

Simms[38,65] proposed that autoignition occurs only at the time and location where turbulence is first established in the gas stream. It is clear that if turbulence is present, it will enhance the mixing of the fuel vapors into the air and decrease the time at which the LFL first occurs. However, it does not seem to be a primary criterion, and no other researchers have adopted his point of view. For piloted ignition, Alvares et al.[39] suggested that a criterion would be the attainment of a 6% concentration of flammable pyrolysis vapors at the place where the igniter is located. Again, no work using such a criterion has been reported.

Deverall and Lai[40] constructed a model of the solid phase and considered the requirement that ignition will occur when gas temperature first becomes higher than the surface temperature, i.e., the direction of the flow of heat is reversed locally. Their model then predicted that ignition will occur when the irradiance first becomes equal to {conductive heat loss of the solid at the surface + 2× heat of gasification}. Determining either of these quantities accurately enough has been found to be exceedingly difficult, so the criterion lacked practicality. A related criterion sometimes considered[41] is that ignition occurs if the temperature gradient just inside the front face of the solid becomes flat. This instantaneously-flat condition is seen as being followed by a positive slope, i.e., that the solid has now become a net source of heat rather than a net sink. This criterion appears useful for the ignition of solid propellants but has not seen much application to common solids.

Janssens[76] lists 6 other criteria that have been proposed, generally only by a single researcher. Vilyunov[153] lists a total of 10 mathematical criteria that have been proposed for ignition. Kulkarni et al.[42] list 14 mathematical criteria and 6 experimental criteria that have found usage. Most of them have been developed since some purely numerical calculations do not 'know' when ignition has occurred. As such, these will mainly be of interest to researchers planning a particular numerical solution. For example, one of these criteria states that ignition corresponds to the inflection point on the curve of the front-face temperature vs. time. Criteria of this sort are relatively removed from the physics of the problem since it still remains necessary to prove that something of interest actually happens at the time when the particular mathematical condition becomes fulfilled.

Ignition from radiant heating

In this section, we address a major concern of this Chapter: quantifying how materials ignite when exposed to a radiant heat flux from an external heat source. The events taking place in the gas phase are considered first. This is a brief treatment, both because there is very little experimental information and because most current-day theories that lend themselves to practical application ignore the gas-phase events. Next, some comprehensive models that do consider events in both the solid phase and the gas phase are presented. Finally, the remainder of this Section focuses on engineering models which have been specifically developed to treat experimental data.

GAS PHASE EVENTS

For a majority of pyrolyzing solids under most thermal exposure conditions, ignition occurs as a gas-phase event, after the solid has produced a sufficient amount of fuel gases. Yet, surprisingly, the details of the gas-phase ignition have not been probed extensively. Yoshizawa and Kubota[43] studied the ignition of thick (13 mm) cardboard specimens oriented horizontally and exposed to xenon lamp heating at the high heat flux of 300 kW m^{-2}. They found that the first flame kernel (Figure 11) appeared at 7 mm above the surface and proceeded to grow in both directions—towards and away from the surface. About 14 ms later, a second kernel appeared at 10 mm and also proceeded to grow. By about 22 ms, both kernels had expanded to reach the surface, after which a customary diffusion flame continued to propagate. Surprisingly, the point at which the flame originally appeared was found to correspond to an equivalence ratio of about 4.7, which is extremely rich, even given that the temperature at that locale was about 540ºC just prior to ignition. The combustible gases that ignited were found to be mostly CO. To the accuracy that they could determine, the surface temperature at the time of ignition was nearly identical to the 540ºC measured in the gas phase. In a much less detailed study, Mutoh et al.[114] reported temperatures of ca. 500ºC just prior to ignition of PMMA. Again, temperatures on the surface and in the gas phase location where ignition first took place were essentially identical. The only other measurements that could be found in the literature on the topic of gas temperatures at the time of unpiloted ignition of a solid are those of Durbetaki et al.[44] But they reported some exceedingly high temperature and the reasons for this are unclear.

Bukovec and Urbas[45] measured the flame temperatures in the gas phase in front of a vertical Douglas fir specimen. They found peak temperatures of ca. 1300ºC. Much as Yoshizawa and Kubota did in the horizontal orientation, they found that in the vertical orientation the point of the highest flame temperature originally starts out at some distance away from the surface, then draws closer. For specimens exposed to a 65 kW m^{-2} flux, at the moment of ignition the location of peak temperature was 5 – 7 mm in front of the surface. After 400 s of burning, it became about 2 mm and

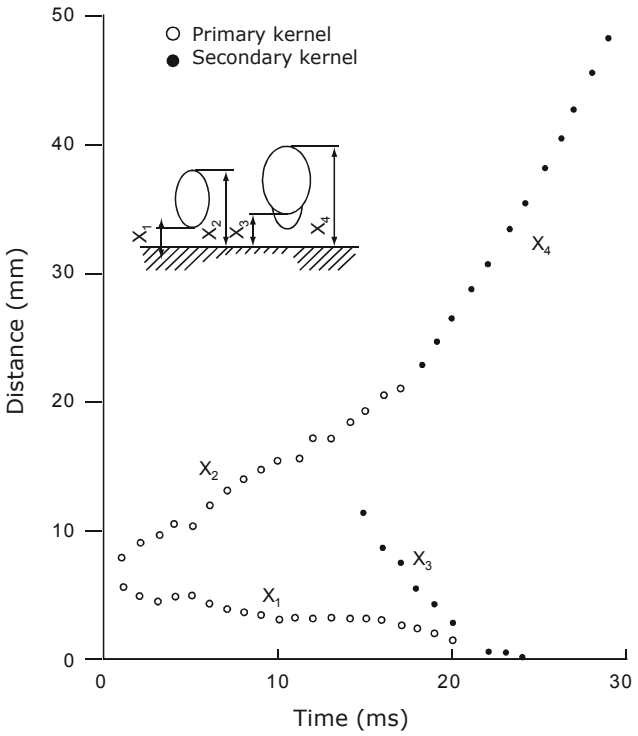

Figure 11 Development of the ignition kernel
(Copyright The Combustion Institute, used by permission)

stayed at that distance subsequently. Flames stayed laminar only for 15 s after ignition, becoming turbulent thereafter.

The gas-phase events during *piloted ignition* are even less well studied than are those during autoignition. Conceptually, one might suppose that a mixed volume of gases exists which, at a certain point, reaches its LFL. The gases, however, are hardly well-mixed unless, possibly, very long ignition times are involved. Furthermore, there does not exist any reasonably simple scheme for computing when this concentration might be attained.

Conceptually, Long et al.[46] pointed out that t_{ig} can be viewed as being a summation of three terms:

$$t_{ig} = t_p + t_m + t_i$$

where t_p is the time needed to raise the surface of the solid to a sufficient temperature so that there would be the minimum needed mass flow rate of pyrolysates; t_m is the time needed for the pyrolysates to mix with air; and t_i corresponds to the induction period of the fuel/air mixture, that is, the time needed for chemical reactions to take place in the gas phase. This type of additive arithmetic has only rarely been explored, unfortunately.

COOL FLAMES

Same as for some gases and liquids (see Chapter 4), solids can also ignite showing 'sub-ignition' in the form of cool flames, or else two-stage ignitions where a cool-flame is followed subsequently by a normal-flame ignition. The

phenomenon was studied by Baillet and coworkers[47,48], who investigated the polyolefin family and found that it occurs in the case of polypropylene, poly-1-butene, and poly-4-methyl-1-pentene, but not in the case of polyethylene. The polyolefins that did show a cool flame ignition only showed it in limited temperature/O_2 concentration regions, with the oxygen limits spanning no more than 20 – 60 vol% for polypropylene and 37 – 60 vol% for poly-4-methyl-1-pentene.

COMPREHENSIVE THEORIES

As a pyrolyzing solid is heated, flammable gases are generated in the chemical breakdown of the solid and these gases leave the heated face of the material. Initially, the concentration of the pyrolysates is low, and ignition is impossible. Since initially there are no pyrolysates in the ambient environment, the difference in concentration acts to diffuse pyrolysates away from the surface. As a result, a fuel/air mixture is created above the surface. When the rate of emission of pyrolysates becomes sufficient to create a zone where the mixture reaches the LFL, ignition can occur if an ignition source is present there. The mixture is premixed, so the initial flame must be premixed. If the production of volatiles from the surface is insufficient, then the event represents a transient flash. If the flow of volatiles is adequate, then a flame gets established some distance above the surface, but this flame now is a diffusion flame, not a premixed one. The entire situation is complex, as illustrated in Figure 12[49]. This figure illustrates the more difficult case of wood or similar materials which possess internal voids, thereby allowing pyrolysates to flow through those spaces. Solid plastics can generally be represented in a slightly simpler manner, since subsurface flows of vapors do not exist. The two cases are sometimes identified[50] as *volumetric decomposition* and *superficial decomposition*.

As will be seen below, 'engineering' theories ignore all features of the gas phase and simply focus on solving a heat transfer problem in the solid phase. A number of studies have been published which attempt to consider both the thermal response of the solid and the gas-phase environment, using at least some chemistry and possibly some fluid mechanics. We shall call these 'comprehensive,' although these vary quite a bit as to the amount of detail incorporated. Both the solid and the gas phase can be formulated as a 1-, 2-, or 3-dimensional problem. Because specimens cannot be infinitely wide nor long, the gas phase concentrations above the fuel surface must necessarily have a 3-dimensional character. But a number of theories which use only a 1- or 2-dimensional treatment of the gas phase have had various degrees of success. However, there is little to be gained by using more than a 1-dimensional treatment of the solid phase, so most theories—even the latest ones—generally treat the solid as a 1-dimensional problem.

Kashiwagi[51] presented an early attempt at calculating the autoignition time for a solid exposed to a radiant heat flux. The formulation was entirely 1-dimensional, so a realistic representation of the plume of combustible gases developing outside the solid could not be made. One of the conclusions from his model was that the surface temperature at ignition should increase with increasing heat flux; this conclusion, however, was not borne out in his later experimental studies[115]. Atreya et al.[52] presented another theory where both the solid and gas phase are treated in a 1-dimensional way. With this theory, Atreya was able to demonstrate that a quenching distance exists for solids, and that locating a pilot closer to the surface will lead to extinction. He also computed that the optimal distance of the pilot above the surface is just slightly greater than the quenching distance, that it increases with increasing fuel mass loss rate, and that ignition times increase as the pilot is moved farther away. Of significant interest is Atreya's conclusion[49] that the presence of a high temperature pilot flame makes details of gas-phase chemical kinetics unimportant. This still leaves the gas phase mixing process as an important aspect that needs to be modeled.

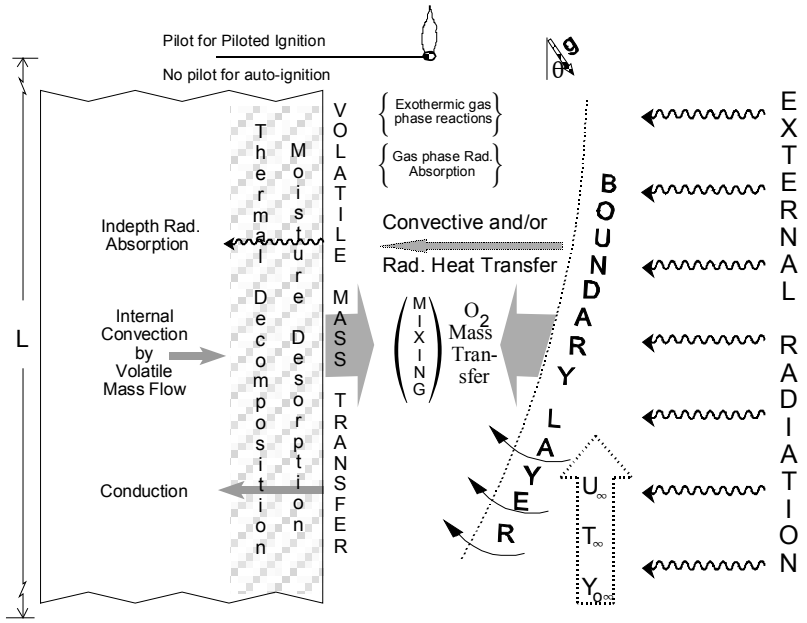

Figure 12 Main physical and chemical processes taking place during the ignition of a solid by radiant heat
(Copyright Royal Society, reprinted by permission)

While studies of simplified geometries, such as Atreya's are highly valuable in understanding the main aspects governing ignition, the fact remains that the gas phase environment may be varied. There can be a strong convective flow, or a minimal one. The surface may be rough, creating local turbulence, or not. Access may be available for oxygen to enter from the sides, close to the surface, or not. Despite some rough assumptions that can be made, the mixture forming above the surface is assuredly *not* uniform. Temperatures are also notably non-uniform in the gas, and their distribution is governed by some of the same factors. Thus, while premixed gas ignition ideas can be applied, they can only be expected to be of qualitative utility.

Gandhi[53] undertook to model a 2-dimensional problem, where a boundary layer over a vertical panel is treated, along with radiant heat flux. The chemistry was represented as separate Arrhenius-form reaction rate equations for the solid and for the gas phase. Gandhi assumed that the criterion of ignition is a change of the gas-phase temperature gradient from negative to positive. The problem formulation was ambitiously encompassing, but the consequence was that there was a very large number of independent variables, and no closed-form or approximate solutions were evolved, nor were comparisons with experiments made.

Amos and Fernandez-Pello[54] presented a 2-dimensional model of ignition in a stagnation-flow geometry where autoignition is assumed to occur due to absorption of radiation by pyrolysate gases. Since the convective flow is an air flow at room temperature, their model predicts that the minimum (radiant) flux for ignition increases linearly with increasing air flow velocity. The model results were presented as numerical calculations, and no comparison to experimental data was made.

The latest research efforts in modeling ignition of solids make use of available computation power to create and solve models which are 1-dimensional in the solid, but 3-dimensional (or axisymmetric, 2-d) in the gas phase. Tsai et al.[55] developed such a model to predict both piloted and autoignition of PMMA in the Cone Calorimeter. The model assumed:

- 3-dimensional conservation equations for continuity, momentum, energy, and species in the gas phase. To represent the Cone Calorimeter geometry, they assumed the flow was laminar and axi-symmetric.
- diffusion represented by Fick's law
- 1-dimensional heat conduction in the solid phase
- radiation from the conical heater represented as 1-dimensional, downward
- absorption of radiation by pyrolysate gases (assumed to be MMA monomer), but neglecting radiative emission from gases.
- single-step Arrhenius kinetics in the gas phase

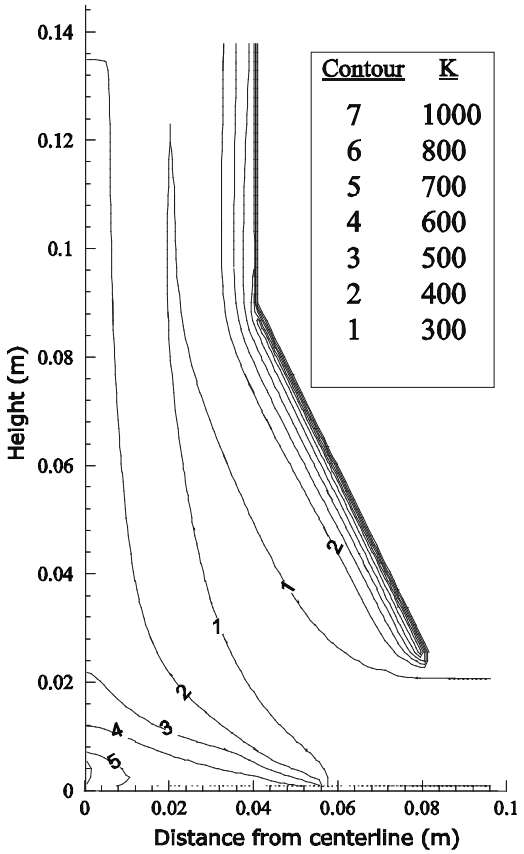

Figure 13 Gas-phase temperatures above specimen at 183.6 s in the model of Tsai et al.
(Copyright The Combustion Institute, used by permission)

- single-step Arrhenius kinetics to represent pyrolysis of the solid
- pyrolysis of fuel occurs only at the surface.
- for piloted ignition, the spark was approximated as a local hot spot of 1000 K.

Autoignition prediction calculations just prior to ignition (Figure 13) show high temperatures mostly localized at the conical heater. However, a small bubble-shaped region of elevated gas temperatures (see contour 5) is forming just above the specimen. Ignition is shown in Figure 14, at which time an 'upside-down tulip' shaped flame surface has formed, and it extends to about 110 mm above the specimen surface. Note that temperature contours now represent much higher temperatures, with small regions indicated as being close to 2400 K. Finally, quasi-steady-state burning is shown in Figure 15. Due to model simplifications, the predicted peak temperatures are higher than measured, nonetheless the calculations capture well the essential features of autoignition.

A somewhat similar model for predicting piloted (only) ignition of wood in the Cone Calorimeter was developed by Yuen[56]. His sub-model for the pyrolysis of the solid is the most ambitious thus far attempted, including, apart

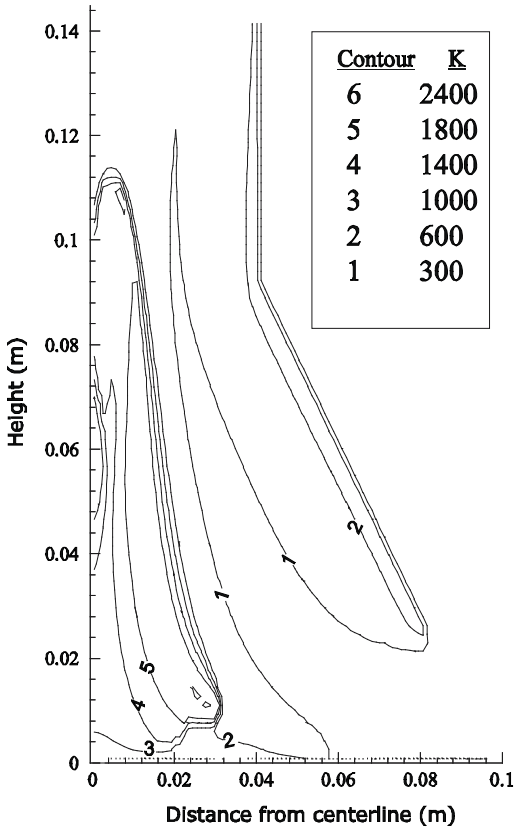

Figure 14 Gas-phase temperatures above specimen at 183.8 s in the model of Tsai et al.

from one-step Arrhenius kinetics, movement of moisture and temperature-dependent thermal properties. The model was able to predict adequately the ignition times at heat fluxes of 40 – 70 kW m^{-2}. For a heat flux of 20 kW m^{-2}, predicted ignition times were only about 1/5 of the times actually measured. Yuen's formulation is noteworthy in that he did not use any adjustable factors—all needed constants were obtained from the literature or from experiments different than the environment of the Cone Calorimeter. A total of 18 constants were used to characterize the physics and chemistry of wood pyrolysis; the number of constants needed for solving the gas-phase problem was not specified. The model that Yuen evolved could conceivably be adapted to solving ignition problems other than for wood. However, obtaining the needed material constants would evidently be quite difficult. Results from Yuen's model show[57] the feature that Yoshizawa found experimentally: flames from the initial kernel move outward and downward towards the specimen face.

Most of the more ambitious theories have treated a thick solid, since this more closely corresponds to the majority of real-life problems. The *thermally-thin* case is theoretically easier to analyze, however, since a 0-dimensional treatment of the solid (no gradients of anything in the solid) can be adopted. Nelson et al.[58,59] created a sophisticated model to represent autoignition of a thermally-thin substance in the Cone Calorimeter. Their theory had no spatial variations for any property and assumes that the pyrolysates form a gas 'slab' of uniform thickness above the surface. Nonetheless, five differential equations needed to be solved simultaneously to obtain a solution for the gas temperature, a rapid jump in which indicates ignition. Results computed with their model showed the presence of a minimum flux for ignition and, in certain circumstances, exhibited flashing, in addition to sustained ignition. Despite its mathematical complexities, the model is physically simplified and in its present stage of development is not yet intended for predicting the response of real materials.

Nakamura et al.[60] modeled the autoignition of a thermally-thin solid using a 2-dimensional (axi-symmetric) formulation in the gas phase. Their results for cellulose filter paper indicated that autoignition within the plume above a horizontally-oriented thin slab can occur either near the surface (Type 1) or near the tip of the plume (Type 2). Increasing oxygen concentration of the atmosphere promotes the case where ignition occurs at the tip, while raising the acceleration of gravity promotes occurrence of ignition near the surface. Some of their main results are shown in Figure 16, while vertical plume sections are shown in Figure 17. Their modeling predicts the Type 1/Type 2 breakpoint at a higher

oxygen concentration than is normally observed (see later in this Chapter), but otherwise the model captures the main features of autoignition.

The theoretical problem of the ignition of pyrolyzing solids is identical, apart from minor issues, to that for the ignition of non-hypergolic propellants. Thus, the major review papers in the latter specialty, discussed in Chapter 10, can be viewed as providing additional insights into the problem of ignition of pyrolyzing solids.

ATREYA'S MODEL

As a specific example of one of the simpler comprehensive models, Atreya's 1-dimensional solid+gas phase model[49] sets up the following equations:

Fuel stoichiometry:

1 kg fuel + r_o kg O_2 → (1 + r_o) kg products + Δh_c (heat)

Gas-phase continuity:

$$\frac{\partial \rho}{\partial t} + \frac{\partial (\rho u)}{\partial x} = 0$$

Gas-phase energy conservation:

$$\rho \frac{\partial T}{\partial t} + \rho u \frac{\partial T}{\partial x} = \frac{\partial}{\partial x}\left(\frac{\lambda}{C}\frac{\partial T}{\partial x}\right) + \frac{1}{C}\frac{\partial \dot{q}_r''}{\partial x} + \frac{\Delta h_c}{C}\dot{m}'''$$

Gas-phase fuel conservation:

$$\rho \frac{\partial Y_F}{\partial t} + \rho u \frac{\partial Y_F}{\partial x} = \frac{\partial}{\partial x}\left(\rho D \frac{\partial Y_F}{\partial x}\right) - \dot{m}'''$$

Gas-phase oxygen conservation:

$$\rho \frac{\partial Y_O}{\partial t} + \rho u \frac{\partial Y_O}{\partial x} = \frac{\partial}{\partial x}\left(\rho D \frac{\partial Y_O}{\partial x}\right) - r_o \dot{m}'''$$

Equation of state at constant pressure:

$$\rho T = \rho_\infty T_\infty$$

Gas-phase reaction rate:

$$\dot{m}''' = A \rho^2 Y_F Y_O e^{-E/RT}$$

Solid-phase mass balance:

$$\frac{\partial \rho_S}{\partial t} + \frac{\partial \rho_m}{\partial t} = -\frac{\partial \dot{m}''}{\partial x}$$

Solid-phase energy balance:

$$\rho_S \frac{\partial h_S}{\partial t} + \rho_m \frac{\partial h_m}{\partial t} + \dot{m}'' \frac{\partial h_g}{\partial x} = \frac{\partial}{\partial x}\left(\lambda_S \frac{\partial T_S}{\partial x}\right)$$

$$+ \frac{\partial \dot{q}_r''}{\partial x} + \left(Q_S - h_S + h_g\right)\frac{\partial \rho_S}{\partial t} + \left(Q_m - h_m + h_g\right)\frac{\partial \rho_m}{\partial t}$$

Solid-phase decomposition kinetics:

$$\frac{\partial \rho_S}{\partial t} = -A_S\left(\rho_S - \rho_{Sf}\right)\exp\left(-E_S / RT_S\right)$$

The initial and boundary conditions are:

at $t = 0$, $0 < x < \delta$:

$$Y_F(x,0) = 0, \quad Y_O(x,0) = Y_O \quad , \quad T(x,0) = T$$

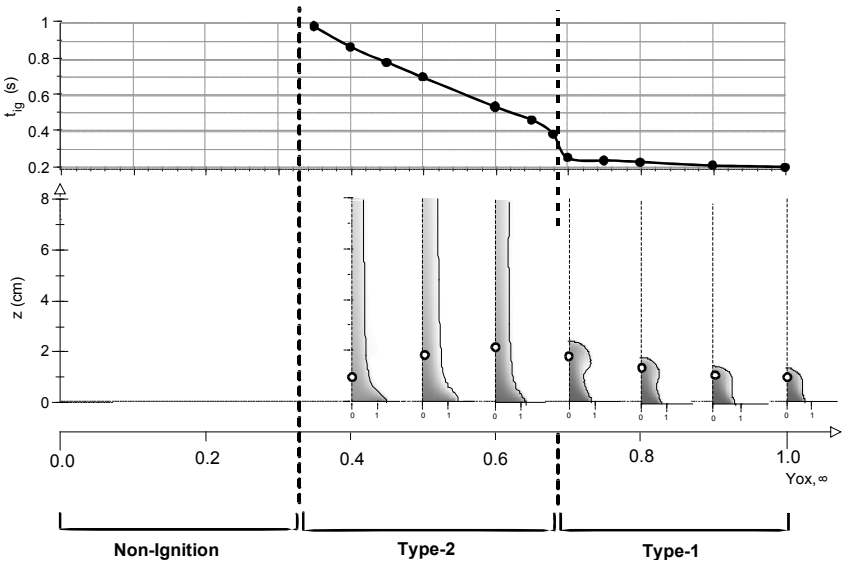

Figure 16 Effect of oxygen concentration on the location of point of autoignition according to the modeling results of Nakamura et al.; hollow black dot indicates location at which flame kernel first appears

at the solid/gas interface $t > 0$, $x = 0$:

$$\rho D \left.\frac{\partial Y_F}{\partial x}\right|_{x=0} = \dot{m}_S''\left(Y_F - Y_{FS}\right),$$

$$\rho D \left.\frac{\partial Y_O}{\partial x}\right|_{x=0} = \dot{m}_S''\left(Y_O\right),$$

$$-\lambda_S \left.\frac{\partial T_S}{\partial x}\right|_{x=0} = -\lambda \left.\frac{\partial T}{\partial x}\right|_{x=0} - \varepsilon\sigma\left(T_S^4 - T_\infty^4\right)$$

$$= \alpha_s \dot{q}_e'' - h_c\left(T_S - T_\infty\right) - \varepsilon\sigma\left(T_S^4 - T_\infty^4\right) - \dot{m}_S'' Q$$

at the edge of the boundary layer $x = \delta$, $t > 0$:

$Y_F(\delta,t) = 0$, $Y_O(\delta,t) = Y_{O\infty}$, $T(\delta,t) = T_\infty$, $\dot{q}_r'' = \dot{q}_e''$

at the back face of a thick solid:

$T_S(L,t) = T_\infty$

where:

A = gas-phase pre-exponential factor ($m^3\ s^{-1}\ kg^{-1}$)
A_S = solid-phase pre-exponential factor (s^{-1})
C = gas-phase heat capacity (kJ $kg^{-1}\ K^{-1}$)
E = activation energy of gas phase reaction (kJ mol^{-1})
E_S = activation energy of solid phase reaction (kJ mol^{-1})
h = enthalpy (kJ kg^{-1})
h_c = convective heat transfer coefficient (kW $m^{-2}\ K^{-1}$)
Δh_c = heat of combustion (kJ kg^{-1})
L = fuel thickness (m)
$\dot{m}''$ = fuel mass flux from solid (kg $m^{-2}\ s^{-1}$)
$\dot{m}_S'' = (\rho u)_S$
$\dot{q}_e''$ = specified external heat flux (kW m^{-2})
$\dot{q}_r''$ = radiant flux (kW m^{-2})
Q_m = heat of moisture desorption (kJ kg^{-1})
Q_S = heat of gasification of fuel (kJ kg^{-1})
t = time (s)
T = gas temperature (K)
T_S = surface temperature (K)
u = gas velocity (m s^{-1})
x = distance perpendicular to fuel surface (m)
Y_F = mass fraction of fuel vapors in the gas phase (--)
Y_O = mass fraction of oxygen in the gas phase (--)
α_s = absorptivity of surface (--)
δ = boundary layer thickness (m)
ε = emissivity of surface (--)
λ = thermal conductivity (kW m-1 K^{-1})
ρ = density of gas (kg m^{-3})
ρ_S = density of solid (kg m^{-3})
ρ_{Sf} = density of char (kg m^{-3})
σ = Stefan-Boltzmann constant (5.67×10^{-11} kW $m^{-2}\ K^{-4}$)

and the subscripts F, g, m, O, and S denote fuel, gas, moisture, oxygen, and surface, respectively.

Atreya made certain simplifications in the above equations, based on physical insight. In the gas-phase energy balance, the term $\partial \dot{q}_r'' / \partial x$ was neglected since its effect is small except at very large heat flux values. In the solid-phase equations, the terms with the subscript m denote fuel-moisture and Atreya confined his solutions to situations where moisture effects can be ignored. The term $\partial h_g / \partial x$ represents the heat transfer due to flow of volatiles within the solid; Atreya ignored this contribution since it is small prior to ignition. The term $\partial q_r / \partial x$ represents the diathermancy of the solid and was ignored. A number of other simplifications can be made on the solid-phase energy balance equation, depending on the traits of the material being considered, and Atreya illustrated several of those.

The above model can represent both autoignition and piloted ignition. For piloted ignition, it is necessary to add a pilot energy source. Atreya did this following the scheme of Tzeng[50], whereby a t hin gas layer at some distance above the surface is intermittently brought up to adiabatic flame temperature in order to 'test' for the possibility of establishing a flame.

Atreya's model was able to show very successful predictions for the mass loss rate of wood needed for ignition. Figure 18 shows the graphical solution from his model using parameter values that are representative for wood. The solution is defined by the point where the straight line (representing the gas phase solution) intersects the rising curves. Since the chemical kinetics of the solid phase was not fully known, Atreya used two values for a non-dimensional pre-exponential factor A*, where $A^* = \frac{A_S L^2 \rho_S C_S}{\lambda_S}$. Depending on which one is chosen, $\dot{m}'' \approx 1.5 - 1.6$ g $m^{-2}\ s^{-1}$ was predicted. Since the lowest (and presumably the most accurate) experimental measurement, as shown above, is 1.8 g $m^{-2}\ s^{-1}$, the agreement can be considered excellent. Atreya's theoretical calculations also show that over the heat flux range 20 – 40 kW m^{-2}, both the minimum $\dot{m}''$ and T_{ig} are essentially independent of heat flux.

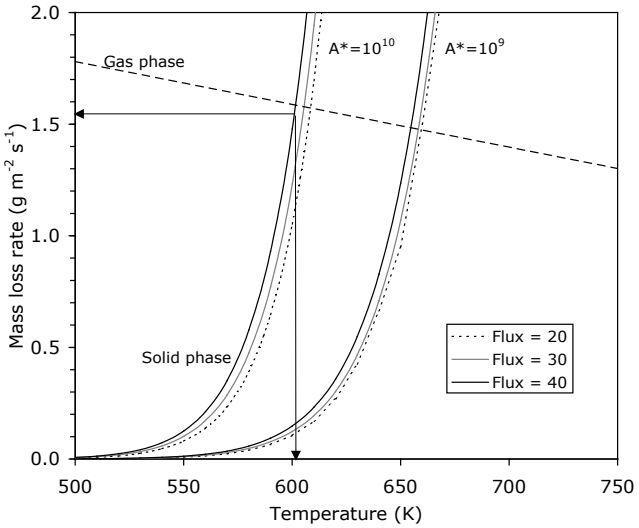

Figure 18 Atreya's theoretical prediction of the MLR of wood needed for piloted ignition. Ignition point occurs at the value where solid phase and gas phase MLR values are identical. The point shown corresponds to heat flux = 40 kW m^{-2}, A* = 10^{10} and gives T_{ig} = 605 K, MLR = 1.59 g m^{-2}.

ENGINEERING TREATMENTS FOR THERMALLY THICK SOLIDS

In the discussion above, it was made clear that, at the present time, computation of the ignition of solids (as with most ignition problems) cannot be done from first principles without a tremendous computational effort. Even if computational effort were not a consideration, all of the advanced theories necessarily require a large collection of input constants which will not be available for most materials, except perhaps if the chosen material has already been the subject of a doctoral dissertation. But this does not mean that only task-specific testing is of value. Theories of modest complexity exist which allow experimental data to be interpolated, extrapolated, and collapsed to just a few constants. The normal radiant ignition experiment consists of exposing a specimen to a known heat flux and recording the ignition time. This can be done at a range of heat fluxes and the result will be a table of data pairs (flux, time). It is the purpose of a simplified theory to enable these data to be analyzed in such a way that all of the information is captured in only a few variables, which can be viewed as 'quasi-properties' of the substance. Thus, as shown below, a data table which may have dozens of entries is collapsed to 3 variables.

Most of the practical work has been done for the 1-dimensional simplification, thus, this will be the focus of the present section. We divide the problem first into thermally-thick and thermally thin materials, then consider the situation when thick/thinness is uncertain. By 1-dimensional, it is meant that width and length of the specimen face are much larger than the depth and that the heated area is either the full size of the face or at least much larger than the specimen thickness. This criterion for 1-dimensional behavior is highly simplified, and we shall also consider experimental data on this point later in this Chapter.

Most of the theoretical analyses intended to be used as aids for data analysis ignore all chemistry, both in the gas phase and in the solid. With models of this type, a mathematical solution cannot be made for the ignition temperature. Instead, the ignition temperature is treated:

- as an experimentally measured value; or
- as a data-fit parameter; or
- by formulating the model to avoid the ignition temperature concept.

Measuring surface temperatures accurately is highly challenging. If thermocouples are used, very fine thermocouples are required and great pains taken to make sure they are truly at the surface, neither standing proud nor being recessed. It has been concluded within the profession that making these measurements accurately is only feasible in the context of research programs, not for ordinary testing purposes. If optical radiation methods are used, different sets of difficulties and errors are encountered, but an accurate measurement is not made easier. This leaves schemes that impute the T_{ig} from quantities that are experimentally measured, versus methods which bypass the need for an ignition temperature. Most of the practical schemes have focused on the former, but it will be shown that, for many purposes, the latter approach has significant merit.

In this section, we will consider the solid as being inert. The assumption that the solid is inert may seem to be an unreasonably drastic one—after all, if the solid were inert, no ignition would ever occur! Nonetheless, several investigators[11,61] found that experimental temperature distributions measured in ignition studies are very similar to those computed for inert bodies, and that effects such as diathermancy (non-opaqueness) and heats of reaction and phase change can often be neglected. Both from experiments and from numerical calculations, it has been found that at modest heat fluxes most of the ignition time is devoted to thermal heating of the solid. Actual chemistry in the solid, at the interface, or in the gas phase plays a significant role only during a short time interval just preceding ignition. For this reason, reasonable agreement between experiment and calculation can be obtained by using solutions which entirely ignore chemistry and simply solve the inert heating of a slab. The above simplification becomes progressively less accurate at high heat fluxes (say, over 200 kW m^{-2}) and short ignition times (milliseconds). The latter conditions will rarely be encountered in accidental fires, but are common in many combustion studies, especially where propellants are being modeled. When using a model that represents the substance as an inert solid, in addition to not being able to obtain a theoretical value of ignition temperature, there is a second limitation—since the substance is assumed inert, the loss of mass during heating is not modeled, thus, a mass loss rate criterion cannot be used to determine when ignition occurs. However, as the review of the topic above showed, it is also difficult to determine accurately the MLR at ignition experimentally. Thus, most engineering treatments ignore MLR.

To formulate the problem, it is first necessary to understand (or to review, as the case may be) concepts of heat conduction. To do this, it is appropriate to begin with the First Law of thermodynamics, which states that—if mechanical work is not involved in the problem—for any control volume:

$$\begin{bmatrix}\text{Amount of energy}\\ \text{added to system}\end{bmatrix} + \begin{bmatrix}\text{Stored energy of mass}\\ \text{entering system}\end{bmatrix} - \begin{bmatrix}\text{Stored energy of mass}\\ \text{leaving system}\end{bmatrix} = \begin{bmatrix}\text{Net increase in stored}\\ \text{energy of system}\end{bmatrix}$$

We will consider the material to be inert, and will consider the simplest case of a slab where changes only in one direction (the x-direction) need to be considered. The second and third terms in the above equation will be zero if no mass is entering or leaving the control volume. The rate at

which heat flows in at any location x is $\dot{q}$ and the rate at which heat flows out at location $x+dx$ is

$$\dot{q} + \frac{\partial \dot{q}}{\partial x} dx$$

Thus, the net heat flow in is

$$\dot{q} - \left(\dot{q} + \frac{\partial \dot{q}}{\partial x} dx \right) = - \frac{\partial \dot{q}}{\partial x} dx$$

For an inert solid, the heat flow at any location is governed by the *Fourier equation*. This empirically-derived equation states that the heat flow per unit area is proportional to the gradient of temperature in the body and to a material property which is termed the *thermal conductivity*. The Fourier equation is:

$$\dot{q} = - \lambda \frac{dT}{dx}$$

where λ = thermal conductivity (W m^{-1} K^{-1}). The minus sign in the above equation comes about because of the axiom of thermodynamics which states that heat flows from the hotter place to the cooler one. Then, the net heat flow (what is coming in one face of the slab, minus what is leaving the other) is:

$$- \frac{\partial}{\partial x} \left(- \lambda \frac{\partial T}{\partial x} \right) = \lambda \frac{\partial^2 T}{\partial x^2}$$

where we were able to take λ outside the outer derivative by assuming that it is a constant, independent of x. If the heat capacity and the density are constant (not necessarily always a realistic assumption) and there are no changes of phase (e.g., melting), then the heat stored in the control volume can be expressed as:

$$\rho C \frac{\partial T}{\partial t} dx$$

Then equating the net heat flow in to the heat stored gives:

$$\rho C \frac{\partial T}{\partial t} = \lambda \frac{\partial^2 T}{\partial x^2}$$

This is a partial differential equation for T, as a function of x and t. By consulting any textbook on heat transfer, the extension of this result to three dimensions can be found. For the three-dimensional case, the heat conservation equation is written as:

$$\rho \, C \frac{\partial T}{\partial t} = \lambda \nabla^2 T$$

where the notation $\nabla^2 T$ denotes $\dfrac{\partial^2 T}{\partial x^2} + \dfrac{\partial^2 T}{\partial y^2} + \dfrac{\partial^2 T}{\partial z^2}$

The initial condition for the problem is:

$$T(x) = T_o \qquad \text{for all } x, \text{ for } t < 0.$$

If the front face is heated by an incident heat flux $\dot{q}''_e$ (kW m^{-2}) and loses heat by convection and re-radiation, then the front-face boundary condition is:

$$- \lambda \frac{\partial T_s}{\partial x} = h_c \left(T_o - T_s \right) + \alpha_s \dot{q}''_e - \varepsilon_s \sigma \left(T_s^4 - T_o^4 \right)$$

where h_c = convective heat transfer coefficient (W m^{-2} K^{-1}), the temperature of the gas near the surface is T_o (K) which is taken to be the same as the solid's initial temperature, σ = Stefan-Boltzmann constant (5.67 $\times 10^{-11}$ kW m^{-2} K^{-4}), ε_s = emissivity of surface (–), and α_s = absorptivity of surface (–). Atreya[62] obtained an approximate analytical solution for this case, however, the solution was cumbersome. Panagiotou and Delichatsios[63] provided another approximate analytical solution, although, again, experimental data could not be evaluated or correlated without the use of a computer program. Consequently, they do not appear to have promise for engineering applications. It is interesting to note that Atreya examined in detail the ignition behavior of wood and concluded that the inert-body assumption is not a serious limitation for that material. The heat of pyrolysis of wood, of course, is not zero, but has both endothermic and exothermic peaks over a range of temperatures. But, unless highly accurate solutions are sought, Atreya concluded that assuming a zero heat of pyrolysis does not lead to appreciable errors.

DEVELOPMENT OF APPROXIMATE SOLUTIONS

Lawson and Simms[12] were the first to consider the inert-heating equation as a starting point for developing a method for treating experimental data. Their solution was based on the solid being very thick. This is called 'semi-infinite' in mathematical terminology and is referred to as a 'thermally-thick' body in heat transfer studies. We will return below to consider what thickness a real solid must have in order to be treatable as a thermally-thick body. Lawson and Simms took the boundary condition at the front face of a semi-infinite solid to be:

$$- \lambda \frac{\partial T}{\partial x} = \dot{q}''_e - h_{eff} \left(T_{ig} - T_o \right)$$

Thus, it is assumed that all of the incident heat flux $\dot{q}''_e$ is absorbed by the body, in other words, that the surface is black ($\alpha_s = 1$). Except possibly for very brief ignition times, realistic solutions will not be obtained if front-face heat losses are ignored. The heat losses are twofold: (1) as the surface temperature starts rising, it begins to exceed the ambient temperature and, therefore, a convective cooling stream starts in motion; and (2) the surface can radiate heat, in addition to absorbing it, and as the surface temperature rises, its re-radiated component will start becoming significant. Since the latter is proportional to T^4, an exact solution would be difficult. Thus, Lawson and Simms lumped the re-radiated term into the convective term by use of a fictitious value of the convective transfer coefficient h_{eff}, where h_{eff} has some value greater than the purely-convective heat transfer coefficient h_c. With this boundary condition, and the initial condition $T(x) = T_o$ for all x, the heat transfer problem has the classical solution[137]:

$$T_{ig} - T_o = \frac{\dot{q}''_e}{h_{eff}} \left[1 - \exp(\tau) \, \text{erfc}\left(\sqrt{\tau} \right) \right]$$

where $\tau = h_{eff}^2 t_{ig} / \lambda\rho C$ is the non-dimensional ignition time. If $\alpha_s \neq 1$, then the results are the same, except that the non-dimensional ignition time becomes defined as: $\tau = h_{eff}^2 \alpha_s t_{ig} / \lambda\rho C$. The above is a mathematically complete solution, but it is not readily usable. A minor obstacle is the fact that the complementary error function *erfc* is a mathematical function which requires use of tables or approximations. If a program is available* which evaluates *erfc*, then the bigger obstacle remains that the solution is not explicit for the dependent variable. Normally, one specifies a value of $\dot{q}_e''$ and wishes to compute the value of t_{ig}. Yet, the above solution is readily workable only if one knows t_{ig} and wishes to solve for $\dot{q}_e''$. Another difficulty is that there are two separate groups of variables which have embedded in them the physical properties: $h_{eff}\left(T_{ig} - T_o\right)$ and $h_{eff}^2 \alpha_s / \lambda\rho C$. If the values of those were known, then $\dot{q}_e''$ could be obtained by specifying t_{ig}. But from the user's point of view, the desired scheme is the following:

(a) measure the ignition time at several values of $\dot{q}_e''$;
(b) obtain some constants from these results;
(c) insert these constants into some simple formula which will give t_{ig} for any value of $\dot{q}_e''$ inputted.

A number of schemes have been proposed to accomplish this, and we now examine some of the better-known ones.

Lawson and Simms proposed that for large τ values an approximation based on a series expansion can be made, giving:

$$T_{ig} - T_o = \frac{\dot{q}_e''}{h_{eff}}\left[1 - \frac{1}{\sqrt{\pi}}\left(\frac{1}{\tau^{1/2}} - \frac{1}{2\tau^{3/2}} + \frac{3}{4\tau^{5/2}} - \ldots\right)\right]$$

$$\approx \frac{\dot{q}_e''}{h_{eff}}\left[1 - \frac{1}{\sqrt{\pi\tau}}\right] = \frac{\dot{q}_e''}{h_{eff}}\left[1 - \frac{1}{h_{eff}}\sqrt{\frac{\lambda\rho C}{\pi\, t_{ig}}}\right]$$

This equation was not highly accurate in correlating their experimental data, which did not extend to very long ignition times. Thus, Simms[64] provided a second approximation, for $\tau \rightarrow 0$:

$$T_{ig} - T_o = \frac{\dot{q}_e''}{h_{eff}}\left[\frac{2}{\sqrt{\pi}}\tau^{1/2} - \tau + \frac{4}{3\sqrt{\pi}}\tau^{3/2} - \frac{1}{2}\tau^2 + \ldots\right]$$

$$\approx 2\dot{q}_e''\sqrt{\frac{t_{ig}}{\pi\lambda\rho C}}$$

It can be noted that the convective heat loss coefficient h_{eff} does not enter the above approximation; thus, it cannot be expected to be realistic for correlating real data, except at very large irradiances, where convective losses are indeed negligible. At high heat fluxes, if a thermally-thick solid ignites very fast, then the effect of convective cooling of the front face can properly be ignored. Simms[65] proposed that convection may be neglected if:

$$h\sqrt{\frac{t_{ig}}{\lambda\rho C}} \leq 0.12$$

The two expressions of Lawson and Simms allowed trends to be identified for very short and very long ignition times, but did not give an equation which would be accurate for correlating a full range of experimental data. It can be shown that range $0.1 < \tau_{ig} < 5$ is not acceptably approximated even by using the 'full' 4-term approximations given above; using only one or two terms leads to a much more serious 'missing middle.'

In a similar vein, Quintiere[66] suggested another two approximations, but he proposed that the whole range of ignition times can be covered by a piecewise-continuous approximation:

$$T_{ig} - T_o \approx \frac{\dot{q}_e''}{h_{eff}}\frac{2}{\pi}\sqrt{\tau} = \frac{\dot{q}_e''}{h_{eff}}\frac{2}{\sqrt{\pi}}\sqrt{\frac{h_{eff}^2 t_{ig}}{\lambda\rho C}} \qquad \text{for } \tau \leq 0.8$$

$$T_{ig} - T_o \approx \frac{\dot{q}_e''}{h_{eff}} \cdot 1 = \frac{\dot{q}_e''}{h_{eff}} \qquad \text{for } \tau > 0.8$$

Or, grouping the constants,

$$T_{ig} - T_o \approx \frac{\dot{q}_e''}{h_{eff}} b\sqrt{t_{ig}} \qquad \text{for } t \leq t_m$$

and

$$T_{ig} - T_o \approx \frac{\dot{q}_e''}{h_{eff}} \qquad \text{for } t > t_m.$$

where t_m is the value of dimensional time that corresponds to the dimensionless $\tau = 0.8$ and b is a constant. Quintiere proposed that, for convenience, the function $[1 - \exp(\tau)\,\mathrm{erfc}(\sqrt{\tau})]$ be designated as $F(\tau)$. Figure 19 shows his approximation, the 4-term versions of Simms' approximations, and the true value of the function.

In order to progress from mathematical approximations to a viable data-handling protocol, Buschman[10] was the first to suggest that what is needed to correlate experimental data is simply a relation between the heat flux and the time. He proposed that:

$$t_{ig}^{-n} = C\left(\dot{q}_e'' - \dot{q}_{cr}''\right)$$

where C, n, and $\dot{q}_{cr}''$ are experimental constants. As discussed above, Atreya had obtained a comprehensive solution to the inert-solid problem, including both convection and re-radiation at the face. Abu-Zaid[67] took Atreya's complex solution and demonstrated that, to a reasonably small error, it could be represented as

* Current-day spreadsheets normally have the function *erfc* built in, however, it must be noted that using directly the *exp* and *erfc* functions of spreadsheet programs leads to gross errors for τ_{ig} greater than about 30; this occurs because a very large number is being multiplied by a very small one. To make a correct evaluation for $\tau_{ig} > 30$, it is necessary to use an approximation that is suitable for large τ_{ig}, instead.

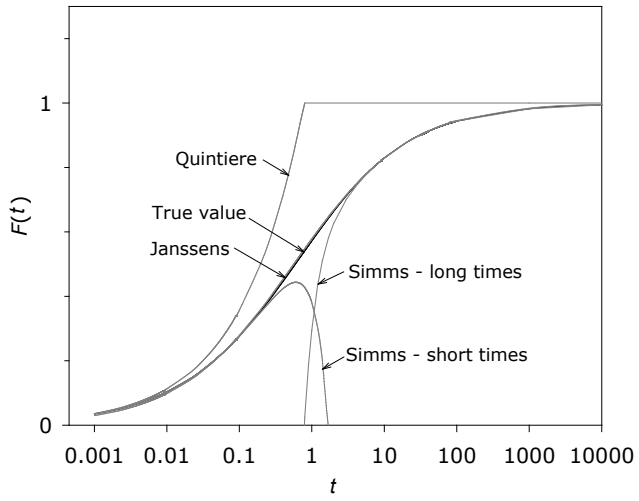

Figure 19 Various approximations to the semi-infinite solid ignition function

$$t_{ig}^{-0.5} = C\left(\dot{q}''_e - \dot{q}''_{cr}\right)$$

and where C and $\dot{q}''_{cr}$ remain experimental constants. Thus, he provided a theoretical justification for Buschman's empirical approach. While the same conclusion can be arrived at by extreme simplifications of the heat transfer problem, Abu-Zaid demonstrated that it is not necessary to ignore re-radiation or convection, nor to limit the validity to very small or very large ignition times. In the same vein, Smith and Satija[68] proposed that the concept be generalized to non-constant heat fluxes by adoption of a *flux-time product*, FTP, where:

$$FTP = \int_0^{t_{ig}} \left(\dot{q}''_e(t) - \dot{q}''_{cr}\right) dt$$

These authors did not provide a mathematical justification for their procedure and replaced n = ½ with n = 1, which would be appropriate only for thermally-thin materials. Later, several authors[69,70] revived the idea, but provided for a variable n, so that thermally-thick and thermally-thin materials could be encompassed:

$$FTP = \int_0^{t_{ig}} \left(\dot{q}''_e(t) - \dot{q}''_{cr}\right)^n dt$$

In what was the most ambitious study of piloted ignition to that time, in 1971 Hallman[71] published a dissertation where he included the first systematic determination of the spectral absorption characteristics for a large variety of plastics and enabled values of α_s to be computed. With these data in hand, Hallman started with the Lawson/Simms approximation for very short ignition times:

$$t_{ig} \approx \frac{\pi}{4} \frac{(\lambda\rho C)\left(T_{ig} - T_o\right)^2}{\left(\alpha_s \dot{q}''_e\right)^2}$$

He then attempted to use the above equation as a basis for a correlation, but with adjustable exponents. Using handbook values of room-temperature $\lambda\rho C$ data, he arrived at the best-fit formula:

$$t_{ig} = \frac{1035\left(\lambda\rho C\right)^{0.75}\left(T_{ig} - T_o\right)^{1.04}}{\left(\alpha_s \dot{q}''_e\right)^2}$$

The results, however, showed a high degree of scatter about the predicted values. The notably low exponent for the ignition temperature term arose because Hallman did not follow the recommendation of Buschman to include the $\dot{q}''_{cr}$ term. In a similar exercise, Tewarson[72] proposed that data be plotted in the form:

$$t_{ig} = \frac{\pi}{4} \frac{(\lambda\rho C)\left(T_{ig} - T_o\right)^2}{\left(\dot{q}''_e - \dot{q}''_{cr}\right)^2}$$

or

$$t_{ig} = \frac{\pi}{4}\left[\frac{TRP}{\dot{q}''_e - CHF}\right]^2$$

where the *thermal response parameter*, TRP (kW s$^{1/2}$ m^{-2}), is defined as: $TRP = (\lambda\rho C)^{1/2}\left(T_{ig} - T_o\right)$ and $CHF \equiv \dot{q}''_{cr}$. In this formula, the value of α_s has effectively been set to 1.0, since in the Factory Mutual Flammability Apparatus, which is the test method used by FM to determine the TRP, the specimen surface is blackened prior to test. Tewarson's procedure uses reasonable exponents for the various factors, since he does not leave out the important $\dot{q}''_{cr}$ term. Koohyar[73] reviewed a variety of additional early approximate treatments.

The *minimum flux for ignition* is also a variable which is amenable to theoretical analysis. By definition, this heat flux is the minimum for which a surface temperature of T_{ig} may be achieved. If it is assumed that the minimum flux for ignition will occur at such a long time that the substance will be in thermal equilibrium, then the temperature gradient at the surface of a semi-infinite solid becomes zero. Consequently, the conduction loss is zero, and the heat balance at the surface is:

$$\alpha_s \dot{q}''_{\min} - h\left(T_{ig} - T_o\right) - \varepsilon_s \sigma T_{ig}^4 - \dot{m}''_{\min} L_v = 0$$

where ε_s = surface emissivity (--), $\dot{m}''_{\min}$ = minimum mass loss rate for ignition (kg m^{-2} s^{-1}), L_v = total heat of gasification (kJ kg^{-1}), and values of temperature are expressed in Kelvins. This equation can be directly solved for $\dot{q}''_{\min}$ if all the other quantities are known. But, in practical applications, the other quantities will rarely be known. The variables α_s, ε_s, and L_v can be obtained only with laborious measurements*, while correct values of $\dot{m}''_{\min}$ are so diffi-

* In many cases, the assumption is made that $\varepsilon = \alpha_s$. This is not necessarily true. According to Kirchoff's Law, ε is equal to α_s at a *given* radiation wavelength. But since the spectral distribution of the source radiation is not the same as that of the target being emitted by the target, the wavelength-averaged ε will generally be somewhat different from the wavelength-averaged α_s. In practice, for most problems there is no alternative but to assume that $\varepsilon = \alpha_s$.

cult to determine that it is still unclear whether the best-available results are sufficiently accurate. By contrast, it is simple and inexpensive to determine $\dot{q}''_{\min}$ experimentally; consequently, this variable is almost always measured, not computed.

JANSSENS' PROCEDURE

In 1966, Keller et al.[74] observed that data from the ignition of propellants at high radiant or convective heat fluxes could be well correlated if heat flux is plotted on the x-axis, square root of ignition time on the y-axis, and a line with a slope of –0.92 is drawn to the points. This, of course, is equivalent to plotting heat flux on the x-axis and $t_{ig}^{-0.543}$ on the y-axis. Some 25 years later, Janssens rediscovered this same fact, and proceeded to place it on a sounder mathematical footing. The procedures he evolved are today the best means of analyzing ignition data for thermally thick solids and for interpolating or extrapolating from those results.

Janssens[75,76] started with the solution for the case of a semi-infinite slab being heated by radiation and cooled by convection (that is, lumping the surface re-radiation term into an effective convection coefficient h_{eff}). The difficulty is that solution for the front-face temperature,

$$T_{ig} = T_o + \frac{\alpha_s \dot{q}''_e}{h_{eff}} \left[1 - \exp(\tau)\operatorname{erfc}\left(\sqrt{\tau}\right)\right]$$

cannot be evaluated by simple means, and most previous efforts at producing an approximation gave expressions which were only accurate at the extremes of $t_{ig} \rightarrow \infty$ or $t_{ig} \rightarrow 0$, but not for a wide range of intermediate values. Janssens attacked the problem by a statistical approach, and found that a good approximation* was:

$$\left[1 - \exp(\tau)\operatorname{erfc}\left(\sqrt{\tau}\right)\right] \approx \frac{1}{1 + 0.73\tau^{-0.55}}$$

Janssens then demonstrated that the approximation also holds for the more realistic case where heat losses include both a convection term, proportional to T^1, and a radiation term, proportional to T^4. At the critical flux, it can be assumed that the ignition time $t_{ig} \rightarrow \infty$ (although we shall later see that this is not exactly true). Thus:

$$T_{ig} \approx T_o + \frac{\alpha_s \dot{q}''_{cr}}{h_{eff}}[1.0]$$

which allows the effective convective coefficient to be expressed as:

$$h_{eff} = \frac{\alpha_s \dot{q}''_{cr}}{\left(T_{ig} - T_o\right)}$$

Combining the above equations and eliminating ($T_{ig} - T_o$) gives:

$$\dot{q}''_e = \dot{q}''_{cr}\left[1 + 0.73\left(\frac{\lambda\rho C}{h_{eff}^2 t_{ig}}\right)^{0.55}\right]$$

This result has great significance for the practical application of radiant ignition data. It implies that if experimental data are plotted such that $\dot{q}''_e$ is put on the x-axis and $t_{ig}^{-0.55}$ on the y-axis, then the data will fall in a straight line, with the x-axis intercept being $\dot{q}''_{cr}$. The plot to be made is illustrated in Figure 20. In some cases, it is found[77] that the minimum flux at which ignition takes place, $\dot{q}''_{\min}$, is substantially greater than $\dot{q}''_{cr}$. The minimum flux is determined experimentally as being halfway between the lowest flux at which ignition was found and the highest flux at which no ignition occurs for long exposure times. The critical flux, on the other hand, is a variable only determined by data plotting, and is simply the x-axis intercept. When $\dot{q}''_{\min}$ is substantially larger than $\dot{q}''_{cr}$, it is empirically found that more realistic predictions of T_{ig} are obtained if $\dot{q}''_{\min}$, and not $\dot{q}''_{cr}$, is used in the above series of equations. This is illustrated in the example problem below. The collection of experimental data points, in any case, is represented by just three variables: $\dot{q}''_{cr}$, $\dot{q}''_{\min}$, and the slope of the straight line.

While the concept has received little study, clearly the existence of a $\dot{q}''_{\min} > \dot{q}''_{cr}$ implies that there is a *maximum time of ignition*. In other words, there are not ignition times that $\rightarrow \infty$, instead, no ignition is feasible beyond some finite time. This is mandated by elementary chemical kinetics, since reactants are progressively exhausted at any finite temperature. In this case, the reaction products, which also diminish if the reactants are consumed, are the combustible pyrolysis gases that will or will not ignite.

Once a plot such as shown in Figure 20 is made, interpolations or extrapolations can be made directly from the straight line plotted. But for some modeling purposes, it is also desired to deduce the effective thermophysical properties of the specimen. Using Janssens' procedure this is done as follows. The assumption is made that values of h_c and α_s are known. The former is a function of the test environment, rather than of the specimen. The actual value of h_c is not a true constant, but has a slight dependence on the temperature difference between the gas stream and the surface. In the case of the Cone Calorimeter apparatus (test method details are presented at the end of this Chapter), a number of slightly different values have been proposed[78-80], but commonly $h_c \approx 0.013$ kW m^{-2} K^{-1} is chosen for both horizontal and vertical specimen orientations. For more precise work, Janssens recently found that that h_c varies somewhat with the irradiance used. This is understood to be due to the fact that the heater acts as a pump of air, thus creating, in effect, some forced convection. For specimens in the hori-

* Janssens also showed that a usable approximation can be made by using $\tau^{-0.5}$, although a less good one.

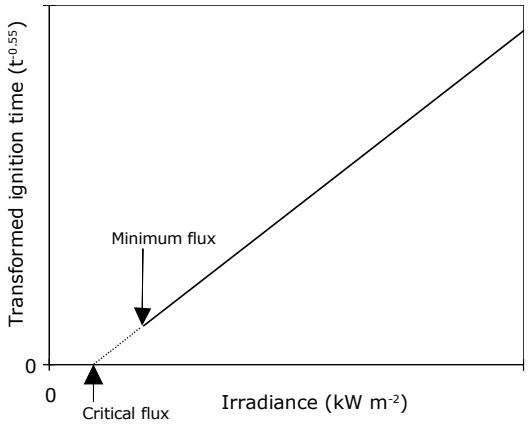

Figure 20 The main variables of the ignitability plot

zontal orientation[81,82] Janssens obtained results that could be well represented by:

$$h_c = 6.56\times10^{-3}\cdot\dot{q}_e''^{0.35}$$

These newly-recommended values are quite a b it higher than found by previous researchers, for unidentified reasons. For example, in his new study, h_c = 0.0202 kW m^{-2} K^{-1} at 25 kW m^{-2} irradiance and h_c = 0.0258 kW m^{-2} K^{-1} at 50 kW m^{-2} irradiance. Janssens further recommended that a linear approximation can be used:

$$h_c = 0.0118 + 3.4\times10^{-4}\,\dot{q}_e'' \qquad \dot{q}_e'' < 50 \text{ kW m}^{-2}$$

$$h_c = 0.0255 + 6.5\times10^{-5}\,\dot{q}_e'' \qquad \dot{q}_e'' \geq 50 \text{ kW m}^{-2}$$

For the vertical orientation, Janssens[83] found values about 10 – 15% than for the horizontal orientation. This is as expected from normal considerations of convective heat transfer. For the LIFT apparatus, which likewise uses vertically-oriented specimens, a value of h_c = 0.015 kW m^{-2} K^{-1} is specified in the ASTM standard[66]. However, Dietenberger showed that this quantity is also flux-dependent[84]. His suggested relation is:

$$h_c = \left(0.0139 - 0.0138x\right)\left(\dot{q}_{50}''\right)^{1/4}$$

where x = lateral distance (m) along specimen, measured from the hot end, and $\dot{q}_{50}''$ denotes the heat flux measured at the 50 mm distance. Using this expression for the location x = 0.05 m, h_c = 0.0295 kW m^{-2} K^{-1} at 25 kW m^{-2} irradiance and h_c = 0.0351 kW m^{-2} K^{-1} at 50 kW m^{-2} irradiance. The LIFT value is higher than for vertical specimens in the Cone Calorimeter because a more powerful heater is present in the LIFT apparatus, and this raises the convective heat flow. Using any of the non-constant expressions makes data analysis difficult. Thus, it may be best to adopt an average, constant value for the flux range of interest. This is especially true in view of the fact that the flux-dependent studies have all thus far been done only in one laboratory each and have not been corroborated by testing in other laboratories.

For the absorptivity α_s, a measured value should be used if available. If it is not, Table 32 indicates that the average value for a wide range of plastics is 0.88, which is also the identically same value as adopted by Janssens for use with wood products; thus α_s = 0.88 should be used for treating Cone Calorimeter data. For LIFT data, the physics is, of course, no different, but the standard data treatment procedure[66] mandates that $\alpha_s \equiv 1.0$ be used. With values of h_c and α_s in hand, the procedure becomes:

1. Obtain a series of ignition times at varying heat fluxes.
2. Plot $t_{ig}^{-0.55}$ on the y-axis, as a function of $\dot{q}_e''$ on the x-axis. Note that the units for the x-axis are to be (kW m^{-2}).
3. Fit a straight line to the data points and determine the critical irradiance $\dot{q}_{cr}''$ as the x-axis intercept.
4. Evaluate the slope of the straight line. The inverse of slope is defined as a constant, B_{ig} :

$$B_{ig} = \frac{1}{\text{slope}}$$

5. Obtain T_{ig} by a trial-and-error solution of the relationship:

$$\frac{\dot{q}''_{\min}}{\left(T_{ig} - T_\infty\right)} = \frac{h_c}{\alpha_s} + \frac{\sigma\left(T_{ig}^4 - T_\infty^4\right)}{\left(T_{ig} - T_\infty\right)}$$

6. Solve for h_{eff} using :

$$h_{eff} = \frac{\alpha_s \dot{q}''_{\min}}{\left(T_{ig} - T_o\right)}$$

7. Compute the apparent $\lambda\rho C$ as:

$$\lambda\rho C = h_{eff}^2\left[\frac{B_{ig}}{0.73\,\dot{q}''_{\min}}\right]^{1.828}$$

In adopting specific procedures for presenting data, such as outline above, it must be kept in mind that the slope of the line (and B_{ig}) is not a general material property, but depends on the exact theory used. For example, if, as in the Tewarson procedure, time to the –0.5, instead of –0.55 power were plotted, the slope will be different. What does *not* change, regardless of theory used, is the value of $\dot{q}''_{\min}$; this is because it is a direct experimental determination and is not subject to interpretation according to a mathematical theory.

Some materials may not show straight lines when plotted in the way suggested. The theory described above only pertains to thermally thick materials, and if the material is too thin, then data points at higher heat fluxes will fall on a straight line, but data points at low heat fluxes will deviate and will lie above that line. Janssens proposes that such cases be treated by only utilizing the data points which do fall on a reasonably straight line in deriving thermal properties. If a material is so thin as to be thermally thin over most of the exposure range, then it should be treated as thermally thin (see below).

Example

The values experimentally determined by Thomson for polyethylene using an apparatus similar to the Cone Calorimeter were:

Flux (kW m^{-2})	15	19	23	27	29	34	39
Ignition time (s)	NI	524	315	223	172	114	85

From these results, the minimum flux is determined as (15+19)/2 = 17 kW m^{-2}. The derived values to be plotted are heat flux on the x-axis and $t_{ig}^{-0.55}$ on the y-axis. These values are:

x-axis: Flux (kW m^{-2})	19	23	27	29	34	39
y-axis: $t_{ig}^{-0.55}$	0.0319	0.0423	0.0511	0.0589	0.0739	0.0869

The results are shown in Figure 21. A least-squares routine was used to pass the line of best fit through the 7 data points, giving an x-intercept of 7.9 kW m^{-2} and a slope of 0.00279. The critical irradiance, $\dot{q}''_{cr}$ thus is 7.9 kW m^{-2}. The value of B_{ig} = 1/0.00279 = 358. The values h_c = 0.013 kW m^{-2} K^{-1} and α_s = 0.88 are also used. If calculations are based on $\dot{q}''_{cr}$, then a trial-and-error solution for T_{ig} is obtained from:

$$\frac{\dot{q}''_{cr}}{(T_{ig} - T_\infty)} = h_c + \frac{\sigma(T_{ig}^4 - T_\infty^4)}{(T_{ig} - T_\infty)}$$

giving T_{ig} = 537 K = 264ºC. Thomson measured T_{ig} = 363ºC experimentally, thus this computed value is much too low. On the other hand, if calculations are based on $\dot{q}''_{\min}$:

$$\frac{\dot{q}''_{\min}}{(T_{ig} - T_\infty)} = h_c + \frac{\sigma(T_{ig}^4 - T_\infty^4)}{(T_{ig} - T_\infty)}$$

this gives T_{ig} = 675 K = 402ºC. The error here is much smaller than with the use of $\dot{q}''_{cr}$. Continuing the problem solution on the basis of using $\dot{q}''_{\min}$, h_{eff} is obtained from:

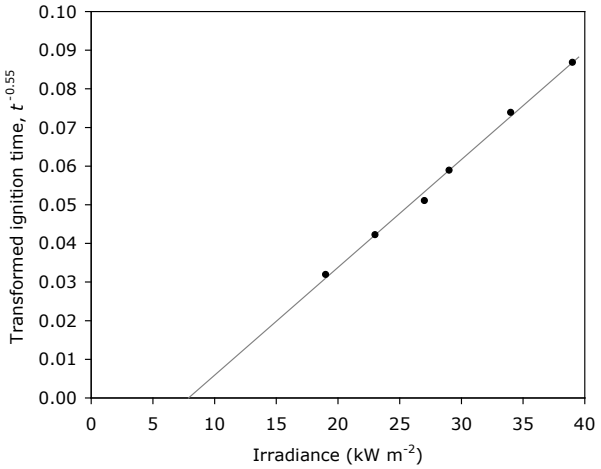

Figure 21 Polyethylene example problem—Janssens procedure

$$h_{eff} = \alpha_s \frac{\dot{q}''_{\min}}{(T_{ig} - T_\infty)}$$

giving $h_{\rm eff}$ = 0.0392 kW m^{-2} K^{-1}. Finally, the apparent thermal inertia $\lambda\rho C$ is obtained as:

$$\lambda\rho C = h_{eff}^2 \left[\frac{B_{ig}}{0.73\,\dot{q}''_{\min}}\right]^{1.828}$$

giving $\lambda\rho C$ = 0.716 kJ^2 m^{-4} s^{-1} K^{-2}.

Non-constant heat flux—generalization of Janssens' procedure

Generally, the external heat flux will not be constant. Then, there are two ways of dealing with this. For very rough approximations, one can simply average the heat flux and insert this value into the pertinent ignitability plot. For a more accurate solution, however, a time-resolved calculation must be made. To do this, we use Duhamel's theorem[85]. In Janssens' methodology, observe that in the ignitability plot, any point above the diagonal line denotes non-ignition, while any point on or below the line denotes ignition. We also note that B_{ig} is 1/slope. To find out if ignition occurs for any given time history of $\dot{q}''(t)$ then, the following integral must be evaluated[86]:

$$B = t^{0.05} \times \frac{1}{2}\int_0^t \frac{\dot{q}''_e(\tau) - \dot{q}''_{cr}}{\sqrt{t - \tau}}\, d\tau$$

The ignition criterion thus becomes: *Ignition occurs if* $B \geq B_{ig}$. The technique can be applied whenever a non-constant irradiance occurs and the $\dot{q}''_e(t)$ history is known. This procedure is only approximate, however, since the loss term is assumed to have a constant value, $\dot{q}''_{cr}$. But this value will only be attained at the moment of ignition—at earlier times, losses will be lower, since the surface temperature will be lower. Consequently, the method leads to lower values of B being computed than is actually the case.

QUINTIERE'S PROCEDURE

Because it has been used to develop a significant amount of published data, it is also important to understand Quintiere's procedure[66]. It is a part of the LIFT test procedure (see the *Test methods* section of this Chapter) but has sometimes also been used in connection with other experimental apparatuses. In this procedure, first a value of $\dot{q}''_{\min}$ is found experimentally. This is assumed to be occurring at steady state, thus

$$\alpha_s \dot{q}''_{\min} = h_c(T_{ig} - T_o) + \alpha_s \sigma(T_{ig}^4 - T_o^4)$$

As explained above, Quintiere assumes $\alpha_s \equiv 1$ and h_c = 0.015 kW m^{-2} K^{-1}. Inserting those values in the above gives:

$$\dot{q}''_{\min} = 0.015(T_{ig} - T_o) + \sigma(T_{ig}^4 - T_o^4)$$

From the above equation, T_{ig} is then calculated. Next, the linearized (effective) heat transfer coefficient h_{eff} is, by definition:

$$\dot{q}''_{\min} = h_{eff}\left(T_{ig} - T_o\right)$$

Thus, it can be solved for as:

$$h_{eff} = \frac{\dot{q}''_{\min}}{\left(T_{ig} - T_o\right)}$$

The expression for the ignition temperature of a thermally-thick slab is approximated as:

$$T_{ig} = T_o + \frac{\dot{q}''_e}{h_{eff}} F\left(\tau_{ig}\right)$$

where

$$F\left(\tau_{ig}\right) = \begin{cases} \dfrac{2h_{eff}\sqrt{t_{ig}}}{\sqrt{\pi\lambda\rho C}} & \text{for small } t_{ig} \\ 1 & \text{for large } t_{ig} \end{cases}$$

According to this, if $\sqrt{t_{ig}}$ is plotted on the x-axis and $\dot{q}''_{\min} / \dot{q}''_e$ on the y-axis, the data will fall along a straight line which passes through the origin and has the slope of $2h_{eff} / \sqrt{\pi\lambda\rho C}$; this slope is identified as b and has units of s^{-1}. In addition to the slope, the user must also determine the x-value at which the line crosses the horizontal line located at y = 1. The time at which this occurs is the break-point between 'small' and 'large' t_{ig} values and is denoted as t_m. Thus, the user procedure is summarized as follows:

1. Determine the value of $\dot{q}''_{\min}$ experimentally (Quintiere refers to this variable as $q_{o,ig}$).
2. Plot the data points by plotting $\sqrt{t_{ig}}$ on the x-axis and $\dot{q}''_{\min} / \dot{q}''_e$ on the y-axis.
3. Pass a straight line going through the origin through the data points. Quintiere's original study implies that data points should be left out of the correlation at the higher x-values if they visually appear to deviate from a reasonable line, but this is not explicitly explained there nor in the ASTM standard. The slope of the line is identified as b.
4. Calculate T_{ig} (K) by trial-and-error using the equation:
$$\dot{q}''_{\min} = 0.015\left(T_{ig} - T_o\right) + \sigma\left(T_{ig}^4 - T_o^4\right)$$
Alternatively, there is a chart provided in the ASTM standard for the LIFT test that presents the relationship between $\dot{q}''_{\min}$ and T_{ig}. Note that this equation, while generally similar to the one used by Janssens, produces significantly higher T_{ig} values, since the minimum, rather than the critical, heat flux is used.
5. Determine h_{eff} from:
$$h_{eff} = \frac{\dot{q}''_{\min}}{\left(T_{ig} - T_o\right)}$$
6. Determine the apparent thermal inertia, $\lambda\rho C$, from
$$\lambda\rho C = \frac{4}{\pi}\left(\frac{h_{eff}}{b}\right)^2$$

The final values that are reported using the Quintiere procedure are: $\dot{q}''_{\min}$, T_{ig}, and $\lambda\rho C$. Note that Quintiere's procedure, unlike Janssens', has no alternative for treating thermally-thin materials—all materials are treated as thermally-thick, irrespective of thickness.

Example

The same example as was used to illustrate Janssens' method will be used to illustrate Quintiere's method. The experimentally determined ignition times for polyethylene were:

Flux (kW m^{-2})	15	19	23	27	29	34	39
Ignition time (s)	NI	524	315	223	172	114	85

From these results, the minimum flux is determined as (15+19)/2 = 17 kW m^{-2}. The derived values to be plotted are obtained as:

x-axis points: $\sqrt{t_{ig}}$	22.89	17.75	14.93	13.11	10.68	9.22
y-axis points: $\dot{q}''_{\min} / \dot{q}''_e$	0.895	0.739	0.630	0.586	0.500	0.436

These values are now plotted as shown in Figure 22. The data point x = 22.89 was omitted from the correlation, since it appeared not to follow a straight line. Passing a straight line through the remaining points gave b = 0.0435. Given $\dot{q}''_{\min}$ = 17, trial-and-error solution gives T_{ig} = 674 K = 401ºC, compared to a value of was 363ºC measured by Thomson. Using T_{ig} = 674 K and solving, gives h_{eff} = 0.0446 kW m^{-2} K^{-1}. Finally, the apparent thermal inertia $\lambda\rho C$ is determined as 1.34 kJ^2 m^{-4} s^{-1} K^{-2}. As Janssens has observed[75], the value of thermal inertia obtained by the Quintiere procedure is higher than obtained by the Janssens procedure, due to the less-accurate approximation used for the analytical solution.

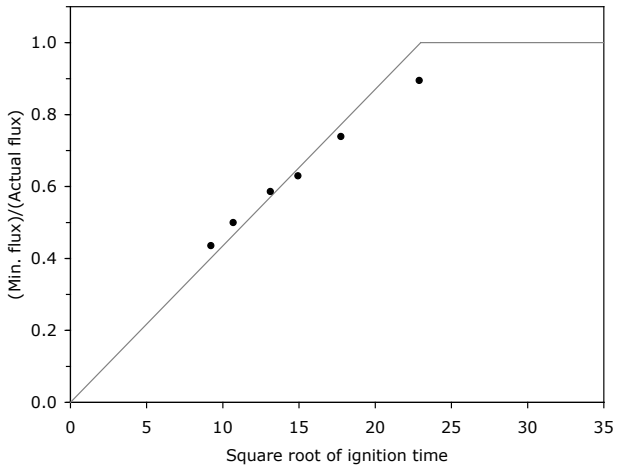

Figure 22 Polyethylene example problem—Quintiere procedure

TEWARSON'S PROCEDURE

Tewarson[72] starts from the equation

$$t_{ig} = \frac{\pi}{4}\frac{TRP^2}{(\dot{q}''_e - \dot{q}''_{cr})^2}$$

which was developed above. The procedure could be applied to any test apparatus, but in practice, most of the data using his analysis procedure has been obtained on the FM Fire Propagation Apparatus (see *Test methods*). In his procedure, ignition tests at even-5 kW m^{-2} irradiance values are run. The lowest value for which ignition is obtained is identified as the CHF, 'critical heat flux.' Note that this definition is not consistent with Janssens'. In fact, the CHF is a rough, biased determination of $\dot{q}''_{\min}$: rough because normally 1 or 2 kW m^{-2}, not 5 kW m^{-2}, steps are recommended; biased because the value of CHF that is reported is the lowest heat flux at which ignition did occur, not the mean between the lowest occurring and the highest non-occurring. The FM Fire Propagation Apparatus exposes specimens to radiation from a source which has a much higher effective radiating temperature than do room fires. Since under these conditions many materials show a much lower absorptivity than they do for radiation from room fires, a systematic error would be introduced into the procedure. An effort is made to reduce the error by blackening the specimens in the Tewarson procedure. For a black surface, $\alpha_s \equiv 1$, and this more closely represents the absorptivity of common materials for room-flame radiation. The ignition data are then plotted with $\dot{q}''_e$ on the x-axis and $t_{ig}^{-1/2}$ on the y-axis. A straight line is passed through the data points, from which TRP, the thermal response parameter, is obtained as:

$$TRP = \sqrt{\frac{4}{\pi}}\frac{1}{slope}$$

The units of TRP are kW s$^{1/2}$ m^{-2}. The only two values reported are TRP and CHF. Since the x-axis intercept will generally not be equal to CHF, the reporting procedure does not allow the user to construct a specific straight line: the slope is known, but the intercept is not. The information is deemed sufficient for FM purposes, since their hazard assessment procedures rank the ignitability of products solely on the TRP values, and actual ability to interpolate or extrapolate ignition times is not sought. Nicolette and Nowlen[87] have criticized Tewarson's procedure on the grounds that straight-line extrapolations can be seriously misleading, if actual data points are not collected to determine $\dot{q}''_{\min}$, since the real curve may be substantially different than an extrapolation from high-flux values.

OTHER DATA TREATMENT PROCEDURES

The procedure described by Janssens is the best available method for deriving thermophysical material properties from ignitability data. It is essential to point out that similar, but slightly different procedures tend to lead to significantly different values of the derived 'constants.' Fangrat has demonstrated[88] this fact quite clearly. This is not unexpected, since the thermal 'constants' are in actual fact temperature-dependent. An example of actual, temperature-dependent values of the thermal inertia is shown in Figure 23. This emphasizes that assigning constants to such non-constant properties over-simplifies the real ignition physics.

Delichatsios et al.[90] offered a procedure for data analysis which is somewhat more complicated than that of Janssens. Unfortunately, when attempting to analyze real experimental data, Dembsey and Jacoby[99] found that, in 7 out of 13 cases, unphysical answers were produced (negative values of minimum fluxes for ignition were computed for ordinary substances that actually require heat fluxes significantly greater than zero to ignite). Similar difficulties were not encountered using the treatments of Janssens or Quintiere. Part of the poor performance of this method may be because, instead of lumping all losses into a single, empirical heat loss term, Delichatsios explicitly treats re-radiation but sets the convective heat loss term to zero. Actual convective heat loss is generally not negligible. Spearpoint[306] offered a method which does take into account both convective and radiative losses, but solves an approximate heat transfer equation by forcing the temperature distribution within the solid to obey a parabolic distribution. Moghtaderi et al.[21] presented a method where the value of T_{ig}, instead of being assumed constant is treated as a variable which is dependent on the irradiance. Experience does not exist with the Spearpoint and Moghtaderi methods apart from the authors' own.

North[89] suggested that if no test data are available, for thick materials the ignition time (s) can be estimated knowing only its room-temperature density ρ (kg m^{-3}):

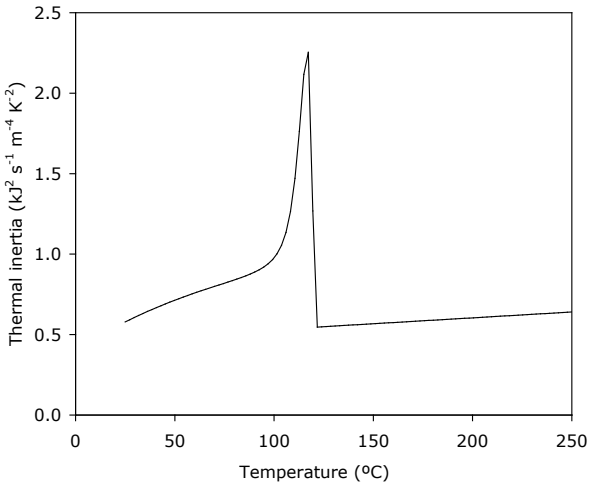

Figure 23 The actual thermal inertia for medium-density polyethylene
(Courtesy J. Staggs and R. Whiteley)

$$t_{ig} = 113 \frac{\rho}{\dot{q}''^{2}_{e}}$$

where t_{ig} = ignition time (s), ρ = density (kg m^{-3}), and $\dot{q}''_e$ = heat flux (kW m^{-2}). For a series of 13 building products tested at heat fluxes in the range of 20 – 75 kW m^{-2}, the formula showed typical errors of 20%, but in extreme cases the errors were up to 200%. The formula, of course, does not take into account variations in T_{ig} among materials, nor factors such as the presence of fire retardants or the effects of the latent heat of phase changes (e.g., melting substances). The formula also cannot predict the minimum flux for ignition, and inserting heat flux values lower than the minimum will give spurious answers. Consequently, heat fluxes lower than ca. 20 kW m^{-2} should not be used in the formula.

Other rough-estimating models have been proposed requiring that the user additionally supply values of thermal conductivity and heat capacity, or that values be provided at some elevated temperature. Since measuring the ignition time in the Cone Calorimeter is simpler than determining these additional properties, methods of that type may not offer much advantage.

RELATION BETWEEN MINIMUM AND CRITICAL FLUXES

Delichatsios et al.[90] proposed that the relation between minimum and critical fluxes should be:

$$\dot{q}_{cr} = 0.7\, \dot{q}''_{\min}$$

To examine whether this relation has enough predictive accuracy to be useful, the results of Babrauskas (Table 8) and Thomson (Table 9) are compiled in Table 7[*]. The average ratio $\dot{q}''_{cr} / \dot{q}''_{\min}$ is 0.4, not 0.7. The range is 0.11 to 0.68, thus even the highest experimental value for the ratio is smaller than Delichatsios' theoretically predicted value. The actual data show that the relation varies substantially and is not a universal constant, nonetheless, for very rough estimating purposes $\dot{q}''_{cr} / \dot{q}''_{\min} \approx 0.4$ might be used. Or, since $\dot{q}''_{cr}$ is more likely to be known than $\dot{q}''_{\min}$, estimation on the basis of $\dot{q}''_{\min} / \dot{q}''_{cr} \approx 2.4$ could be used.

ENGINEERING TREATMENTS FOR THERMALLY THIN SOLIDS

Conceptually, *thermally thin* means responding to heat in such a way that the entire object is being heated to a single temperature. For this to occur, objects need to be physically thin, or have high thermal conductivities (e.g., metals), or both.

Most building products behave as thermally thick materials. Thermally thin materials would include draperies, curtains, decorative bunting and paper decorations, and clothing items. The layman is likely to think that materials such as wallpaper are also 'thin.' This, of course, is true only prior to its being mounted on the substrate. When wallpaper glued on to plaster, for example, responds to heating, it responds as a thick material, since heat flows into the substrate and such a substrate does not rapidly equilibrate to a single temperature.

Table 7 A comparison of the ratio of critical to minimum flux

Code	$\dot{q}''_{\min}$ (kW m^{-2})	$\dot{q}''_{cr}$ (kW m^{-2})	Ratio $\dot{q}''_{cr} / \dot{q}''_{\min}$
PU	13	3.08	0.24
PMMA	8	3.33	0.42
WP	10	3.36	0.34
LD	8	5.44	0.68
CB	12	7.83	0.65
PE	17.5	8.7	0.50
PMMA (PX)	10.6	4.3	0.41
PMMA (FIN)	9.5	4.7	0.50
POM	11.5	2.2	0.19
PP	11.3	1.2	0.11
PS	14	7.1	0.51

The boundary conditions to be considered for thermally-thin objects can be more diverse than those needed to understand thermally-thick ones. For a thermally-thick object, most cases of interest are covered by assuming that the initial object temperature and the initial environment temperature are identical. Furthermore, the object is heated only from one face since the back face is, by assumption, 'infinitely' far away. A thermally-thin object, however, will be exposed on both sides to *something*, and those conditions need not necessarily be identical. In fact, there can be a very diverse collection of front/back boundary condition combinations. For practical work, however, it is sufficient to consider three:

1) the front face is exposed to a radiant heat flux and also undergoes convective cooling and re-radiation; the back face is perfectly insulated (adiabatic).
2) the front face is exposed to a radiant heat flux and also undergoes convective cooling and re-radiation; the back face undergoes convective cooling and re-radiation.
3) the front and the back faces are exposed to identical radiant heat flux and also undergo convective cooling and re-radiation.

In terms of fire incidents, the different boundary conditions can be exemplified in fabric fires. If a person's coat catches fire, and he is wearing several additional layers of clothing underneath, then condition #1 may be approximated. If one side of a room-divider curtain is ignited from a high-power floodlight, while the back side of the fabric is exposed to air, condition #2 will pertain. If a girl tries jumping over a bonfire and misses, the hem of her dress may be exposed to

[*] It must be noted that Delichatsios was working with curve fits of $t^{-0.5}$ power, whereas we adopt Janssens' recommendation of $t^{-0.55}$ power; the above conclusions would change little if replotted to the –0.5 power.

flames fairly evenly from both faces; thus, condition #3 would apply.

CONDITION 1—BACK FACE INSULATED

The theoretical formulation that leads to a simple solution is where the front face boundary condition includes radiation and convection, but the re-radiation term is lumped into an effective convection term, represented by the heat transfer coefficient h_{eff}:

$$2r\rho C\frac{\partial T}{\partial t}=\alpha_s\dot{q}''_e-h_{eff}\left(T_{ig}-T_o\right)$$

where $2r$ is the slab thickness (m). Note that the thermal conductivity λ does not enter this equation. The initial condition is $T = T_o$ at $t = 0$. The solution for the front face temperature is:

$$T_{ig}-T_o=\frac{\alpha_s\dot{q}''_e}{h_{eff}}\left[1-\exp\left(-\frac{h_{eff}t}{2r\rho C}\right)\right]$$

The solution can also be obtained explicitly giving the ignition time:

$$t_{ig}=\frac{2r\rho C}{h_{eff}}\ln\left[\frac{\alpha_s\dot{q}''_e}{\alpha_s\dot{q}''_e-h_{eff}\left(T_{ig}-T_o\right)}\right]$$

For cases where the external radiant flux dominates over convection, the logarithm term can be approximated in a series expansion:

$$t_{ig}\approx 2r\rho C\frac{(T_{ig}-T_o)}{\alpha_s\dot{q}''_e}\left\{1+\frac{(T_{ig}-T_o)}{2\alpha_s\dot{q}''_e}h_{eff}+\ldots\right\}$$

and taking $(T_{ig}-T_o)h_{eff}/2\alpha_s\dot{q}''_e<<1$, this gives:

$$t_{ig}\approx\frac{2r\rho C}{\alpha_s\dot{q}''_e}\left(T_{ig}-T_o\right)$$

This expression suggests the roles of the major variables, but does not give a realistic solution, since it implies that ignition will occur at a heat flux that is only infinitesimally greater than 0. In a similar effort to model the extremely-high radiant flux case, Simms[91] correlated data for radiant autoignition of thin, cellulosic solids subjected to short pulses of extremely high intensities, such as may be expected from nuclear bombs. For $\dot{q}''_e >>$ 100 kW m^{-2}, his data follow the relation:

$$t_{ig}=\frac{2400r\rho}{\dot{q}''_e-110}$$

where r = half-thickness (m).

Janssens[75] obtained numerical solutions and found that, when t_{ig}^{-1} is plotted as a function of $\dot{q}''_e$, most of the data range can be represented by a straight line (Figure 24). The straight line has the following equation:

$$\dot{q}''_e=0.97\dot{q}''_o\left[0.53+\frac{2r\rho C}{h_{eff}t_{ig}}\right]$$

where $t_o=\frac{4r\rho C}{h_{eff}}$, $\dot{q}''_{cr}$ is the x-axis intercept of the straight line, and $\dot{q}''_o$ is the x-value that corresponds to t_o. To obtain the appropriate straight line from the experimental data points, only data points where $t_{ig} \le t_o$ are to be plotted. To illustrate the scope of data that might be included, consider a cellulose paper sheet of 0.5 mm thickness ($2r$ = 0.5 10^{-3} m), density ρ = 600 kg m^{-3}, and heat capacity C = 1200 J kg^{-1} K^{-1}. Then if h_{eff} = 30 W m^{-2} K^{-1}, the criterion is evaluated as t_o = 24 s. Thus, only data points for $t_{ig} \le$ 24 s (or, $1/t_{ig} >$ 0.042 s^{-1}) should be plotted. Now, the effective thermophysical properties contained in the expression for t_o will not be known *a priori*, thus, empirically one would use data points that fall in a straight line, but omit those at the low end that deviate downwards.

The reason for omitting from the data correlation the points at large ignition times is that, theoretically—unlike in the thermally-thick case—data points will not follow a straight line down to the x-axis intercept. Instead, for values of $t_{ig} > t_o$, the curve is approximated as a straight vertical line, as indicated in Figure 24. Janssens showed that the value of $\dot{q}''_o = 1.96\dot{q}''_{cr}$, and it can be taken that $\dot{q}''_{\min} \approx \dot{q}''_o$.

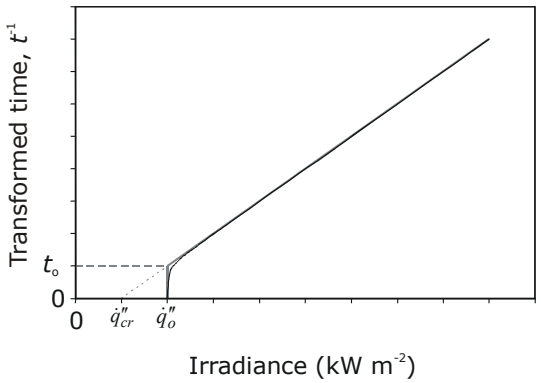

Figure 24 The relation between ignition time and heat flux for thermally thin materials

Thus, having found by data plotting the value of $\dot{q}''_{cr}$, the value of $\dot{q}''_o$ is known. Then, using

$$\dot{q}''_o=\frac{h_c}{\alpha_s}\left(T_{ig}-T_o\right)-\sigma\left(T_{ig}^4-T_o^4\right)$$

the value of T_{ig} can be found. Given that, h_{eff} is solved for as:

$$h_{eff}=h_c+\frac{\alpha_s\sigma\left(T_{ig}^4-T_o^4\right)}{\left(T_{ig}-T_o\right)}$$

There remains the as-yet unknown material property ρC. This is obtained as:

$$\rho C=\frac{1.03h_{eff}B_{ig}}{2r\dot{q}''_o}=\frac{0.53h_{eff}B_{ig}}{2r\dot{q}''_{cr}}$$

where, in parallel with the thermally-thick case, B_{ig} is defined as 1/slope of the straight line.

With the development above, Janssens' thermally-thin procedure becomes:

1. Obtain a series of ignition times at varying heat fluxes.
2. Plot t_{ig}^{-1} on the y-axis, as a function of $\dot{q}_e''$ on the x-axis. Note that the units for the x-axis are to be (kW m^{-2}).
3. Fit a straight line to the data points and determine the critical irradiance $\dot{q}_{cr}''$ as the x-axis intercept. Do not fit the line to any points at the small-flux end of the scale that deviate below a straight line.
4. Evaluate the slope of the straight line. The inverse of slope is defined as a constant, B_{ig} :
$$B_{ig} = \frac{1}{\text{slope}}$$
5. Find $\dot{q}_o''$ from $\dot{q}_o'' = 1.96\dot{q}_{cr}''$.
6. Obtain T_{ig} by a trial-and-error solution of the relationship:
$$\dot{q}_o'' = \frac{h_c}{\alpha_s}\left(T_{ig} - T_o\right) + \sigma\left(T_{ig}^4 - T_o^4\right)$$
7. Solve for h_{eff} using :
$$h_{eff} = \frac{\alpha_s \dot{q}_o''}{(T_{ig} - T_o)}$$
8. Compute the apparent ρC as:
$$\rho C = \frac{1.03 h_{eff} B_{ig}}{2r\dot{q}_o''}$$

There are few experimental studies in the literature where thermally-thin solids were exposed with the use of the adiabatic back-face condition. Thus, data to test the theory directly are lacking.

CONDITION 2—BACK FACE COOLED

Qualitatively, this condition represents a body with the same heat input as for Condition #1, but with 2 the heat losses, since the losses now occur from both faces, instead of just one. In practice, neither the convective loss nor the radiative loss will be the same from the back face as from the front face. There are no known experimental studies where an attempt would have been made to quantify these differences. Thus, a practical treatment is to assume that the back faces losses are identical to those at the front. Then use can be made of Janssens' solution for the adiabatic-back-face case by realizing that the identical heat balance equation will be obtained if, instead of doubling the heat losses, the values of $\dot{q}_e''$ and $2r$ that are used are fictitious values, equal to ½ the real ones.

Example

Pure-cellulose paper is one of the few thermally thin substances that has been explored to any significant extent. Martin and Alvares[92] have provided data on two thicknesses of blackened cellulose paper, exposed to heat from the front only, with the back face free to lose heat by convection and radiation. For the 0.5 mm thick paper, the following ignition data were obtained:

Flux (kW m^{-2})	37.0	38.5	38.3	34.7	41.2	43.3	44.7	
Time (s)	40.6	35.6	33.5	33.4	25.6	25.8	23.8	
Flux (kW m^{-2})	48.2	49.7	46.2	49.9	53.1	68.7	87.7	98.1
Time (s)	22.9	22.3	22.4	19.0	17.7	11.3	7.8	7.0

Find the effective thermal properties of this material.

Solution. The data points to be plotted are the following:

Flux	37.0	38.5	38.3	34.7	41.2	43.3	44.7	
1/*t*	0.025	0.028	0.030	0.030	0.039	0.039	0.042	
Flux	48.2	49.7	46.2	49.9	53.1	68.7	87.7	98.1
1/*t*	0.044	0.045	0.045	0.053	0.057	0.089	0.128	0.143

with the flux plotted on the x-axis and 1/*t* plotted on the y-axis. When the data are plotted (Figure 25), the point at 37 kW m^{-2} appears to be an outlier and is excluded. The remaining points are used in the data fit. The fitted straight line has a slope of 0.00191, giving B_{ig} = 525, and an x-axis intercept of 22.6 kW m^{-2}. To obtain values pertinent to the present case of non-adiabatic back face, the heat flux scale must be divided by ½. Thus, the x-axis intercept becomes 11.3 kW m^{-2}, the slope = 2×0.00191 = 0.00382, and B_{ig} = 525/2 = 263. According to Janssens' scheme, the minimum heat flux is computed as 1.96×11.3 = 22.1 kW m^{-2}. Using h_c = 0.013 kW m^{-2} K^{-1} and α_s = 0.96, T_{ig} is computed by trial-and-error, as 735 K = 462ºC. The value of h_{eff} is computed as 0.0481 kW m^{-2} K^{-1}. Finally, using the value $2r$ = 0.5×10^{-3} m, ρC is computed as 1486 kJ m^{-3} K^{-1}. The room temperature value for cellulose paper is $\rho C \approx 600 \times 1.200$ = 720 kJ m^{-3} K^{-1}.

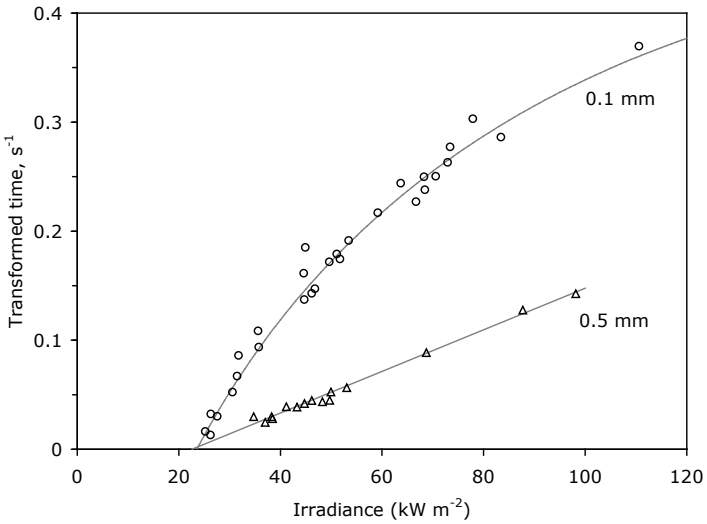

Figure 25 Thermally-thin material—blackened cellulose paper of two thicknesses

As far as $\dot{q}''_{\min}$ is concerned, it will be found that its value is about 2× of that for a thermally thick solid. This is because, roughly speaking, there is twice the amount of cooling available per unit frontal area of solid.

When materials of the same chemical composition, but different thicknesses or densities are encountered, Janssens' governing equation can be re-stated as:

$$\frac{W}{t_{ig}} = A\left(\dot{q}''_e - \dot{q}''_{cr}\right)$$

where $W = 2r\rho$ = the material's mass per unit area or 'basis weight' (g m^{-2}), and A and $\dot{q}''_{cr}$ are constants to be determined empirically. For practical purposes, it is generally much more useful to use W, rather than attempting to separately determine $2r$ and ρ, both of which are difficult to measure for thin materials. The data of Rangaprasad[93] on piloted ignition of off-white cotton fabrics, exposed vertically to flame radiation on one side and to room air on the back face, are plotted according to this procedure in Figure 26. A very good correlation with no systematic deviations is found for fluxes up to 100 kW m^{-2}. At higher fluxes, the ignition times are very short and most likely the deviations are due to difficulties in providing an instantaneous 'turn-on' of the exposure. For these data, the values obtained are $A = 0.744$ g kJ^{-1}, $\dot{q}''_{cr}$ =13.1 kW m^{-2}.

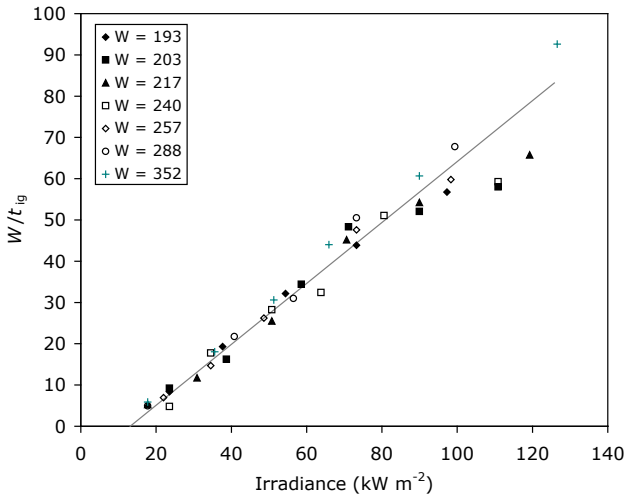

Figure 26 Ignition from flame radiation (single-sided heating, back-face cooled) of cotton fabrics of various weights

CONDITION 3—BACK FACE ALSO HEATED

When the specimen is subjected to heating on both faces (condition #3), by symmetry no heat can flow across the mid-thickness of the specimen. Thus, the mid-thickness is an adiabatic plane. Condition #1 represents a specimen with imposed heat flux on one face and the second face adiabatic. Thus, condition #3 can be represented by the same equations as condition #1, but with the real thickness being $4r$ instead of $2r$.

OTHER ISSUES FOR THIN SLABS

The engineering models for the ignition of thin solids are typically purely-thermal in character, that is, only the time for the temperature to rise to a given T_{ig} is tracked. A thin solid can be readily raised to a high temperature, so this would suggest that thin fuels would always ignite at low $\dot{q}''_{\min}$ values. But experimentally, this does not always occur. For example, Hilado and Brauer[94] reported on a series of fabrics exposed to radiant heating. In many cases, specimens did not ignite at notably high fluxes: 58 – 105 kW m^{-2}. The materials showed smoking and charring early in the exposure period, but ignited late or not at all. Behavior of this kind can be attributed to *fuel exhaustion*. Chemically, the reaching of a specific T_{ig} is merely a correlational indicator of reactions taking place, it does not guarantee that a reaction will actually take place. If there does not exist any location where the fuel-air mixture has reached its LFL and where an ignition source is also present (or, a location with high enough temperatures for autoignition), then ignition will not occur, despite high temperatures elsewhere in the system.

ILLUSTRATIVE DATA

An assortment of data obtained using the Cone Calorimeter are shown in Figure 27 (thermally-thick specimens) and Figure 30 (thermally-thin specimens). The specimens represented are identified in Table 8. The data are from Babrauskas and Wetterlund[95] except CB which is from Grant and Drysdale[79]. The minimum flux for ignition was determined by trial and error, using steps of 2 kW m^{-2}. For example, PMMA ignited at 9 kW m^{-2} but did not ignite at 7 kW m^{-2}; thus its $\dot{q}''_{\min}$ is 8 kW m^{-2}.

Some additional data[96] on solid plastics are given in Figure 28 and Table 9. The materials were all 6 mm thick. It can be noted that the –0.55 power law representation fits most of the data very well, with the exception of the lowest point of PMMA (FIN). The authors repeated their study in the ISO 5657 rig[97] and a comparison of the results is shown in Figure 29. Data obtained in the ISO 5657 test does not show an anomalous data point, but there is a modest systematic difference between the two rigs, with ignition times being slightly lower in the experimental rig. While both apparatuses used a radiant electric heater, numerous other details were different, so a unique reason is hard to assign for the difference.

Table 10 showed that for a number of plastics the effective value of thermal inertia that is pertinent to the whole temperature excursion from T_o to T_{ig} is about 2.7× the value at room temperature. Additional data for wood are shown in Table 11[21]. The effective $\lambda\rho C$ was found to be roughly 1.9× the value at room temperature. Findings of this kind seem to be quite plausible, since thermal conductivity is a strongly-increasing function of temperature. For instance, between room temperature and 300ºC, the thermal conductivity of wood increases[98] by about 3.5×, while that of PMMA increases over 10 .

COMPOSITE MATERIALS

When composites contain a thin combustible face backed by a thick layer of another material, it may not be evident whether ignition data will follow thermally-thin, thermally-thick, or some unique trend. Upholstered furniture often consists of a composite comprising a layer of fabric atop a thick layer of polyurethane foam. Ignitability plots of two different furniture composites are shown in Figure 30. Note that the AC series is almost perfectly fitted to the t^{-1} power. The other series, CO, is also well fitted to t^{-1}, with the exception of the two lowest points, which are slightly above the curve-fit line. It can be readily shown that furniture composites do *not* show a good fit when thermally thick fitting is attempted. The reason is that the ignition behavior is dominated by the fabric alone. The density of the foam layer behind is so much lower than the fabric density, that during the ignition period the foam simply acts as thermal insulation.

If a thin combustible layer is attached to a high-density non-combustible substrate, the opposite result may be found—the data correlate as thermally thick, not thermally thin. Janssens has illustrated this for paper-faced gypsum wallboard (see Chapter 14), which correlates as a thermally-thick material, despite the fact that the only combustible component is the thin paper facing. He also found that the slope of the line reflects the thermal inertia of gypsum, not paper. Composites of this type are likely to show $\dot{q}''_{\min}$ values which are significantly higher than $\dot{q}''_{cr}$. The elevated values of $\dot{q}''_{\min}$ occur since the amount of fuel present in the thin layer is so low that at lower heat fluxes the fuel gets exhausted before the surface temperature can reach to an ignition value.

CRITERIA FOR DISTINGUISHING THERMALLY THICK VERSUS THIN MATERIALS

To distinguish thermally thin and thermally thick materials rigorously requires knowing their thermal properties (λ, ρ, C) along with the heating and geometry conditions. For a 1-dimensional slab, a *thermal penetration depth* can be defined as the thickness of the specimen which has been heated to a certain temperature. An expression for thermal penetration depth δ_p that is sometimes used is:

$$\delta_p \approx 4\sqrt{\alpha t}$$

The numerical factor is quite arbitrary. The factor of 4 comes from solving the heat transfer problem for the case of a fixed surface temperature being imposed and defining the penetration depth to occur at the place where the temperature rises to 0.005 of the surface temperature rise[99]. Choosing such a tiny temperature rise creates an exceedingly conservative criterion. A more appropriate factor was suggested by Chomiak:

$$\delta_p \approx \frac{2}{\sqrt{\pi}}\sqrt{\alpha t} = 1.13\sqrt{\alpha t}$$

A similar expression was offered by Dusinberre[100]:

$$\delta_p \approx 1.2\sqrt{\alpha t}$$

Table 12 Minimum estimated fluxes to comprise thermally-thick samples, for the data of Ngu

Type	Minimum flux (kW m^{-2})	
	20 mm	40 mm

Macracarpa	15.5	8.3
Monterey pine	13.6	7.9
Rimu	17.0	8.9
MDF	21.8	10.9
plywood	15.2	7.6

Since the elevated temperature zone progressively penetrates the solid after the start of exposure, the thermal penetration depth increases with exposure time t. Thus, all materials start behaving as thermally thick the instant that they are exposed to heat, then behave as thermally thin at infinite time. For the ignition problem, however, the value which is important is the thermal penetration depth at the time of ignition: products can be considered thermally thick if the penetration depth at the time of ignition does not exceed the thickness. Products *exposed to heating from both sides* are thermally thick only if δ_p is less than ½ of the value computed from the above formulas which assume single-sided heating.

A useful rule of thumb is that products of $\leq$ 1 mm thickness will be thermally thin; products thicker than about 20 mm will be thermally thick, unless they are foams. The response of foams varies a great deal according to their melting or charring characteristics and no simple generalization is likely to be adequate. For products falling in between 1 mm and 20 mm, a more detailed examination should be made. A suggested guideline for wood products to be considered thermally thick is[101]:

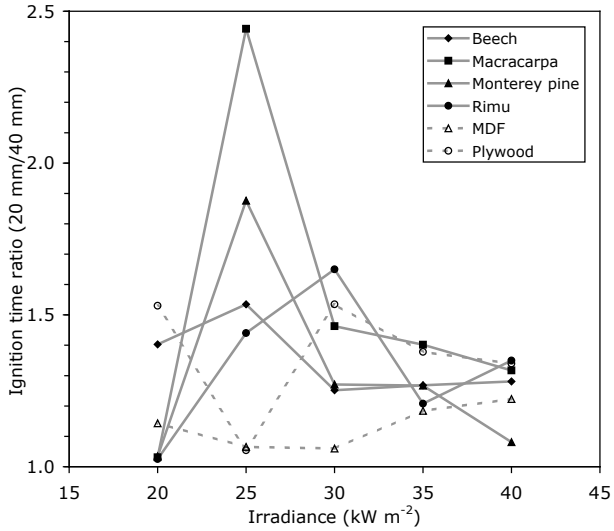

Figure 31 Effect of thickness for various woods tested by Ngu (each test condition represents the average of 5 test results)

$$2r > \frac{0.6\rho}{\dot{q}''_e}$$

where $2r$ = thickness (mm), ρ = density (kg m^{-3}), and $\dot{q}''_e$ = irradiance (kW m^{-2}). As an example, for a density of 310 kg m^{-3}, the prediction is that 6 mm wood samples will behave in a thermally-thick manner at heat fluxes greater than 31 kW m^{-2}. But the formula is not always obeyed, for reasons which are not entirely clear. Akita[271] ran tests on Japanese cedar boards of this density and found that thermally-thick behavior was seen down to 25 kW m^{-2}, the lowest heat flux used. Ngu[102] tested a number of wood types in the ISO 5657 apparatus. These results, shown in Figure 31, imply that even 20 mm samples are not quite thermally thick at 40 kW m^{-2}, yet the estimating formula would predict (Table 12) that thermally-thick behavior should be seen at fluxes less than half of that.

GENERAL AND INTERMEDIATE-THICKNESS MATERIALS

By 'thermally thick,' we mean a substance, in which when exposed to a heat flux on its front face, appreciable temperature rise has not yet occurred on its back face. Conversely, 'thermally-thin' means that, at a given instant, the back face is a temperature which is close to that of the front face. From this elementary consideration, it is clear that the classification is not absolute: at very high heat fluxes, all substances are effectively thermally thick, while at very low heat fluxes, all are thermally thin. A categorical classification becomes sensible only when it is understood that the range of heat fluxes of interest in accidental fires is relatively small, with the bulk of interest being centered on fluxes in the range of 35 – 100 kW m^{-2}. A certain attention also has to be paid to the minimum flux for ignition, which for common building products may be in the range of 10 – 20 kW m^{-2}.

Thus, there will be thicknesses of products where, in the crucial 35 – 100 kW m^{-2} range, at the time of ignition the back face temperature will be roughly halfway between ambient and front face temperature. For engineering purposes, we can identify these as 'intermediate thickness' products. Mikkola and Wichman studied such possibilities[103] and recommended that, for intermediate-thickness products, plots against $t^{-2/3}$ be made; however, they did not give rules for assigning products into the intermediate-thickness category. Much earlier, Lawson and Simms[12] tested various woods of a 19 mm thickness and also concluded that a $t^{-2/3}$ law gave the best representation. But their own data showed substantial deviations from straight lines when thus plotted, so their conclusion was hardly a robust one. Janssens[75] evaluated the possibility of plotting data according a $t^{-2/3}$ law, but found that the results do not yield useful material thermophysical properties. Thus, he recommended that a $t^{-0.55}$ relation still be used, but that only points at the high flux end of the scale be used in fitting a straight line.

Table 13 Cone Calorimeter ignition results obtained at NRCC

Material	Thick. (mm)	Density (kg m^{-3})	Ignition time (s) at flux

Thick. (mm)	Ignition time (s), at a given heat flux (kW m^{-2})					
	15	20	30	40	50	70
2		83±15	32±6	23±4	16±3	
6		285±25	54±7	36±5	14±4	10±3
37	2070±150	470±70	63±10	29±4	16±3	8.5±1.5

Bamford et al.[7] tested panels of an unidentified softwood species, exposed to flames on both sides. On the basis of testing specimens 11 – 51 mm thick, they proposed an empirical formula for ignition time which includes a thickness variable. Their experimental results, however, were anomalous and their proposed scaling relation was mathematically incorrect, since they proposed that the ignition time should be proportional to L^2, where L = specimen thickness. In fact, for thermally thick specimens, the thickness can play no role, while for thermally-thin specimens, the ignition time must be proportional to L, not L^2.

Koohyar[73] tested wood panels of intermediate thicknesses (12 – 19 mm), exposed both from a single side and from both sides. Based on his results, he offered several empirical correlations, which can be expressed as $t_{ig} \propto L^{-n}$. Since in these correlations n ranges from 0.13 to 2.0, they are evidently unphysical, since thicker specimens take a longer time, not shorter, to ignite. At the same laboratory, Wesson[104] later obtained ignition data on oak specimens of various thickness, exposed to tungsten lamp radiation. His results (Figure 32) sensibly show that the thinner specimens do ignite more rapidly, but the data have a large amount of scatter. From these results, along with those for other wood species, Wesson et al.[105] concluded that over the heat flux range 25 – 146 kW m^{-2} wood materials are thermally thick if the thickness is 20 mm or greater. For thinner specimens, they proposed the relation:

$$t_{ig} = \frac{35\rho^{0.9}\left[erf\left(\sqrt{\frac{\rho C_p L^2}{4\lambda t_{ig}}}\right)\right]^{1.2}}{\left(\alpha_s \dot{q}''_e\right)^{2.8}}$$

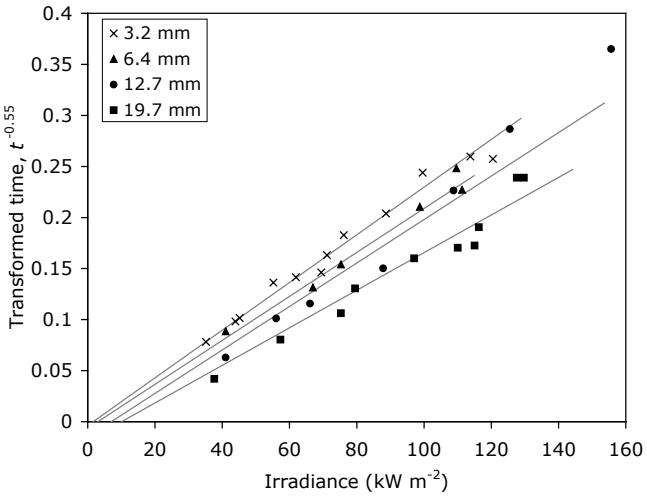

Figure 32 Effect of thickness on the ignition of oak specimens using tungsten-lamp radiant heating

This relation is not particularly satisfying, since t_{ig} shows up on both sides of the equation and, thus, only an iterative solution is possible.

More recent studies[106] were done at NRCC where the Cone Calorimeter was used (Table 13). Standard procedures (electric spark piloting, lightweight fiber blanket substrate) were used. For the irradiances examined, clearly the whole-wood samples show a thickness effect below 5 mm; the results on plywood, however, suggest that for thicknesses greater than 6 mm, any thickness effect is below the repeatability level of the material.

Additional data were obtained by Mikkola[107], who tested spruce specimens of 440 kg m^{-3} and 10% moisture content in the Cone Calorimeter. His results, shown in Table 14, indicate that:

- At heat fluxes of 50 kW m^{-2} or greater, there is no statistical difference even between 2 and 37 mm panels.
- At heat fluxes of 30 – 40 kW m^{-2}, results for 6 – 37 mm panels are indistinguishable, but 2 mm panels ignite quicker.
- At a heat flux of 20 kW m^{-2}, even the 37 mm panel becomes thermally thin.

These are probably the most reliable results so far, and properly verify that the thermally thin/thick breakpoint thickness increases with rising heat flux.

Table 15 Minimum thickness for wood specimens to be thermally thick

Min. thickness to be thermally thick (mm)	Heat flux (kW m^{-2})					
	20	**30**	**40**	**50**	**60**	**70**
Rule-of-thumb	13.2	8.8	6.6	5.3	4.4	3.8
Mikkola results	≈20	≈5	≈5	< 2		< 2

Mikkola's results can be compared to predictions from the rule of thumb mentioned above. Table 15 indicates that the rule provides viable estimates at medium heat fluxes, but that the estimated values become quite conservative at heat fluxes > 50 kW m^{-2}.

Table 16 Results of Cone Calorimeter tests on clear PMMA exposed to a heat flux of 50 kW m^{-2}

Thick. (mm)	Ignition time (s)
1.5	15
3	17
10	24
20	25
25	22

Paul[108] reported data on clear PMMA tested at various thickness; his results are given in Table 16. If 24 s is taken as the ignition time for thermally thick material, then the 1.5 mm material ignites about 38% faster. Some data on polyethylene[109] tested at a heat flux of 50 kW m^{-2} indicate that 1 and 2 mm thick samples ignite faster, but that ignition times for specimens of 3 – 10 mm thickness are essentially independent of thickness.

Jacoby[110] tested several materials where both the thickness and the heat flux were varied. His Cone Calorimeter results for a glass-reinforced vinyl ester composite material are shown in Table 17. The substrate used was not the standard lightweight ceramic fiber blanket, but rather a ceramic board with a density of 258 kg m^{-3}. A distinct difference in ignition time between the 1.5 and the 3.0 mm thick samples is seen up to the highest flux used, 90 kW m^{-2}. But ignition time differences become small between the 3.0 and the 8.0 mm thick samples when a flux around 60 – 75 kW m^{-2} is reached.

Table 17 Ignition times (s) for glass-reinforced vinyl ester composites in three different thicknesses

Thick. (mm)	Heat flux (kW m^{-2})								
	20	**25**	**30**	**35**	**40**	**50**	**60**	**75**	**90**
1.5	291	148	95	64	61	44	26	16	18
3.0	450	239	158	103	99	67	53	34	24
8.0	735	382	284	152	163	91	61	43	

According to Janssens[77], the issue of thermal thickness category should be addressed empirically. If it is not clear *a priori* that the product is thermally-thick or thermally-thin, then a curve-fitting procedure should be used where the exponent n is variable, with the limits of –1.0 and –0.5. Thus, in practice, a general procedure can be suggested as follows:

1. Guess whether the product is thermally thick or thin
2. Plot the data using n = –0.55 (or –1.0)
3. Determine if the line is reasonably straight

4. If neither $n = -0.55$ nor -1.0 give a reasonable straight line, conduct a least-squares curve-fit where the exponent n is allowed to vary.

As mentioned above, intuition does not always provide the correct results. As an example, studies on composite shipbuilding panels having a thickness slightly over 30 mm[111], showed that the optimum n was –0.78 (for one type of core) or –1.0 (for a second core type). The large overall thickness might have induced the user to presume that n = –0.55 was the appropriate value. The explanation lies in the fact that the face coverings on these products had a density of about 20 times that of the core material. Thus, the contribution of the core is effectively unseen in the ignition process. Grenier and Janssens[112] provide further illustrations of curve-fitting for composite products which are possibly of intermediate thermal thickness. Dietenberger[84] has presented a method for intermediate-thickness specimens which is essentially an interpolation scheme.

When data are available only at a single thickness which is judged to be 'intermediate,' it is best to realize that any specimen will show thermally-thick results when irradiated with very high heat fluxes and thermally-thin results when heated at a very low rate. Thus, two different plots can be made from the same data, with a straight line being fitted at the high-flux region to a thermally-thin plot (y-axis = t^{-1}), and a straight line being fitted at the low-flux region using a thermally-thick plot (y-axis = $t^{-0.55}$). Data on 6.4 mm thick plywood provided by de Ris and Khan[25] are plotted this way in Figure 33 and Figure 34. (Note that the data were obtained using the FM procedure with blackened specimen face, so there is a systematic bias with respect to the irradiance scale). The authors consider that the thermal-thickness effect is complicated by moisture movement in the sample, which in a thermally-thin sample will more likely leave through the front face and thereby dilute the gas stream.

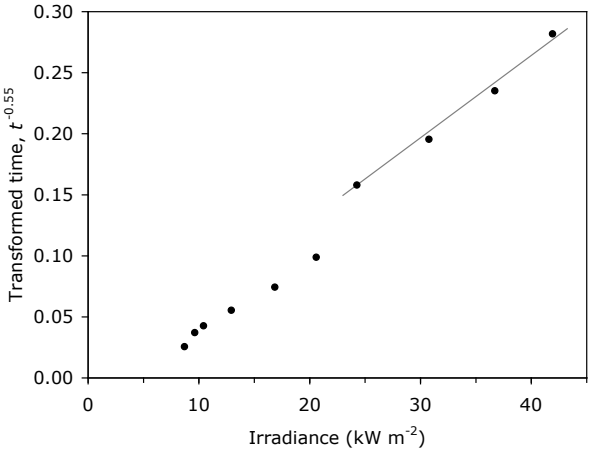

Figure 34 Plywood specimen, 6.4 mm thick: high-flux regime plotted as thermally-thick

ENERGY NEEDED FOR IGNITION

Experimentally, heat flux (kW m^{-2}) is the driving force for ignition. But sometimes it is considered that a substance requires a certain minimum energy fluence (kJ m^{-2}) to ignite (energy fluence is defined as the energy that flowed through a unit surface area). Can the minimum energy fluence be a constant for a substance? If (1) the ignition temperature of the substance were a constant, (2) the substance sustained no heat losses, and (3) it had infinite thermal conductivity, then the answer would be Yes. In such a case, the energy increase occurring during the heating is:

$$Q = \rho L C \Delta T$$

where L is the thickness of the substance and ΔT is the temperature increase from ambient to T_{ig}. But also:

$$Q = \dot{q}'' t_{ig}$$

where $\dot{q}''$ is the heat flux imposed on the specimen. Since none of the three necessary conditions for this simple relation to hold are true for real combustibles, the minimum ignition energy is not a constant and thus is generally not a variable of much utility. To illustrate this, the same materials examined above can be considered for their minimum ignition energy fluence requirements. Figure 35 shows this for thick solids, while Figure 36 illustrates thin solids. For thick solids, the minimum energy decreases with increasing heat flux, although gradually tapering off at higher heat fluxes. It is possible that a plateau might be reached at higher irradiance values than the maximum explored in this work. For thermally-thin specimens, a plateau is reached for irradiances greater than about 35 – 40 kW m^{-2}. The fact that a constant-energy condition roughly holds for thermally-thin bodies at high irradiance could have readily been expected from Janssens' plots. If

$$\left(\dot{q}''_e - \dot{q}''_{cr}\right) \propto t_{ig}^{-1}$$

then clearly $\dot{q}''_e t_{ig} = Q \approx$ constant for $\dot{q}''_e >> \dot{q}''_{cr}$.

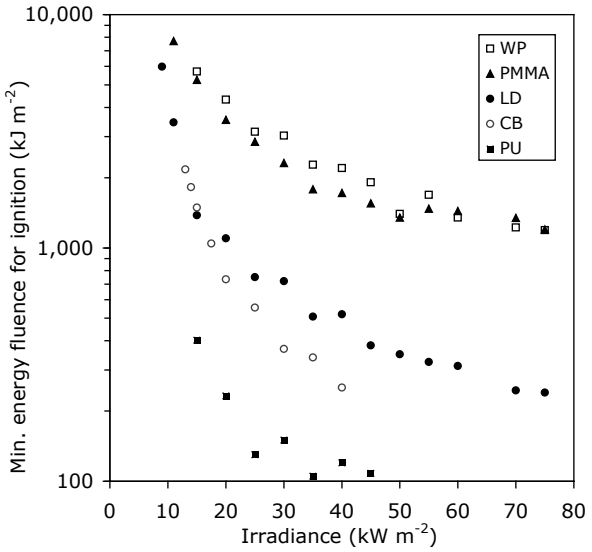

Figure 35 Minimum energy fluence for ignition of some thermally-thick solids

Martin[113] examined this question for thin sheets of cellulose using a carbon arc ignition source. Over a very wide range of high irradiance values (40 – 4000 kW m^{-2}), he found that the minimum ignition energy varied only by a factor of 2.

It must be emphasized that the minimum energy fluence, which is taken as the product of the irradiance × t_{ig}, is only an *apparent* value. The actual energy which enters the body is lower than that which is computed in this simple way, because some of the energy is re-radiation, and also because convective losses occur. There is no simple way to compute the *net* energy that actually entered into the body, thus, calculations requiring this value may not be of practical value. The reason that assuming a constant ignition energy is a fair assumption for thin solids, but a poor one for thick ones is due to the non-uniform temperature distribution which exists within a thick body. For thermally thin bodies, assuming that the entire substance is at a single temperature is a valid assumption, thus at least one of the three requirements outlined above is satisfied.

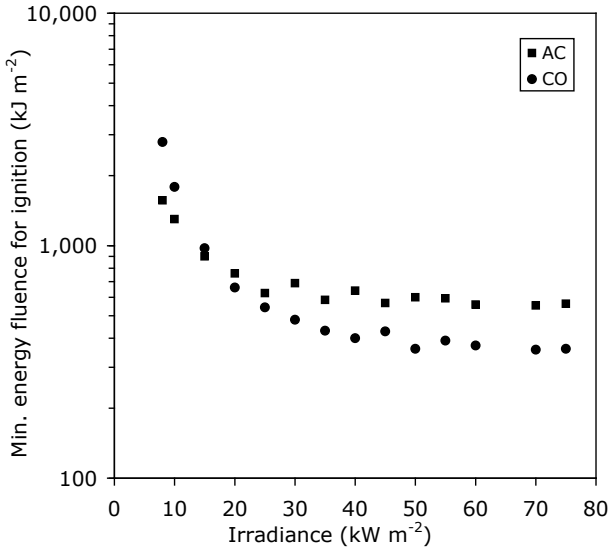

Figure 36 Minimum energy fluence for ignition of some thermally-thin solids

LASER IGNITION

A laser is a high-energy source of electromagnetic radiation in the visible or the infrared portions of the spectrum. Its distinguishing trait, of course, is coherent radiation, which is emitted at one unique wavelength. If the wavelength is one at which a material has substantial absorptivity, then laser energy may cause ignition. Laser ignition has been explored for warfare and is used in industrial processes. Neither of these usages results in significant unwanted fires. However, because lasers are a convenient, precisely controllable source of heating, a large number of ignition experiments have been reported in the literature.

Autoignition. Most laser ignition experiments have been in the autoignition mode. Mutoh et al.[114] exposed 30 mm thick, horizontal PMMA samples to a CO_2 laser beam at the wavelength of 10.6 μm. Lasers cannot heat large-area specimens, and in their experiments the beam diameter was 12 mm. They found that the minimum flux needed for autoignition was 250 kW m^{-2} (Figure 37). Steady-flaming ignition was found for the heat flux range of 250 – 600 kW m^{-2}. For heat fluxes in the range of 600 – 800 kW m^{-2}, only a transient-flaming ignition could be created. The time scale was also notable. Whereas steady ignition took place in ca. 40 s at 600 kW m^{-2}, transient ignition at heat fluxes just slightly greater occurred in only 3 – 4 s. In the same experimental arrangement, the minimum flux for vertical-orientation specimens was 185 kW m^{-2}, with the jump occurring at 340 kW m^{-2}. Also shown in Figure 37 are results from Kashiwagi[15], who exposed 12 mm thick clear PMMA samples and found $\dot{q}''_{min} \approx 160$ kW m^{-2}. In that test series[115], Kashiwagi also reported that $\dot{q}''_{min} \approx 110$ kW m^{-2} for specimens oriented at a 45° angle, and 90 kW m^{-2} for vertical specimens. Mutoh et al. also obtained data in the vertical orientation and found that ignition times were about 5 to 50× shorter than for the horizontal orientation. By contrast, for ignition by typical black-body heat sources, ignition times in the vertical orientation are slightly longer than in the horizontal. This suggests that attenuation of radiation while traversing the pyrolysates plume is a dominant effect with laser radiation, since a much deeper layer must be traversed in the horizontal orientation. However, even with vertical orientation, Mutoh et al. obtained a large value of $\dot{q}''_{min} \approx 180$ kW m^{-2}. For the transient ignition regime, there was essentially no difference between ignition times in the two orientations. This is evidently because transient ignition is primarily a gas-phase phenomenon and differences

in the efficiency of delivering radiation to the surface do not play a major role.

Kashiwagi additionally conducted tests using a gas-fired radiant panel providing 60 kW m^{-2}. Horizontally-oriented samples ignited in about 75 s, while vertically-oriented samples did not ignite at all. Kashiwagi's data indicate that minimum fluxes for autoignition are higher with a laser source than for conventional radiant sources (note that Kashiwagi's determination was not that the minimum flux for ignition with the radiant panel is 60 kW m^{-2}, rather that ignition was possible at that flux; presumably the minimum flux was lower than that). The extraordinarily high minimum heat fluxes found by Mutoh are hard to explain, but suggest that data obtained from laser ignition experiments may not be relevant to building fires. Averson et al.[116] (also shown in Figure 37), did not determine a minimum flux, however their data indicate (a) identical results in horizontal and vertical orientations; (b) no jump. Averson further obtained data for obliquely-upside-down orientations; not surprisingly, longer ignition times were obtained in these orientations.

In later tests[117] Kashiwagi exposed 15 mm thick clear PMMA and found $\dot{q}''_{\min} \approx 90$ kW m^{-2}, in the horizontal orientation, and 100 kW m^{-2} in the vertical. The difference between 160 and 90 kW m^{-2} is substantial, and Kashiwagi considers it may be due to a more drafty environment and a slightly greater beam size (35 mm vs. 30 mm) in the second series.

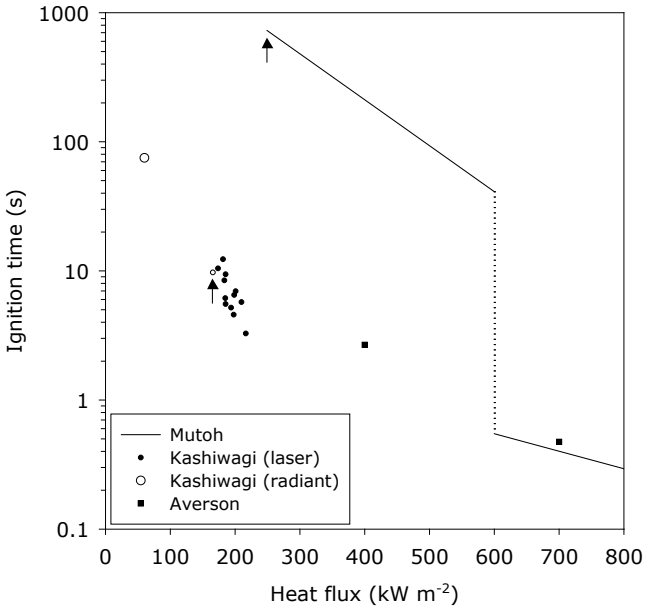

Figure 37 The autoignition of clear, horizontally-oriented PMMA using laser ignition sources (arrows denote minimum flux for ignition)

In his laser exposures, Kashiwagi found that the autoignition temperature for PMMA did not depend on the heat flux, but did depend on orientation, being 400ºC in horizontal and 450ºC in vertical orientation. As can be seen below, these values are at least 100ºC higher than required for piloted ignition. For red oak, he found a very strong dependence on heat flux, with T_{ig} going from 570ºC at 85 kW m^{-2} to 410ºC at 165 kW m^{-2} in the horizontal orientation; in vertical orientation, autoignition temperatures were roughly 80ºC higher.

A study on autoignition of dust layers by focused, high-intensity xenon-lamp radiation has been reported[118]. While not coherent, this radiation source is also very intense and concentrated into a small area. For a variety of dust types, a minimum ignition flux of about 280 kW m^{-2} was found. No comparable data exist for exposures of these substances to conventional radiant heat sources, but the flux value is enormous. Part of the reason for the enormous $\dot{q}''_{\min}$ value might be attributable to the very small heated area used, 3 cm^2. The question why laser ignition is so much different from radiant-panel ignition was indirectly addressed by Hertzberg and Zlochower[119], who studied the mass loss rate of PMMA under radiant-panel and laser heating conditions. They found huge differences between the two sets of results: for example, to obtain an MLR of 10 g m^{-2} s^{-1} required an absorbed radiant flux (incident flux × absorptivity) of about 25 kW m^{-2} with a radiant panel, versus 85 kW m^{-2} using a CO_2 laser. They attributed the differences to (a) the smaller sample dimensions necessary with laser heating, and (b) the indirect effect of higher surface temperatures. Concerning the latter effect, they concluded that the specimen showed T_{ig} values that increase with increasing flux, thus, laser experiments run at high fluxes would intrinsically imply the material is harder to ignite. The authors claimed to have successfully reconciled the two sets of results by calculating the surface heat losses for the two cases, but did not present details to support this.

Piloted ignition. Similarly unusual results are found for pilot-ignition studies with laser sources. Kashiwagi[15] used a CO_2 laser to expose horizontally-oriented samples, with the laser beam providing a heated diameter of 20 – 30 mm on the face of the specimen. He found that 70 kW m^{-2} was the minimum flux for ignition of 12 mm thick samples of clear PMMA (Figure 38). A comparative data point obtained by Thomson[2] using a laser with a 12 mm exposing diameter is also shown. Thomson did not test for the minimum flux, but evidently it was less than 34 kW m^{-2}, which is her data point shown in Figure 38. Also shown are tests done by Thomson using the same specimen material and the same basic experimental rig, but with a radiant heater. It is evident that (1) the slope of the line through Thomson's points is substantially different from that through Kashiwagi's, (2) the *highest* flux used by Thomson was substantially below the *minimum* flux found in the Kashiwagi experiment, and (3) Thomson's ignition time using a laser is about 4 times longer than using a radiant heat source. Thomson speculated that the very long ignition times observed with laser

ignition may be due to certain difficulties that a laser source might create for attaching a weak flame at the surface.

Thomson found little difference in the piloted ignition temperatures for the two types of ignition sources. At a heat flux of 34 kW m^{-2}, the ignition temperature was 320 – 334ºC using the laser source, compared to 305 – 338ºC when igniting specimens of small area with a radiant source (slightly lower values of 306 – 312ºC were obtained when igniting normal-size specimens in radiant-heater ignition tests). Kashiwagi[120], however, obtained different values of T_{ig} for clear PMMA: 360 – 400ºC using a laser source, compared to 280ºC when using a conical radiant very similar to the kind used by Thomson. He attributes this to the fact that his conical heater data were obtained at a low flux of 18 kW m^{-2}, while the laser data were obtained at much higher heat fluxes. But this interpretation must be contrasted to the results of Thomson, who found an extremely small flux dependence for T_{ig}, at least if one leaves aside the question of enormous fluxes, which she did not study. Kashiwagi further considered that the pyrolysis of PMMA has different mechanisms that operate at different temperature regimes, and that this material's chemistry may affect the value of T_{ig} obtained under different heating conditions. Kashiwagi also pointed out that other experiments on the same material indicated that the surface temperature is 390ºC for a sample over which flame is spreading, and is 400ºC for a sample undergoing steady-state burning. Drysdale and Thomson[121] considered that Kashiwagi's high T_{ig} values are unrelated to the nature of the laser radiation, but are simply attributable to the fact that his ignition source was an 0.25 mm platinum wire at 950ºC. As developed in Chapter 4, hot wires are an inefficient form of piloting and some very high temperatures may be needed for ignition to be successful.

It is hard to draw firm and systematic conclusions from studies on laser ignition, apart from the obvious one that the laser ignition mechanism is substantially different from flame or grey-body radiation sources. Consequently, laser-ignition results cannot be intermixed with other types, nor should the results be applied to accidental fires not involving lasers. The following effects may play a role in creating these systematic differences:

(1) Greater attenuation of incident 10.6 μm laser radiation by pyrolysates near the specimen surface than occurs for blackbody radiation which is emitted at shorter wavelengths.
(2) Exposed-area effects, since the exposed area is sometimes very small with laser heating and a smaller exposed area leads to a higher fraction of the heat being lost.
(3) Sample diathermancy effects, since materials may be more diathermanous at 10.6 μm than at the shorter wavelengths characteristic of blackbody sources.

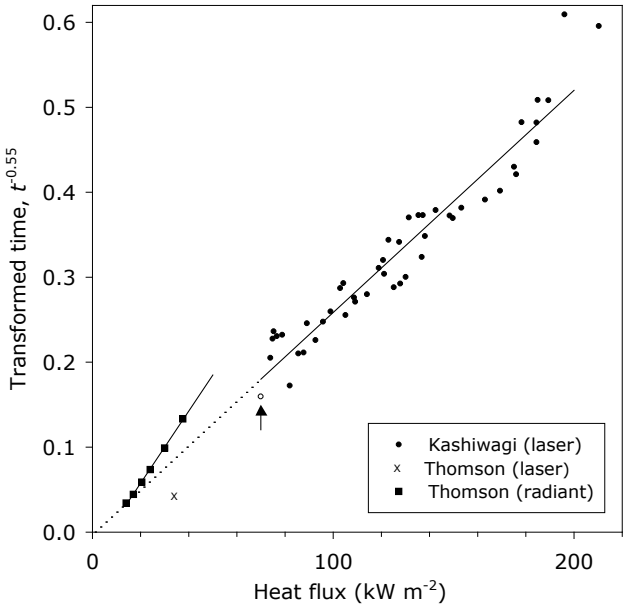

Figure 38 The piloted ignition of clear, horizontally-oriented PMMA (arrow denotes minimum flux for ignition)

(4) Definition of the heat flux used, since the beam from a laser is intrinsically non-uniform (commonly, Gaussian distribution) and it is not clear if the peak, the average, or some other statistic should be considered.
(5) Difficulties in achieving autoignition. The high surface temperatures required for autoignition suggest that there may be gas-phase mixing or autoignition difficulties that are not experienced with other heat sources.
(6) Problems related to rapid turn-off of radiation. Some tests using lasers are run where the beam is turned off after initial ignition, and those results may be influenced by the very rapid rate at which laser radiation can be cut off, which can lead to flame destabilization.
(7) Indirect effects, due to laser experiments commonly being run at much higher heat fluxes than ones using radiant heat sources. The intervening variable here is the surface temperature, which may be higher at very high fluxes, leading to higher surface heat losses and, consequently, a smaller fraction of the incident radiation being available to heat the solid.

Ignition from convective heating or immersion in a hot environment

Until the last few decades, it was most common to study ignition of solid materials by immersing a small specimen into a heated furnaces cavity. The variable being controlled in this type of exposure is the furnace temperature, measured in some arbitrary location. The specimen is heated by a combination of convective and radiative heat flux. Convection—rather than simple conduction—occurs because even if the cavity had no convective currents before the start of test, inserting a cold body into the middle of a hot gas volume will create convective movement. The ASTM

D 1929 test (Setchkin furnace) is the typical example of an environment of this type. The actual convective heat flux is somewhat hard to determine in that environment, and there has not been any research where heat transfer details in the apparatus were probed.

A theoretically more tractable configuration is that of convective heating, where a stream of hot gas with a known velocity and temperature is directed against a specimen. In practice, however, it is hard to arrange this type of heating, since if a high-temperature air stream is being presented to the specimen, there are likely to be equally hot, radiating solid surfaces in the vicinity. Under convective heating, for moderate flow velocities, increasing the velocity simply increases the convective heat flux, and this causes the material to pyrolyze faster and to ignite quicker. Eventually, however, a non-thermal effect comes in: the *residence time* becomes too short for chemical reactions to be completed and this becomes a limit to ignition. The residence time is the time that a molecule has available in an environment where chemical reaction is possible, i.e., where the temperature is high enough. This is sometimes known as a 'Damköhler number effect.' In addition to decreasing the available reaction time, increasing the velocity of the air stream also dilutes the pyrolysates.

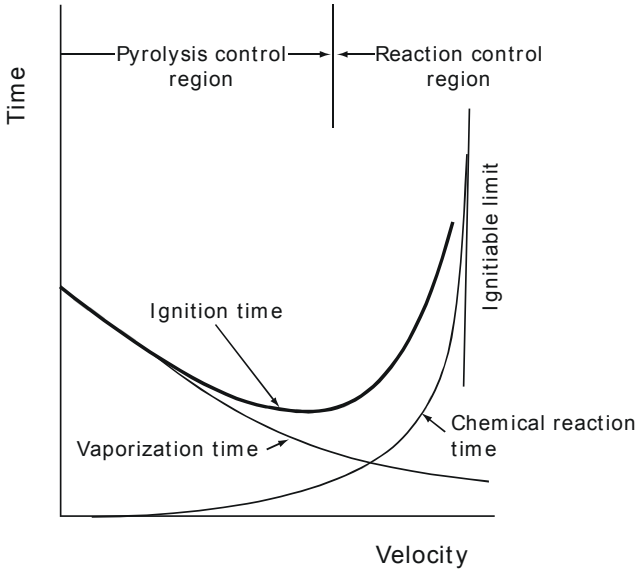

Figure 39 Effect of convective flow velocity on ignition time
(Copyright The Combustion Institute, used by permission)

Niioka et al.[122] illustrated the residence time effect as shown in Figure 39. There is an optimum air flow velocity, and increasing or decreasing it will cause the ignition times to get longer. They also obtained experimental results for several polymers which were configured as hemispherical samples and presented with an impinging-jet flow of heated gas. Figure 40 shows their results for several polymers ignited with an air stream having 60% O_2 and heated to 840ºC (HTPB denotes hydroxyl-terminated polybutadiene). The convective heat flux plotted on the x-axis is the value determined with reference to the specimen's face temperature (20ºC) before its temperature starts rising. For heat fluxes up to 70 kW m^{-2} in the case of PMMA and up to 120 kW m^{-2} for the other two specimens, the ignition time decreases with increasing heat flux. For larger convective heat fluxes, however, the ignition times start rising again. The velocity corresponding to 70 kW m^{-2} was 4 m s^{-1} and for 120 kW m^{-2} it was 10 m s^{-1}. Niioka also showed that for any given gas-stream temperature and oxygen concentration there exists a maximum flow velocity, beyond which ignition is impossible. This maximum velocity increases with increasing gas-stream temperature. Wang and Yang[123] presented some limited data on PMMA spheres, showing that an optimum flow velocity exists and that ignition times get longer for faster or slower flows.

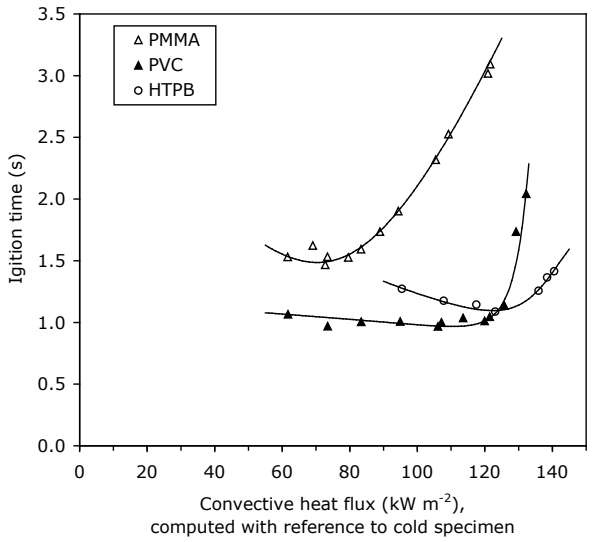

Figure 40 Effective of high flow velocities on convective ignition

Di Blasi et al.[124] studied the autoignition of loosely-packed straw beds (ρ = 50 kg m^{-3}) by subjecting them to a high-temperature air stream. For air stream temperatures below 270ºC, no ignition was obtained. For higher temperatures, increasing the air stream temperature also increased the temperature of ignition, as shown in Figure 41. It may also be that the air stream velocity influences the specimen's T_{ig}, but the effect, if any, was smaller than the data scatter. At a given air stream temperature, ignition times monotonically decreased with increasing velocity. The trends shown in Figure 42 indicate that $t_{ig} \propto u_{\infty}^{-1.2}$. Thus, in the study of Di Blasi et al., an 'optimum' velocity was not found. This is most likely due to two factors: (1) only low ($\leq$ 2 m s^{-1}) velocities were explored, and (2) there may be some peculiarities associated with the material tested, which exhibits a propensity for glowing ignition. Over the range $0.2 < u_{\infty} < 2.0$, their ignition time results can be represented by:

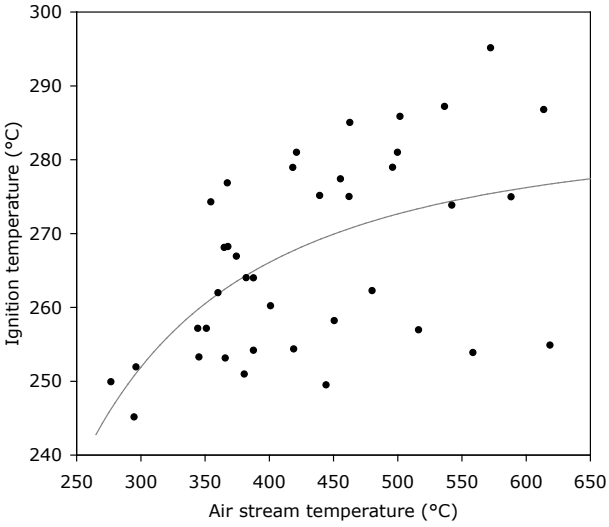

Figure 41 Effect of air stream temperature on the ignition temperature of straw beds

$$t_{ig} = 1.4 \times 10^4 u_\infty^{-1.2} \left(T_g - T_{ig}\right)^{-1.5}$$

however, in view of the limited amount of data collected, this relation should be viewed only as a rough trend.

Akita[125] conducted a convective-ignition study on PMMA samples, independently varying the temperature and the velocity of the hot air stream. Figure 43 shows that the surface temperature at ignition varies with the heating conditions. Using higher velocities requires that higher air-stream temperatures also be used, and this results in a higher surface temperature at ignition. From these results it can be seen that—unlike in radiative ignition—for convective ignition, the heat flux is not a useful data correlating variable, since air stream velocity and temperature affect the results not simply in proportion to the computed heat flux. Akita's results imply that the optimum velocity is very low, below 0.5 m s^{-1}, and this suggests that gas-phase effects militate against a simple inert-solid conceptual model of convective ignition.

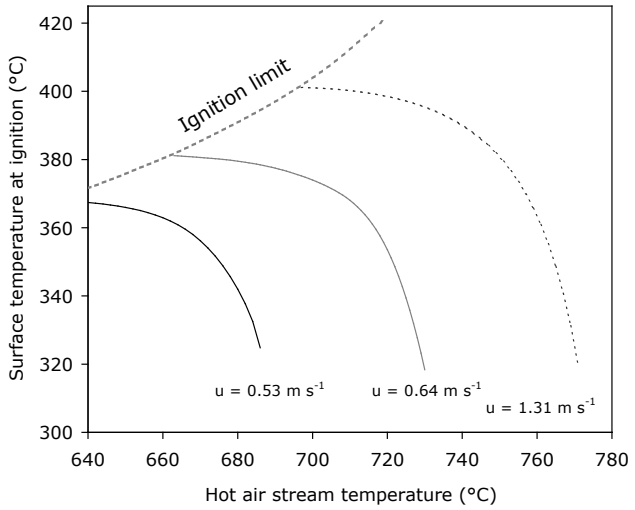

Figure 43 Convective autoignition of PMMA in a hot air stream for three different air-stream velocities
(Copyright Elsevier Science, used by permission)

Convective heating was also used by Clark, who studied the ignition of several polymers[126-128]. In his experiments, he subjected the specimens to the high-temperature products of a very lean H_2/O_2 flame, directed at the specimen in the form of an impinging jet and producing quite low heat fluxes of 11 – 20 kW m^{-2}. Clark found that T_{ig} values for

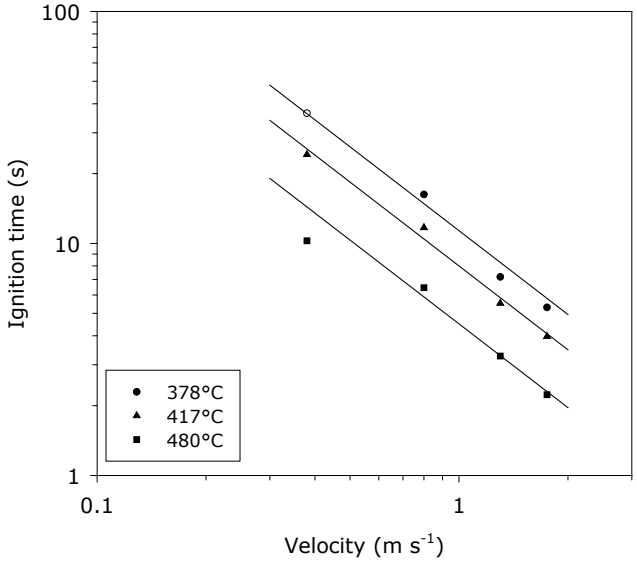

Figure 42 Ignition of straw beds from a hot air stream

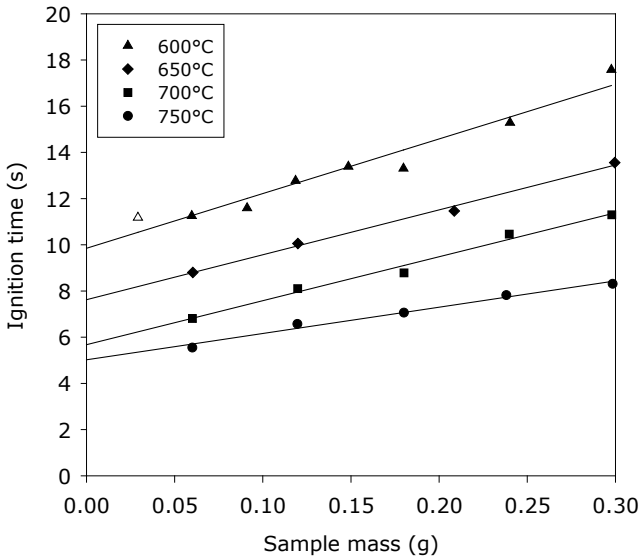

Figure 44 Ignition times for nylon 6,6 specimens

PMMA ranged from 227ºC to 420ºC, depending on temperature/velocity conditions.

Miller and coworkers[16] reported on a study using an apparatus somewhat similar but not identical to the Setchkin furnace to study autoignition of very small specimens. They observed that, for most materials, the ignition time varies linearly with specimen mass (Figure 44). Based on this, they concluded that it is possible to describe a 'characteristic' ignition time which is obtained by extrapolating the mass vs. time data to zero mass. For seven materials tested, this proved to be reasonable for all except polyacrylonitrile (PAN). In the case of PAN, there was no effect of specimen mass on ignition time, except at the lowest temperature examined, 525ºC.

Having obtained 'characteristic' ignition times for each exposure temperature, Miller et al. then correlated the results as shown in Figure 45. As explained by Hertzberg and Zlochower[119], results of this type should not be interpreted to imply that the slope is an activation energy associated with a chemical reaction. The activation energy obtained from the slopes, here typically 35 kJ mol^{-1}, correspond to the energy requirement for a *physical* process* (the gasification of the polymer) and not a chemical one.

IGNITION THEORIES FOR CONVECTIVE HEATING

LUMPED-CAPACITANCE MODEL

The simplest analytical treatment of the convective heat transfer environment is by what is called in heat transfer literature a *lumped-capacitance model*. If a solid body is thin enough, then at any instant it can be assumed that it is all at one temperature, $T_s(t)$, which is a function of time, but not a function of location. By heat conservation,

$$\textit{heat in} - \textit{heat out} = \textit{heat stored}$$

or,

$$2h_{eff}\,S\left(T_g - T_s\right) = \rho V C \frac{dT_s}{dt}$$

where we have assumed that heat transfer occurs over two faces, each of area S (m^2). Other terms are: T_g = gas temperature (K), h_{eff} = effective heat transfer coefficient (W m^{-2} K^{-1}), ρ = density (kg m^{-3}), V = volume (m^3), C = heat capacity (J kg^{-1} K^{-1}). If the thickness is $2r$, then $V = 2rS$, giving

$$\frac{dT_s}{dt} = \frac{h_{eff}\left(T_g - T_s\right)}{r\rho C}$$

The initial condition is $T_s = T_o$, at $t = 0$. With this, the solution can be obtained as[129]:

$$T_s(t) = T_g - \left(T_g - T_o\right)\exp\left[-\left(\frac{h_{eff}}{r\rho C}\right)t\right]$$

The heat transfer solution becomes a solution to the ignition problem, once a specific ignition temperature, T_{ig}, is associated with the temperature of the body at ignition.

$$t_{ig} = \frac{r\rho C}{h_{eff}}\ln\left[\frac{T_g - T_o}{T_g - T_{ig}}\right]$$

In some cases, the values of T_{ig} do not vary greatly for a group of materials being considered. The above relation then shows that $t_{ig} \propto r\rho$. In other words, for thin materials the ignition time should be directly proportional to the mass per unit area (kg m^{-2}) of the material. This has been experimentally shown to be true for fabrics (see Chapter 14).

THERMALLY-THICK SOLID—CONSTANT HEAT FLUX

In some cases, materials are ignited by very hot convective heat streams. If $T_g >> T_{ig}$, then the heat flux remains approximately constant during the heating of the specimen. In that case, the same treatment can be used as is described by Janssens for radiant heating; this type of data treatment was originally proposed by Keller et al.[74].

THERMALLY-THICK SOLID—CONSTANT CONVECTIVE TRANSFER COEFFICIENT

In 1954, Hicks[130] published the first study of this problem. He started with the basic equation:

$$\rho C\frac{\partial T}{\partial t} = \lambda\nabla^2 T + \dot{q}'''$$

where $\dot{q}'''$, the energy of pyrolysis per unit volume, is expressed as:

$$\dot{q}''' = \rho Q A e^{-E/RT}$$

* More precisely, a quasi-physical process. Gasification of liquids is a purely physical process but gasification of polymers is accompanied by chemical changes.

and the front face boundary condition is:

$$-\lambda \frac{\partial T}{\partial x} = h_c\left(T_g - T_s\right) \qquad \text{at } x = 0$$

where T_g = temperature of gas (K) and T_s = temperature of front face of slab (K). From this theory, Hicks could construct plots of ignition time versus front-face temperature, given explicit values of the material constants. This unfortunately is the inverse of the problem which is normally encountered—one normally starts with measured data, then a procedure is needed to convert the data into material 'properties,' and only then can the properties be used in calculating what would have happened under different conditions. Later, the Russian researchers Lisitskii and Merzhanov[131] conducted a number of experiments and concluded that $t_{ig} \propto h_c^{-1.64}$. By itself, this is not too useful since one normally wishes to find the dependence on the flow velocity u_∞ and the gas temperature T_g, instead. By using a kinetic model and making a number of approximations, they did produce a closed-form (but not explicit) equation relating t_{ig}, h_c, T_g, T_o, and a number of chemical kinetics constants. In the absence of the latter, the method would not be useful. More problematically, their basic heat-transfer coefficient dependence is questionable. For flow past a flat plate, the dependence of h_c on u_∞ in their theory is such as to give $t_{ig} \propto u_\infty^{-0.82}$, in other words, the ignition time is predicted to monotonically decrease with increasing gas flow velocity. But the available experimental data discussed above indicate that the actual relationship is not monotonic and that different regimes exist where raising the velocity may either help ignition occur quicker or retard it.

THERMALLY-THICK SOLID—BOUNDARY LAYER SOLUTION

Kashiwagi et al.[132] used a shock-tube apparatus to create a heated gas stream, which was directed past a flat plate specimen of polybutadiene-acrylic acid (PBAA). They found that ignition occurred at a varying distance upstream of the leading edge, with this distance decreasing as the oxygen concentration of the air stream was increased. They explained this as a reaction-time effect—since reactions take longer at a lower oxygen concentration, a longer travel time along the flow stream was required for ignition. They also developed a theory based on a self-similar, laminar boundary-layer, treating the gas-phase in a 2-dimensional way, but the solid only as an inert solid subjected to 1-dimensional heating. In a follow-on study[133], they eliminated the similarity assumption. Both models made use of single-step Arrhenius kinetics in the gas phase, but the authors pointed out that the constants needed for a reaction-rate term of this kind were not available. Furthermore, the model solutions required difficult numerical computations and did not lead to any closed-form approximations. A similar theory was presented more recently by Cordova et al.[134]; again, it did not lead to user-accessible solutions. Coffin[135] performed numerical modeling of the autoignition of PMMA in a boundary layer flow with radiative heating. The results showed a decrease in ignition time with increased sample length, the decrease being substantial for laminar flows and small for turbulent.

IGNITION THEORIES FOR SUBMERSION IN HOT ENVIRONMENTS

Unlike in the radiant-heating problem (where the specimen is convectively cooled), in this problem, both the radiant and the convective heat transfer terms are heat gains. The radiant heating term is:

$$\alpha_s \sigma\left(T_f^4 - T_s^4\right)$$

where the view factor, for reasons of thermal submersion, is unity. Unlike in the standard radiant-heating problem, however, *all* of the sides of the specimen are subject to this heating flux. The convective heat transfer term is:

$$h_c\left(T_f - T_s\right)$$

Since typically the tests where this environment is created involve thin specimens, the problem becomes difficult since 3-dimensional heat transfer must be calculated in the solid. No published solutions to this problem have been found.

Hermance et al.[136] treated the case of *conduction* heating, where convective velocity is negligible, as is radiation. They formulated the problem as 1-dimensional and included chemical reactions both in the solid and in the gas phase. Example computed results and extensive sensitivity analyses were presented, but no closed-form approximations were obtained. Furthermore, the simplifying assumptions they needed to make will rarely apply to accidental ignitions of solids. Lack of convective flow can be arranged if the specimen is presented with a hot gas in a face-down orientation, but to ignite solids generally a temperature is needed which is high enough that ignoring radiation is not reasonable.

Theoretical solutions for other problem conditions

For solids being heated in a 1-dimensional way, as we have developed above, the most common practical situation will be radiant heating, with simultaneous convective cooling and re-radiation from the front face. Occasionally, purely convective heating may be a reasonable representation of physical events. A large number of additional theoretical studies have been published that use boundary conditions which are only rarely encountered with practical substances. In this section, we briefly overview studies of this type.

THERMALLY-THICK INERT SOLID WITH FIXED NET HEAT FLUX

For one very simple case, exact solutions can be found in the classical heat conduction literature. If chemical reactions are ignored, the body is assumed to be infinitely thick, and the surface boundary condition is couched in terms of a

net heat flux (convection, plus absorbed radiation, minus surface re-radiation), then the solution is[137]:

$$t_{ig} = \frac{\pi \lambda \rho C_p}{4} \frac{\left(T_{ig} - T_o\right)^2}{\dot{q}''^2_{net}}$$

This solution, while mathematically easy, is unlikely to be useful, since under almost any heating conditions that arise in fires, the net heat flux varies with time even if the externally-imposed radiant flux is fixed.

THERMALLY-THICK INERT SOLID WITH FIXED HEAT FLUX AND CONVECTIVE COOLING

This problem resembles the practical one treated earlier in this chapter, except that re-radiation is omitted. The front face temperature is given by[138]:

$$T = T_o + \frac{\dot{q}''}{h_c}\left[1 - \exp\left(\frac{h_c^2}{\rho C}\right)\operatorname{erfc}\left(\frac{h_c t^{1/2}}{(\lambda \rho C)^{1/2}}\right)\right]$$

THERMALLY-THICK REACTIVE SOLID WITH FIXED HEAT FLUX

For many common solids, exothermic reactions within the solid can be ignored if the solid is heated at a relatively high heat flux. As heat fluxes get progressively lower, however, it becomes less accurate to use an inert-solid model. Already in 1959 Thomas et al.[6] observed that the effect may be significant. Some example data obtained by Urbas are shown in Figure 46. In his experiments, he exposed 16 mm particleboard using the ICAL apparatus and measured the surface temperature without, however, continuing the tests until ignition. The specimens reached a quasi-steady state at about 250 – 260ºC, then self-heating became pronounced and a new quasi-steady-state at 350 – 400ºC was noted.

A large number of studies have been published which consider the fixed-heat-flux case where a single, Arrhenius-form reaction is assumed to occur in the solid. The gas phase is still ignored. Liñán and Williams[139,140] solved the basic heat conservation equation:

$$\rho C \frac{\partial T}{\partial t} = \lambda \frac{\partial^2 T}{\partial x^2} + \rho A Q \exp\left(-E / RT\right)$$

where zero-order Arrhenius kinetics was assumed. They obtained an approximate solution for T_{ig} as:

$$T_{ig} \approx \frac{E}{R}\left[\ln\left(\frac{\lambda \rho C T_o A}{\dot{q}''_e}\right)\right]^{-1}$$

Using the above value, they proposed that the ignition time can be iteratively obtained from:

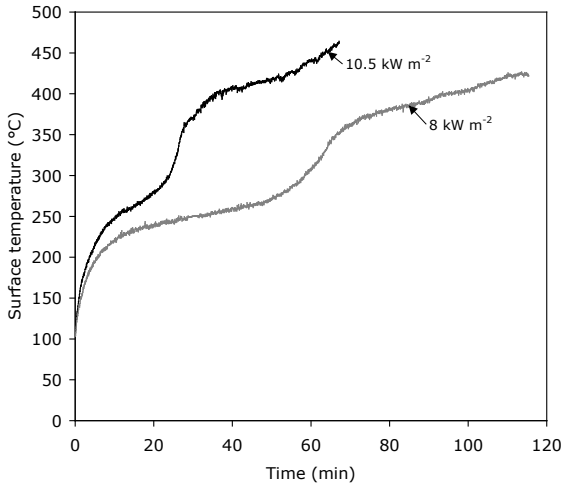

Figure 46 Front surface temperatures on 16 mm thick particleboard (back face open to air) exposed to low heat flux radiant heating
(Courtesy Joe Urbas)

$$t_{ig} = \left(\frac{\pi \lambda \rho C T_o^2}{4 \dot{q}''_e}\right) \times$$

$$\left\{\left[\ln\left(\frac{\lambda \rho C T_{ig} A}{0.65 \dot{q}''^2_e \sqrt{E / RT_o}}\left(\frac{\pi \dot{q}''^2_e t_{ig}}{\lambda \rho C T_o^2}\right)^{1/4}\right)\right]^{-1}\left(\frac{E}{RT_o}\right) - 1\right\}^2$$

Another approximate, closed-form (but not explicit) solution was provided by Harrach[141]:

$$t_{ig}^{1/2} \exp\left[-\frac{E/R}{\dot{q}''_e z t_{ig}^{1/2} + T_o}\right] = \frac{\dot{q}''_e z C}{2QA}$$

where $z = \alpha_s \sqrt{\frac{1.26}{\lambda \rho C}}$

Andersen[142] used a similar starting point, a solid undergoing a single Arrhenius-form reaction. In his case, he assumed a diathermanous solid being heated by a radiant heat flux; convective heat transfer was ignored. He proposed that a quasi-ignition temperature, T_c, can be determined in the following way. The time to ignition is defined as:

$$t_{ig} = t_{inert} + t_{ad}$$

where t_{inert} is the time needed to heat the specimen to the temperature at which reactions start, while t_{ad} is the chemical reaction time needed, considering only events in the solid phase. For t_{ad}, he took the Frank-Kamenetskii expression for the adiabatic induction period of a thermal explosion (this concept is covered in Chapter 9). The value of T_c is then found by making the reasonable, but *ad hoc*, assumption that this temperature corresponds to the time at which the rate of temperature rise due to chemical heating becomes equal to the rate of rise due to external heating. By differentiating the expressions for temperature rise due

to external heating and temperature rise due to chemical reactivity and setting them equal to each other, a value of T_c is found. This value of T_c is then inserted into the inert-substance equation and a time is obtained to reach T_c. The expression for t_{ad} is explicitly available, and the ignition time is then obtained by summing the two times. The procedure, while relatively straightforward, does not yield a single equation for expressing ignition time, thus it has not seen much use.

Another theoretical formulation was developed by Staggs[143,144], who incorporated a more generalized pyrolysis model into the problem. He writes the fundamental energy equation as:

$$\rho C \frac{DT}{Dt} = \lambda \frac{\partial^2 T}{\partial y^2} - \rho L_v A \mu^{n-1} \exp(-E/RT)$$

where y is the distance measured from the initial location of the top surface and D/Dt represents the 'convective derivative,' that is, the derivative with respect to time, following a material element. If the material flows past position y at a speed v, then $D/Dt = \partial/\partial t + v\partial/\partial y$. The chemical reaction term is based on a scalar μ which describes the progress of degradation in the solid phase, evolving according to

$$\frac{D\mu}{Dt} = -A\mu^n \exp(-E/RT)$$

where $v(y,t) = A\int_y^L \mu^{n-1} \exp(-E/RT)dy$. The instantaneous position of the top surface is denoted as $y = s(t)$. Then, the limits of the solid at any time are $s(t) \le y \le L$. The boundary conditions are:

$$-\lambda \frac{\partial T}{\partial y} = \varepsilon \dot{q}'' + h(T_o - T) + \varepsilon\sigma(T_o^4 - T^4) \qquad \text{at } y = s(t)$$

$$\frac{\partial T}{\partial y} = 0 \qquad \text{at } y = L$$

where it is assumed that the specimen is thick enough so that adiabatic rear face conditions will apply. Staggs obtained numerical solutions to the above equations and used them to evaluate the differences between various simplified ignition criteria that have been proposed. If the reaction kinetics is fast, then when the incident heat flux is varied there is little variation in the surface temperature at which a certain critical mass loss rate is reached. For slow reaction kinetics, however, raising the heat flux causes the critical mass loss rate to occur at a notably higher temperature. The model also predicts that, after ignition, the 'quasi-steady' front-face temperature is higher for thin specimens and lower for thick ones. Thus, it becomes clear that, in the general case, the problem does not have a 'characteristic temperature' which would be governed solely by its physicochemical properties: both the ignition temperature and the quasi-steady surface temperature vary with dimensions or heat flux conditions. Kinetics, while not being the only factor controlling the surface temperature, of course does affect it: faster reactions do result in lower quasi-steady surface temperatures.

Other studies of a mathematical nature on the problem have been published by Thomas[145] and by Adler and Thorne[146]. These have not culminated in closed-form expressions for problem solving.

FINITE-THICKNESS INERT PLATE WITH FIXED HEAT FLUX

A solid of finite thickness L is amenable to theoretical solutions if the back face is insulated while the front face receives a fixed heat flux. Carslaw and Jaeger[137] give the front face temperature solution as:

$$\frac{(T_x - T_o)\lambda}{\dot{q}''_{net} L} = Fo + \frac{1}{3} - \frac{2}{\pi^2}\sum_{j=1}^{\infty} \frac{1}{j^2} e^{-j^2\pi^2 Fo}$$

where $Fo = \dfrac{\alpha t}{L^2}$ = Fourier number.

FINITE-THICKNESS REACTIVE PLATE

Annamalai and Durbetaki[147] formulated a solution for a thin, porous plate heated by an impinging hot-gas jet. The plate gasifies according to a single-step Arrhenius kinetics. They were able to obtain an explicit solution (in quite complex form) only under the additional assumption that the rear face of the plate is adiabatic.

FINITE-THICKNESS POLYMER UNDERGOING CHARRING

Staggs and coworkers[148] developed at interesting, first-order theory to represent the ignition of a polymer which undergoes charring when subjected to heat. Ignition was assumed to occur the moment that a specified minimum mass loss rate is first attained. The physics of the model is probably too simple for it to be calculationally useful, but the authors found a number of notable trends:

- materials which produce a low amount of char behave qualitatively similar to non-charring ones;
- materials with an intermediate charring tendency show a time jump below a certain heat flux—ignition times become abruptly much greater at lower fluxes
- materials showing a high char-yield fraction become non-ignitable below a relatively critical heat flux and there is no region of long ignition times below the critical heat flux.

Charring materials tend to produce a two-hump mass-loss-rate curve, and the nature of this behavior becomes more clear when viewed in the context of this curve. If the mass loss rate at, or before, the first peak exceeds the minimum rate needed for ignition, then ignition takes place relatively rapidly. On the other hand, if the mass loss rate at first peak does not reach the minimum MLR value, it may take a long time before sufficient MLR is attained on the second peak. The second peak, by the way, corresponds to a time when the material has become thermally-thin and virgin material

is no longer available deeper into the sample to absorb supplied energy.

THERMALLY-THICK REACTIVE SOLID HELD AT A FIXED FACE TEMPERATURE INDEFINITELY

The front face of a semi-infinite body is held at a temperature T_s indefinitely. The situation physically corresponds to an infinitely thick solid being placed on a hot plate. A flaming ignition is impossible in that case, since there exists no surface open to air, but a smoldering ignition could occur. The problem has no meaningfulness for an inert solid, but can be useful in analyzing test data on explosives or unstable substances. Consequently, it is assumed that there is a temperature-dependent chemical reaction taking place within the solid. The initial and boundary conditions are: $T = T_o$ for all x and for $t < 0$. $T = T_s$ for $x = 0$ and $t > 0$. According to Vilyunov[153], the ignition time is found to be:

$$t_{ig} = \left[1 + \frac{2E}{RT_s^2}(T_s - T_o) + 0.163\left(\frac{E}{RT_s^2}(T_s - T_o) \right)^2 \right] \times \frac{RT_s^2}{E}\frac{C}{QA}\exp(E/RT_s)$$

A solution was also obtained by Cook[149] using a different numerical method and different approximations. His results for the ignition time expressed non-dimensionally[150] are:

$$\tau_{ig} \approx 0.20\theta(\theta + 8)$$

where $\tau_{ig} = \dfrac{t_{ig}}{t_{ad}}$, $t_{ad} = \dfrac{RT_o^2}{E}\dfrac{C}{AQ}\exp(E/RT_o)$, and $\theta = \dfrac{E}{RT_o^2}(T_s - T_o)$.

The results can be represented as:

$$\ln\left[\frac{t_{ig}}{T_s - T_o} \right] = \frac{E}{RT_s} + b_o$$

where the constant b_o is:

$$b_o = \ln\left[\frac{0.2\rho C}{QA}\left(\frac{E}{R}\frac{T_s - T_o}{T_s^2} + 8 \right) \right]$$

Consequently, plotting the left-hand side quantity on the y-axis and $1/T_s$ on the x-axis should give a slope of E/R. The value of b_o, obtained as the x-axis intercept, can then be used to obtain $\rho C/QA$. Experimentally, it was found that data fall on a straight line only in the short ignition time regime[151]. Liñán and Williams[152] provided another solution to this problem.

THERMALLY-THICK REACTIVE SOLID HELD AT A FIXED FACE TEMPERATURE FOR A FINITE TIME

The front face of a semi-infinite body is held at a temperature T_s for a certain length of time, t_*. Then the front face is maintained at adiabatic conditions. What is the shortest time t_* for the front face to be heated so that ignition can occur (ignition occurs at time t_{ig} which is later than t_*)? The substance is assumed to behave according to zeroth order Arrhenius kinetics, with the heat conservation equation being:

$$\rho C\frac{\partial T}{\partial t} = \lambda\frac{\partial^2 T}{\partial x^2} + \rho AQ\exp(-E/RT)$$

and the initial and boundary conditions are: $T = T_o$ for all x and for $t < 0$. $T = T_s$ for $x = 0$ and $0 < t \le t_*$. $dT/dx = 0$ for $x = 0$ and $t > t_*$. Vilyunov[153] solved the problem numerically and determined that

$$t_* = 0.214\left(1 + 1.44\frac{RT_s}{E} \right)\frac{EC(T_s - T_o)^2}{RT_s^2 QA}\exp(E/RT_s)$$

where E = activation energy (kJ mol^{-1}), R = universal gas constant (8.314 J mol^{-1} K^{-1}), T_o = initial temperature (K), C = heat capacity (kJ kg^{-1} K^{-1}), Q = heat of reaction (kJ kg^{-1}), and A = pre-exponential factor (s^{-1}). It is realized, of course, that for most solids the kinetic constants E, Q, and A will not be known and will have to be treated as data fitting parameters.

THERMALLY-THICK REACTIVE SOLID RECEIVING FIXED RADIANT HEAT FLUX ONLY

If the heat reradiated from the front face is ignored, convection is also ignored, and the only external heat entering the body is a net heat flux at the front face, $\dot{q}_r''$, then Vilyunov's approximate solution can be used. His method is indirect since it first requires that an intermediate variable be solved for, a fictitious temperature T_h. This is given by the implicit equation:

$$QA\lambda\rho e^{-E/RT_h}\frac{\pi}{2}(T_h - T_o) = \dot{q}_r''^2$$

If one know all of the thermochemical and kinetic constants of the material, then the only unknown is T_h, since T_o is the given initial condition. The value of T_h is not given explicitly, but can be obtained by a few trial iterations. Having determined T_h, the ignition time is obtained as:

$$t_{ig} = \left[1 + \frac{E(T_h - T_o)}{2RT_h^2} \right]\frac{RT_h^2}{E}\frac{C}{QA}e^{E/RT_h}$$

The surface temperature at ignition, T_{ig}, is determined from:

$$T_{ig} = T_h\left[1 + \frac{RT_h}{E}\left(1 - \frac{RT_h^2}{2E(T_h - T_o)} \right) \right]$$

The condition for thermal-thickness is that the thickness L obey:

$$L > \frac{\pi}{2}\frac{\lambda(T_h - T_o)}{\dot{q}_r''}$$

Vilyunov's solution is interesting in that it captures much, though not all, of the physics of the real problem and allows some illustrative computations to be made. For example, knowing the thermochemical properties, it is not difficult to determine the dependence of the surface temperature at ignition, T_{ig}, on the heat flux, $\dot{q}_r''$. The computations in-

dicate that T_{ig} rises with increasing $\dot{q}''_r$, which is experimentally found to be true, although the simple solution here over-predicts this increase. In contrast with the above set of equations, which slightly underestimated the ignition time, Vilyunov also offers an alternative solution, which slightly underestimates the ignition time:

$$QA\rho e^{-E/RT_q}\frac{2\lambda RT_q^2}{E}=\dot{q}''^2_r$$

$$t_{ig}=\frac{0.7\lambda\rho C}{\dot{q}''^2_r}\left(T_q-T_o\right)^2$$

The variable T_q is, close to, but not exactly, the surface temperature at ignition.

SOLID RECEIVING A BRIEF, HIGH-INTENSITY PULSE OF RADIATION

This problem was important in the 1950s when thermal ignitions due to nuclear weapons attacks were being studied (see Chapter 11). This problem can be complicated because, in many instances, a pulse of this nature will give a flash ignition but not a sustained ignition. Vilyunov[153] discusses some solutions and limitations.

POROUS SOLIDS

Telengator et al.[154] extended the analysis of Liñán and Williams to the case where the solid was porous. The detailed solution, despite numerous simplifications, could only be achieved by numeric computations. However, a first-order approximation was developed:

$$t_{ig(porous)}\approx t_{ig(non-porous)}\times\left(1-\varepsilon\right)\left(1-\varepsilon+\lambda_g\varepsilon/\lambda_s\right)$$

where $\varepsilon=\dfrac{\text{volume of voids}}{\text{total volume}}$, λ_g = gas phase conductivity (W m^{-1} K^{-1}), and λ_s = solid phase conductivity (W m^{-1} K^{-1}). The above relation pertains to the situation where the surface releases the pyrolysis gases readily. If an impervious surface exists, then ignition times are invariably shortened for a porous solid, since expanding gases drive energy further into the body[155].

DIATHERMANOUS SOLIDS

Many materials absorb heat in depth, not being fully opaque. Diathermancy always increases ignition time and thus, as a conservative approximation, might be neglected. When it needs to be treated, the Beer-Lambert Law is invoked, which states that for a parallel beam of monochromatic radiation passing through an infinitesimally thin slice of a homogeneous absorbing medium, the energy absorbed within the slice is proportional to the incident energy times the slice thickness times a material constant. Using this, the energy balance for the 1-dimensional case becomes:

$$\rho\, C_p\frac{\partial T}{\partial t}=\lambda\frac{\partial^2 T}{\partial x^2}+\alpha_s\dot{q}''_e\beta\exp\left(-\beta x\right)+\dot{q}'''$$

where β = in-depth absorption coefficient (m^{-1}). Because a new, entirely independent variable has been introduced into the problem, it becomes much more difficult to seek a closed form solution. Gardon and Michalik presented numeric and graphical solutions to the basic heat transfer problem[156]. The approximation methods of Vilyunov[153], while not giving closed-form solutions, at least provide the possibility of obtaining a solution without computer programming, although some iterative algebraic calculations need to be done. The asymptote at extremely high heat fluxes is[157]:

$$T_s(t)-T_o=\frac{\beta\,\dot{q}''_e t}{\rho\, C_p}$$

thus, the extreme-heat flux t_{ig} can be approximated by setting $T_s = T_{ig}$. If $\dot{q}'''\equiv 0$, then the surface temperature can be obtained from the following equation[158], although further approximations would be needed to solve explicitly for the ignition time:

$$T_s(t)-T_o=\frac{\alpha_s\dot{q}''_e}{\lambda\beta}\times\left[2\beta\sqrt{\frac{\lambda t}{\pi\rho C}}-1+\exp\left(\beta^2\frac{\lambda t}{\rho C}\right)\operatorname{erfc}\left(\beta\sqrt{\frac{\lambda t}{\rho C}}\right)\right]$$

MISCELLANEOUS GEOMETRIES

Vilyunov[153] provides a number of solutions for a semi-infinite cylinder which is heated by conduction or radiation at its end surface and convectively cooled along the sides. Other solutions include pulses of radiation, combustible material behind thin non-combustible slabs, hot wires passing through thick bodies, and imposed heat fluxes which vary with time. In general, solutions are developed in a way where the differential equations are non-dimensionalized with respect to an arbitrary temperature scale, then a separate solution is made for this normalizing temperature, which has only a conceptual, not a physical meaning. All of these procedures require a fair bit of algebraic manipulation and some trial-and-error iterative solutions of auxiliary equations in order to produce results.

DEPLETION OF REACTANTS NOT IGNORED

A zero-order kinetics is generally a poor assumption for charring or pyrolyzing solids, since reaction rates change significantly due to depletion of reactants. For these materials, Martin[11] considers that first-order kinetics should be used. This makes the problem significantly more difficult, since now there are two variables—temperature and density—that need to be solved for, instead of temperature alone. Assume that there is only one reactant that needs to be taken into account and that its initial concentration is c_o. Then

$$\frac{dc}{dt}=-c^n Ae^{-E/RT}$$

where the minus sign reflects that it is the concentration of reactants, not products, that is being evaluated. The initial condition is $c = c_o$ at $t = 0$. For a solid, it is most convenient to consider that the concentration is the density, thus

$$\frac{d\rho}{dt} = -\rho^n A e^{-E/RT}$$

As discussed above, Melinek[26] solved this problem numerically; no closed-form approximations emerged from his study. In general, if a solution for mass loss rate must be made, two different simplifications can be considered:

1. Assume that the front face does not move, but the material progressively loses density, with the density loss being greatest at the front face. This was the assumption taken by Melinek.
2. Assume that the substance simply sloughs material off the front face, without changing the density of the material which remains. This is the ablative limit and might be appropriate for non-porous thermoplastics exposed to very high heat fluxes.

A large number of authors have developed models with explicit first-order kinetics and some other studies of this type are discussed elsewhere in this Chapter.

Ignition from localized sources

SMALL FLAMES

The engineering theory presented above assumes that the response of a small surface area element *dA* is typical of the entire surface being ignited. This will not be true if: (1) the specimen is small, or (2) the ignition source is small. By small, we mean that edge effects will predominate and that no part of the source/specimen is far away from the edge. A Bunsen burner is a small ignition source, since nowhere in its flux field can there be found a region of uniform heating and one situated far from all edges. A room-heating stove igniting a wallboard is probably not a small source, since typically the ignited area will be substantial in size. Here, both the source and target are large. A small target and a large source could be exemplified by an electric cord igniting from the radiant heat of a nearby malfunctioning furnace.

In each of the 'small' ignition cases, the heating conditions and the combustible gas evolution cannot be represented as a portion of a uniform surface. Thus, the heat flow problem becomes 3-dimensional, instead of being 1-dimensional. While mathematical computation of 3-d heat flow is certainly feasible, nonetheless setting up such computational problems is tedious. Worse yet, the results, because of the numerous geometric variables, do not have enough generality to be reduced to simple formulas, nomographs, etc. Thus the problem has rarely been studied; an example is by Thomas[159].

Another issue with small-specimen ignition is the question of dimensional changes. When a small specimen shrinks, flows, thermally deforms, chars, intumesces, etc., it can significantly change the critical distances between the flame combustion zone and its own surfaces. This becomes almost impossible to represent mathematically; we know of no success stories in this area.

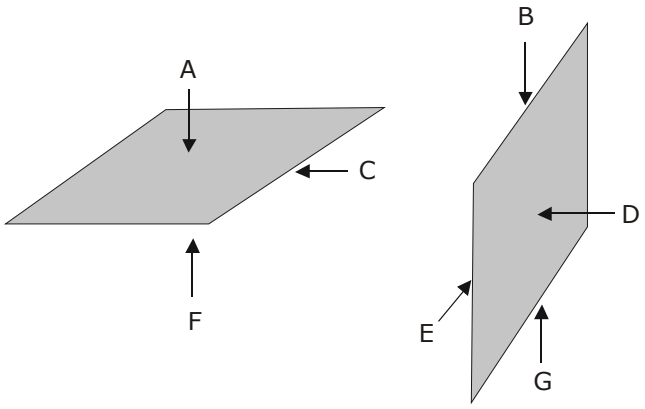

Figure 47 The 7 geometric locations at which it is possible to apply a flame onto a flat solid which has three axes of symmetry

Another problem is the effect of fire retardants. Products treated with FR agents often tend to show very good behavior in the small specimen/small flame situation. Performance may not be as good for the large specimen/large flame geometry. These scale effects are intrinsically 3-dimensional and have not been theoretically studied.

In terms of practical testing, for a planar solid which has three axes of symmetry, there exist 7 distinct locations where a flame may be applied (Figure 47). Taylor[160] conducted tests on a variety of materials using two flames, both applied for a 5 s period. The smaller flame was 12.5 mm long, using a propane burner with a 2.5 mm diameter tube. The larger flame was 50 mm long, using a propane burner with an 8 mm diameter tube. Wilson's results on a variety of 3.2 mm thick samples are shown in Table 18. Preliminary testing showed that results using the **F** position were highly scattered, being greatly affected by the exact specimen to burner tube spacing, consequently, this test position was not used. Otherwise, the results indicate that the propensity to ignition is ranked in the order **A** (least ignitable), **B**, **C**, **D**, **E**, **G** (most ignitable). Additional data on small-flame ignitability are provided in Chapter 14 under *Plastics* and *Wood*.

Taylor did not explore the effect of specimen thickness, but with many materials this variable is important. A limited amount of data exists on wood, as shown in Chapter 14. Some indication can also be had from listing reports of test laboratories using the UL 94 test method, where it is known that it is more difficult for thin specimens to pass and, consequently, the listing is limited to a specified material thickness. Apart from such limited information, data on the thickness effect on small-flame ignitability is basically non-existent.

For experimental testing with small ignition sources, there exists UK standard BS 5852[161] which has a graded series of ignition sources. Table 19 shows the results obtained when 3 mm thick polypropylene sheets were tested with these sources[162]. It must be noted that the wood crib sources are used in the test method by being placed on top of a horizontally-oriented specimen. With wood crib sources, after a certain time of burning, direct conduction from the glowing char is probably more important a heat transfer mode than is radiation from the flames of the crib.

We conclude that, unfortunately, at the present time there are no engineering tools available for treating the general case of ignition with small sources or on small target objects. Some trends can be anticipated using the guidance developed below for large source/target analysis. However, if a specific question must be answered whether a fire could or could not have started on the basis of a small source/target, at the present time one must answer it by experiment. For upholstered furniture and mattresses, small-source ignitability has been studied for a long time. This is partly due to the fact that cigarettes, which may be the smallest commonly occurring ignition source, cause a preponderance of furniture ignitions. Upholstered furniture ignitions are discussed in Chapter 14.

SMALL-DIAMETER, HIGH-INTENSITY HEAT SOURCES

A plumber's or welder's torch can often be applied to a piece of foam plastic with the result that a hole is created in the material, but it is not ignited. Before the US Federal Trade Commission took action against the plastics industry for misrepresentation of flammability[163], this trick was sometimes employed by unscrupulous sales agents to prove that their plastic is 'noncombustible.' No quantitative model of the action of a torch upon a plastic specimen has been produced, but the general principles can be outlined qualitatively. The factors involved are: endothermicity of melting/pyrolysis, shrinkage, and flame blow-off limits. Foam plastics prone to demonstrating this type of phenomenon have some pronounced endotherms in their thermal response curve. Thus, part of the external heat is converted to heat of melting, of vaporization, or of degradative pyrolysis. The flame and hot gas stream issuing from a torch reaches very high temperatures, but is of small diameter. Shrinkage pulls the material out of the direct path of this stream, creating a hole. These plastics do not burn by heterogeneous combustion, thus igniting the surface itself is not the issue; the question is what happens in the boundary layer flowing through the newly-formed hole. It would appear that either violent entrainment disrupts the possibility of a zone where a mixture within its flammable limits can exist, or else that excessive velocities cause blow-off.

HOT BODIES

Hot bodies, in general, include both substances with a finite amount of heat (e.g., a piece of welding slag) and those that are continuously heated, such as an electric heating coil. A hot body placed in contact with combustible material may lead to its ignition. Two possibilities must be considered:

Table 19 The results of small-flame ignition testing of polypropylene sheets

BSI source no.	Type	Avg. HRR of source (kW)	Total heat supplied (kJ)	Duration of exposure (s)	Results for polypropylene
1	gas burner	0.072	1.43	20	no ignition
2	"	0.29	11.4	40	flashing
3	"	0.50	34.9	70	flashing
4	wood crib	0.75	85.9	115	no ignition
5	"	1.54	208	135	sustained ignition
6	"	2.32	777	335	sustained ignition
7	"	4.63	1780	385	sustained ignition

(1) the combustible material is capable of smoldering; or
(2) the combustible material is not smolderable.

If the material does not smolder, then it can only be ignited if the hot body creates sufficient pyrolysis gases, and the gases then ignite either by autoignition or by the surface of the hot body. Most non-porous plastics are not susceptible to smoldering, and it is generally hard to ignite them with hot bodies. When presented with a hot body, thermoplastics melt, gasify, and typically retract from the heated surface. Unless very flammable gases are copiously liberated, the sequence is likely to lead to a non-ignition, with the remaining material separated from the hot body by a gap. Thermosetting plastics, of course, do not melt, but these are typically materials that are much harder to ignite by any means (e.g., radiative heating), since they generally have lower heats of combustion and a lower propensity to gasify. Smolderable materials may first be ignited in a smoldering manner, and this may later transition or not to flaming combustion; or, they may be directly ignited in a flaming mode.

Despite the existence of some standardized tests for hot-surface ignition (described at the end of this Chapter), there has been little experimental work of the ignition of solids by hot surfaces and theoretical studies are equally scarce. Part of the difficulty arises from geometric complications. Several common possibilities must be considered, although the variety is endless:

- a small hot body contacts the much-wider surface of a combustible
- the entire face of the combustible is contacted by a hot body
- a hot body is partly or wholly submersed in the solid.

If the substance is non-smolderable and thermally thick, then ignition can only occur at the edges around the hot surface, since the hot surface is presumed to be impervious to flow of oxygen. The problem, therefore, intrinsically becomes 3-dimensional. If the substance is thermally thin, then flaming can also start on the back face (the assumption is made that the hot body is only pressed against one face), but no studies exist on this arrangement. It must also be noted that, in the case of the small hot body, a convective flow is likely to be created by its presence, and this will influence the thermal response of those parts of the target that are not in direct contact with the hot body.

For a few simple geometries, smolderable bodies can be treated by using self-heating theory (Chapter 9). Reasonably tractable methods are presented there for the cases of a slab with its whole face contacted by a hotplate and for the cylinder geometry that can represent ignition of wire or pipe insulation. Ohlemiller[164] treated these two, along with several more complex geometries, for the case of cellulosic insulation. His study involved mostly numerical solutions and he did not evolve any closed-form approximations. But the most common actual cases of ignition by hot surfaces typically involve a small, flat hot body landing on a large combustible surface. No tractable theory exists for the corresponding cases of a heated disc or a heated small rectangle.

Vilyunov and Sidonsky[165] treated the case on a semi-infinite rod where a hot surface touches its front face for a fixed length of time, then the hot surface is removed and the face becomes adiabatic.

The case of a small hot sphere landing on—and partly embedding itself in—an explosive was treated by Gol'dshleger et al.[166] For the purposes of this discussion, explosives behave similarly to smolderable fuels, in that the exothermic reaction is within the body and there is no need to produce gases and to ignite the gases. In their work, they developed a theory and conducted laboratory tests on nitrocellulose and polyvinylnitrate. For a 2 mm steel ball impacted into nitrocellulose, they found transient flashing for a ball at 430ºC, with sustained ignition occurring for a 450ºC ball. However they defined actual ignition temperature as 410ºC, which was the lowest temperature at which the explosive was largely consumed. For balls of smaller diameter, higher temperatures were required. Over the range of sphere diameters $0.7 \le d \le 2.5$, their results for both explosives (Figure 48) can be fitted by curves of the type:

$$T_s = a + b\exp(-d/c)$$

where T_s = sphere temperature; a, b, and c are constants; and d = ball diameter (mm). This equation, unfortunately, does not have generality, since the constants effectively depend on a combination of the physical and chemical properties of the combustible substance, along with the thermal properties of the hot sphere. With very limited data, Gol'dshleger also showed that a hot sphere of lower thermal conductivity must be raised to a higher temperature. Gol'dshleger's theory itself is discussed in Chapter 9.

A modest collection of purely-experimental data exists, but it is sparse enough that few helpful generalizations can be made. In connection with the development of his furnace, Setchkin[167] reported a small amount of hot-surface ignition data (Table 20). The test details were not stated, but it appears likely that he placed small specimens on a laboratory hotplate which was much larger than the specimens. In his protocol, evidently temperatures were explored only in 50ºC increments.

Kuchta, Furno and Martindill[168] used a 63 × 46 mm heated steel plate which they pressed against various materials in both air and oxygen atmospheres. Some of their results are shown in Table 21. Same as Setchkin, they found that a much higher hot-surface temperature was needed for ignition than the material's T_{ig} obtained under radiant or convective heating conditions. Ignition of solids with a radiant heat flux shows a small-to-nil dependence on oxygen concentration, yet Kuchta's tests revealed a very notable de-

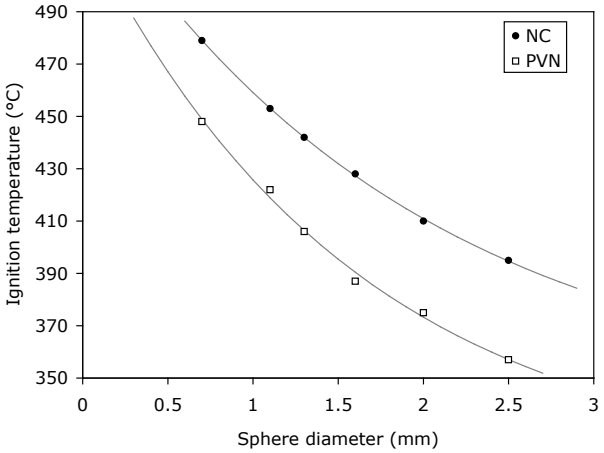

Figure 48 Hot sphere ignition data for two explosives, nitrocellulose and polyvinylnitrate

pendence. In addition, Kuchta et al. found that the minimum hot plate temperature depended on the total pressure, with values at 6 atm being 50 – 100ºC lower than at 1 atm. A direct comparison cannot be made here to radiant ignitability, since pressure dependence is unclear for that mode of ignition. Khalturinskii et al.[169] reported data on the effect of oxygen concentration for hot-surface ignition of PMMA and POM. The needed temperature depended on oxygen concentration at low O_2 values, but beyond a certain minimum concentration (15% for POM, 30% for PMMA) there was no effect at all. Their test conditions are not clear, however, since some exceptionally high temperatures were needed (1000 – 1200ºC).

Table 20 Ignition temperatures determined by Setchkin

Material	Ignition temp. (ºC)		
	Piloted	Auto	Hot-surface ignition
cellulose acetate	305	475	600
cellulose nitrate	141	141	550
melamine formaldehyde, mineral filled	313	455	700
phenol formaldehyde, w. paper reinforcement	306	399	600
PMMA	290	456	600
polyester, w. glass cloth	346	462	600
polystyrene	345	488	600

A small amount of data was presented by Widginton[170] for ignition of coal dust from electrically heated bare wires. Using wires of 0.20 – 0.48 mm diameter, he found that 2.5 to 9.0 A had to be carried by the wire to ignite coal dust, but the spread of the results was not governed by wire diameter. Apparently the thickness of the dust layer was small enough that the problem was not dominated by self-heating effects.

Table 21 Hot surface ignition results by Kuchta et al.

Material	Hotplate temp. needed for ignition (ºC)	
	In air	In oxygen
cellulose acetate	> 600	425
cotton sheets	465	360
cotton sheets, FR	575	310
paper	470	410
PMMA	595	430
PVC	> 600	425
wool	> 600	500

Some further experimental results are compiled in Chapter 11 under *Hot solids or liquids* and in Chapter 14 under *Coal*; *Cotton*; *Fabrics*; *Floor coverings*; *Forest materials, vegetation and hay*; *Plastics*; and *Wood*. These results are typically hot-surface ignition temperatures cited for a particular substance under poorly-defined experimental conditions. Unfortunately, there are no data sets where size, temperature, and thermal conductivity of the hot object were systematically varied. Thus, it is not possible even to provide suitable methods for data plotting and for extrapolation from test data, such as given earlier in this Chapter for the case of radiant heating.

In summary, hot-body temperatures must be substantially greater than normally-reported values of T_{ig} for ignition to occur. It is also evident that increasing the size of the hot body reduces its required temperature, as does increasing the thermal conductivity of the hot body. The sole case for which systematic theoretical treatments and experimental techniques are available is for smolderable (especially granular) materials ignited in hotplate or hot-wire type geometries; these are described in Chapter 9.

Ignition from large flames

Large flames can be characterized in terms of their heat flux (see Chapter 11) and once the pertinent heat flux is known, an ignition analysis as described above for radiant/convective fluxes can be done. A special concern, however, arises in the case of combustible wall/ceiling linings and similar large-surface materials. For those products, the ignition of the material directly adjacent to the flame is often a moot issue; instead, the concern is whether the surface will spread flame or not.

If the flame is in direct contact with the surface, then the convection heat transfer situation is considerably modified from the one customarily adopted for theoretical work, since convection provides heating, not cooling of the surface. Very little data exists for this condition, with the data of Bamford et al. having been discussed earlier in this chapter, while some more current (and more reliable) data on wood are cited in Chapter 14.

Duration of ignited burning

FLASHING VS. SUSTAINED FLAMING

Flashing is often reported in Bunsen burner type tests on solids. In Cone Calorimeter and other radiant-heating tests on solid materials, generally not much use is made of data on the time of occurrence of flashing, since it is not seen as a variable which is useful in predicting hazard in real fires. Consequently, few studies exist where flashing times were reported. Table 22 shows the results from one test series[171] where this point was specifically examined. The data indicate that (a) materials containing FR agents are more likely to exhibit flashing prior to ignition; (b) the difference between the first occurrence of flashing and sustained flaming ignition is usually trivial at heat fluxes of 50 kW m^{-2} or greater. A general comparison concerning effectiveness of FR agents should not be made from these results, since unspecified FR compositions were used, and they differed for the different polymers.

SUSTAINED FLAMING AFTER INITIAL IGNITION

If a solid is exposed to a constant heat flux and the heat flux is discontinued a certain time after ignition, one of two things can happen: (1) the solid will continue flaming; or (2) flaming will cease. The question which will occur is often important for understanding the dynamics of real fires. Conceptually, the reason why extinction takes place is because sustained flaming requires a sustained generation of volatiles to burn, and the latter becomes impossible. A brief, high-intensity heat pulse may be so intense as to vaporize and ignite a certain amount of material, but any given mass of original flammable vapors will stop flaming maybe in 1 s or less. There will subsequently be no fire, unless a mechanism exists that can deliver volatiles at a sufficient rate. A solid which has been heated at a much slower rate but for a long time will have had the opportunity to heat up in depth. Consequently, removing the source of heat may not affect things much for a while, since the solid's temperature will drop only gradually and the mass delivery rate of volatiles is proportional to the temperature of the surface layer. As a result, removing the source of heat a short while after it was first applied is much more likely to cause flaming to stop, than if the heat source is removed after having been applied for a long time.

Actual laboratory research on the topic of sustained flaming is unfortunately very limited. This question was first asked in 1915 by Prince[5], who examined the behavior of Western red cedar shingles. When a 1 min period was allowed between ignition and removal of heat source, he found that unpainted shingles continued burning to completion. Many different paints, though, had the effect that, upon removal of the heat source, burning stopped in a few minutes and most of the specimen was not consumed. When 6 min elapsed before the removal of the heat source, however, all of the tested products continued burning and burned up fully. Much more recently, Tuyen et al.[172] explored the sustained flaming of square wood dowels. The dowels were heated by being inserted horizontally into the cavity of a heated coil. Unfortunately, while the authors describe the coil temperature as being 600ºC, they did not measure the heat flux from the coil. After ignition was achieved, they removed the coil. For specimens of 2 × 2 mm up to 7 × 7 mm, flaming was sustained after heat source removal. For specimens 14 × 14 mm and larger, flaming ceased after heat source removal. Intermediate-size specimens were able to continue flaming only if the heater continued to be applied for 10 – 60 s post-ignition.

Substances which are exposed to extremely high heat fluxes may exhibit only transient flaming, despite the large heat flux. This was shown for thick wood siding which was exposed to nuclear weapons tests[173]. Even though very heavy pyrolysis, massive smoke emission, and some flaming occurred during the nuclear weapon exposure, the wood siding did not continue to burn afterwards. This is strikingly different from other substances, such as cloth, paper, finely-divided combustibles, etc.—all of these ignited in a fully flaming manner and did not self-extinguish. The effect is related to the ability of the heat pulse to establish a sufficiently deep, heated layer within the solid material. As discussed earlier, this effect was studied for cellulose at some length by Martin, but his work did not lead to a general strategy applicable to other materials.

Ohlemiller et al.[174] explored sustained flaming for a double-base propellant. Using very high heat fluxes from a laser source, they found that there was an optimal region in a flux/time plot for maintaining flaming after removal of the radiation source. Excessively high heat fluxes caused extinction due to a 'deradiation' effect, which was under-

Table 22 Cone Calorimeter ignition data for a number of polymers

Polymer	Heat flux (kW m^{-2})	Non-FR grade		FR grade

NI – no ignition

stood to be a rapid change in heat balance at the surface, leading to an abrupt drop in surface temperature. Pantoflíček and Lébr[175] suggested that at high fluxes, there is a limiting temperature gradient within the solid—if the gradient at the surface is steeper than a given value, a sustained ignition is impossible. They also proposed that, apart from a minimum heat flux needed to achieve ignition, there is a minimum energy fluence requirement for combustion to be sustained:

$$q''_e = \frac{\lambda}{u}\left(T_{ig} - T_o\right)$$

where q''_e = energy fluence (kJ m^{-2}), λ = thermal conductivity, and u = regression velocity of surface. The validity of their suggestions would need to be answered experimentally, but suitable data are lacking.

Solids may fail to burn up relatively completely even if the heat source is not removed. This tends to occur if: (a) the material is highly FR-treated or is an 'inherently-FR' substance; or (b) it is exposed at a heat flux which is close to the material's critical flux for ignition. The effect of material type on completeness of combustion when the heat source is not removed is illustrated in Figure 49[176]. At the low flux of 20 kW m^{-2}, there is a very wide range of behaviors among materials. Some, for instance the phenolic/paper, burn up nearly completely. The polyurethane foam example, however, burns only about 35% at this flux, yet burns up fairly completely at 50 kW m^{-2}.

Conceptually, a heat balance for the flame should indicate whether losses are small enough and heat production high enough that flaming can be sustained. In practice, that is hard to do without defining and solving a full 3-dimensional model for the gas phase. Thus, simplified 1-dimensional concepts have been sought. Rasbash[32,177] proposed a concept related to the limit flame temperature idea. The latter states that combustion will not be sustained if the flame temperature drops below a certain value. Rasbash reformulated the concept in terms of heat fluxes, and defined a heat loss factor ϕ which is the maximum fraction of the heat of combustion that can be lost to the solid surface by means of convection. For non-fire-retarded substances, Rasbash suggested that the value of ϕ should range between 0.2 and 0.4. Thomson[2] computed the ϕ values for six plastics and found a range of 0.20 – 0.48 for her materials. This is a very wide spread and does not give a useful numerical criterion. More problematically, the Rasbash formulation is based on assuming that the heat release rate and the heat of vaporization are constants. The reason that some materials show non-sustained burning is precisely because these values are not constant—after an initial peak of HRR, the production of volatiles tails off and flaming is no longer sustained. The HRR curve is easy to measure and could be included into a tractable method. But an accurate determination of the heat of vaporization curve requires a significant research effort, due to noise associated with numerical differentiation of the mass loss curve. Successful research

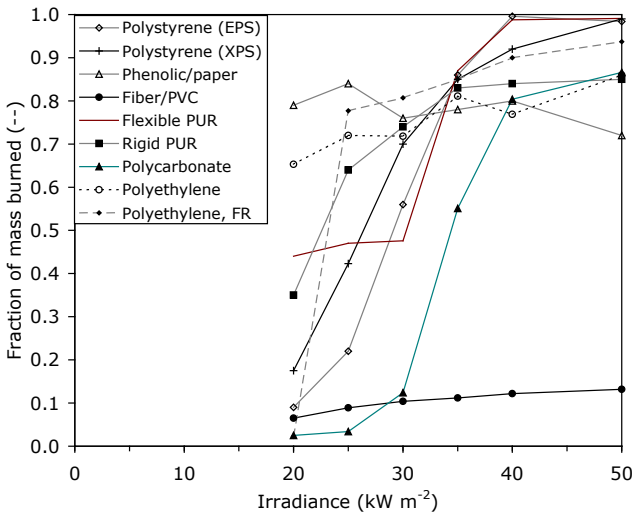

Figure 49 The effect of irradiance on mass fraction burned

studies have been reported[178], but it does not appear that the procedure lends itself to being made routine.

Brindley et al.[179] offered a theoretical solution to the persistence question, solving the case of fixed heat flux at the front face (i.e., no convection or re-radiation). Their solution was wholly numerical and systematic guidance did not evolve from it. In practice, the means of answering the question are currently empirical, e.g., various small-flame ignition tests which limit the 'afterflame' time. In an effort to evolve a closed-form criterion, Lyon[180] suggested that the following expression for heat release be considered:

$$\dot{q}'' = \frac{\Delta h_{c,eff}}{L_g}\left(\dot{q}''_e + \dot{q}''_{fl} - \dot{q}''_{\min}\right)$$

where $\dot{q}''$ = heat release rate (kW m^{-2}), $\Delta h_{c,eff}$ = effective heat of combustion (kJ kg^{-1}), L_g = effective heat of gasification (kJ kg^{-1}), $\dot{q}''_e$ = externally imposed heat flux (kW m^{-2}), $\dot{q}''_{fl}$ = heat flux from specimen's own flame (kW m^{-2}), and $\dot{q}''_{\min}$ = minimum heat flux for ignition (kW m^{-2}). Experimentally, it is found[34,181] that flaming combustion is not sustained unless the heat release rate exceeds a value of about 30 kW m^{-2} to 50 kW m^{-2}. Thus, inserting a value of 40 for HRR and setting the external flux to zero gives the condition for sustained burning as:

$$\frac{\Delta h_{c,eff}}{L_g} \geq \frac{40}{\dot{q}''_{fl} - \dot{q}''_{\min}}$$

The problem with this expression is that it does not readily lend itself to experimental evaluation. Values of effective heat of combustion and minimum heat flux for ignition can easily be found from Cone Calorimeter experiments. Flame flux is difficult to measure accurately, with values determined for specimens in the Cone Calorimeter[182-184] ranging from 5 to 37 kW m^{-2}. More difficult yet is to obtain a realistic value for L_g. In the equations above, L_g is considered a

constant and, in principle, it could simply be obtained experimentally as:

$$L_g = \frac{\dot{q}''_e + \dot{q}''_{fl} - \dot{q}''_c}{\dot{m}''}$$

where $\dot{m}''$ = mass loss rate (kg s^{-1} m^{-2}). However, once actual data are examined, it is found for many materials that (1) rather than being constant, the mass loss rate and the effective heat of combustion vary greatly with time[178,185]; (2) both of these quantities also vary with the externally imposed flux, and it may not be easy to extrapolate to conditions of HRR ≡ 40 kW m^{-2}. Thus, calculationally, this must be considered an unsolved problem. For certain classes of polymers, Lyon[180] suggests an empirical figure of merit be used, based on char fraction and LOI of the material, but the approach is drastically simplified (it assumes that $\Delta h_{c,eff}/L_g$ is a universal constant for all materials) and it lacks corroboration.

In practical applications, ignition and flame propagation are often closely related. Hazard commonly does not exist unless ignition results in propagation, rather than local, non-sustained burning. Propagation can be viewed as a series of ignitions, and it will stop if a necessary ignition along the way cannot happen. This may occur if a zone of low thermal inertia meets up to a zone of high thermal inertia. A practical example is shown in Color Plate 12. The fringe of a rug located close to a fireplace hearth was ignited by a burning ember. A portion of the fringe was consumed, but burning did not propagate into the rug itself. The thermal inertia of the fringe and of the rug were very different, and burning of the fringe could not ignite and cause sustained combustion of the rug, which had a much greater thermal inertia due to its greater density.

Variables affecting ignition of solids

TYPE OF PILOT (OR LACK THEREOF)

For solid materials, a pilot can be viewed as being of one of three types:

(1) no pilot, i.e., autoignition
(2) a pilot located in the gas phase, without direct heating effects to the specimen
(3) a pilot where the flame is directly impinging on the surface of the specimen which is also being radiatively or convectively heated.

For the third case, very little experimental data and no theory exist, thus only a few data will be cited here. Cases #1 and #2 are quite general, but practical application is held back by the unavailability of a tractable theory which would quantify the gas-phase conditions needed to produce autoignition. The simplest conceptual model for autoignition t_{ig} would be that $t_{ig} = t_{ss} + t_{gp}$, where t_{ss} is the identical solid-phase heating time used to predict piloted ignition, and t_{gp} is an induction period needed for autoignition of a gas volume, once it has been brought to a certain temperature. But the temperature history of the pyrolysate+air mixture in front of the solid surface is not well studied, nor is the 3-dimensional distribution of temperatures actually present within this layer. Since the induction period for autoignition is a sensitive function of the gas temperature, t_{gp} appears to not be readily obtainable by any simple approximation. Thus, we resort in this section to simply examining experimental data.

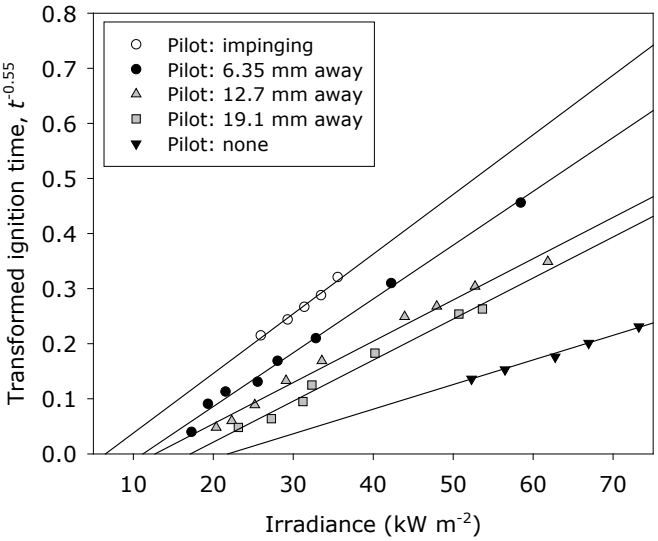

Figure 50 Ignition of vertically-oriented pine samples, for various pilot conditions

For two woods, the Fire Research Station[186] found the following values of the critical flux for ignition (Table 23).

Table 23 Early FRS results on the effect of piloting for ignition of wood

Species	Critical flux (kW m^{-2})		
	Auto	Piloted	Impinging pilot
Western red cedar	27	15	5.0
Douglas fir	28	15	5.0

Later, FRS's Simms and Hird[187] set forth the hypothesis that these three conditions are not separate possibilities, but merely points along a continuum. The variable to be considered is the distance of the pilot from the surface. Zero distance corresponds to impinging pilot; infinite distance corresponds to autoignition; while increasing the distance from the surface (yet still staying within the pyrolysis gas stream) should lead to longer ignition times. To examine their hypothesis, they conducted experiments on vertically-oriented specimens cut to a 51 × 51 mm face size. A gas pilot was located at the top of the specimen, and was positioned at various distances in front of the specimen face. Three oven-dried cellulosic materials were tested: fiber insulating board (250 kg m^{-3}), Colombian pine (500 kg m^{-3}), and oak (700 kg m^{-3}). Their results for Colombian pine are shown in Figure 50. A smooth progression of ignition times is seen, increasing from the impinging condition to the 19.1 mm offset condition. For unpiloted ignition, a

fairly substantial increase in ignition time is seen, even compared to the farthest-away pilot condition. Increasing values of $\dot{q}''_{cr}$ with decreasing pilot effectiveness are clearly to be expected. But the ignition lines also show decreasing slope with decreasing pilot effectiveness. This effectively indicates an increase in $\lambda\rho C$ for far-away pilots or unpiloted ignitions. Under unpiloted conditions, a higher surface temperature will have to be attained before ignition occurs. Presumably, the effective thermal inertia is then higher under such conditions.

The pilot *height* above the top of a vertically-oriented specimen were explored by Muir[207], who found that the effect on ignition time was small until sizable heights (75 – 100 mm) above the top were reached. In a related study, Stockstad[188] used a horizontal tube furnace with very small specimens of unspecified size. For various wood samples, he found that no ignitions occurred up to the maximum furnace temperature of 460ºC if the pilot was located 10 mm or higher above the specimen. Ignition was always possible at a height of 5 – 6 mm, with decreasing probability of ignition for heights of 7 – 9 mm. Other studies comparing piloted ignition to autoignition of wood are reviewed in Chapter 14 under *Wood*. The *length* of a pilot flame does not have an effect on ignition time according to Muir[207], who used pilot flames from 10 to 50 mm long.

Another comparison between piloted and autoignition conditions was made by Starchville[189] who ran Cone Calorimeter tests on flexible PVC electrical tubing and rigid PVC electrical conduit (Table 25). Some estimates on the effect of presence of a pilot on the *minimum flux for ignition* can be made from this study. The steps of 10 kW m^{-2} are very coarse when it comes to minimum-flux studies, but the results are indicative nonetheless. For both the tubing and the conduit, the spark-ignition minimum flux can be taken as 15 kW m^{-2}; the unpiloted flux, however, is 35 kW m^{-2}. Comparing now the ignition times where ignition was achieved in both modes, for the PVC tubing, the spark-ignition times are about 70% of the unpiloted values. For the rigid conduit, the experimental data show a longer ignition time with spark than without. This anomalous result can be explained as being due to data scatter: all of this author's data represent only single trials.

Table 25 Ignition of PVC tubing and PVC conduit

Irradiance (kW m^{-2})	Flexible tubing Ignition time (s)		Rigid conduit Ignition time (s)	
	No pilot	Spark	No pilot	Spark
10	NI	NI	NI	NI
20	NI	375	NI	695
30	NI	210	NI	373
40	195	135	270	293
50	135	90		270
60		75		105
90		45		15
NI – no ignition				

A systematic study of the effect of pilot type was made by Wraight[190], although the study was limited to a single flux of 30 kW m^{-2}. Wraight used the ISO 5657 apparatus for his experiments. His test conditions were the following:

(1) no pilot
(2) a natural gas pilot flame, about 15 mm long and located 15 mm above the specimen
(3) a 0.27 mm diameter Nichrome wire, 40 mm long, located 15 mm above the specimen. The wire was carrying 5 A at 6.4 V.
(4) a 5 mm spark gap, using an 8-15 kV source and located 15 mm above the specimen.

The results are given in Table 24. The values given represent the mean of 3 (in two cases, 2) tests.

Table 24 Results for pilot-type experiments in the ISO 5657 test at a flux of 30 kW m^{-2}

Material	Ignition time (s)			
	No pilot	Flame	Hot wire	Spark
insulating fiberboard, white-finish, type A	31.7	26.7	32.0	30.0
insulating fiberboard, white finish, type B	30.0	21.0	26.0	27.5
insulating fiberboard, unfinished	20.3	9.7	14.3	15.0
hardboard	104.0	57.7	77.0	78.3
hardboard, FR	181.5	6.5	101.5	112.5
polystyrene foam ceiling tile	39.7	18.7	39.0	29.7

The results clearly indicate that, as expected, the autoignition times are always the longest. The hot-wire and spark ignition modes gave statistically indistinguishable results for all products. The flame ignition mode, however, showed a wide variation. For polystyrene foam and unfinished insulating fiberboard, the ignition time for flame mode was about ½ that for hot-wire or spark modes. For plain hardboard and for the two types of finished insulating fiberboard, the flame ignition times were about 20% lower than for hot-wire or spark modes. The FR hardboard clearly showed some special phenomenon, but the author was not able to investigate this. In a more limited comparison, Mikkola[191] compared two products in the ISO 5657 test, using the standard flame and an electric spark igniter. Unlike Wraight, Mikkola observed shorter times with the spark, the two values being 41 vs. 39 s and 5.6 vs. 4.1 s. Cain[192] tested 12 products in the ISO 5657 test and determined $\dot{q}''_{\min}$ for both piloted (flame) and autoignition conditions. His results (Figure 51) show that, on the average $\dot{q}''_{\min}$ for autoignition is 2.37× that for piloted ignition; the range was from 1.6× to 3.7×.

Harkleroad et al.[193] studied the ignition of vertical samples exposed to the radiant panel heat source of the LIFT apparatus, but using various non-standard pilot flame types and

locations. For a flame located 25 mm above the top of a particleboard specimen and 5 mm in front of its surface plane, they found that at low heat fluxes of 17 – 40 kW m^{-2}, ignition took place first in the gas volume above the specimen, and only some 10 – 40 s later flashed down to the face of the specimen. For heat fluxes in the range 13.7 – 15.4 kW m^{-2}, only an ignition of the gas volume above took place, flame never went close to the specimen face. The LIFT apparatus has a strong induced convective flow due to the close-by presence of the gas-fired radiant panel, thus the authors attributed the effect to the relatively high upward flow velocity of the boundary layer at the surface.

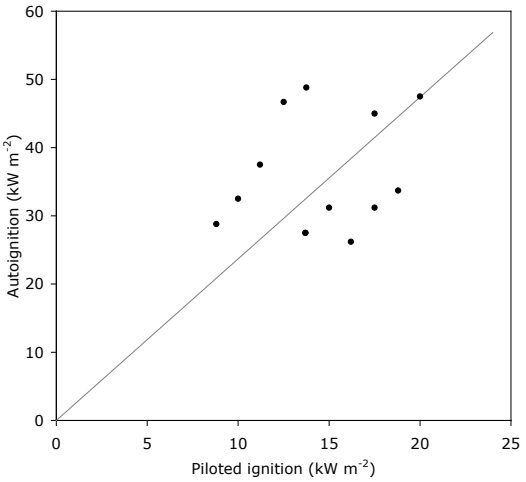

Figure 51 Minimum flux for ignition, as determined in the ISO 5657 apparatus for piloted and autoignition conditions

Shields et al.[195] obtained data for cellulosic products using both a gas flame and spark ignition. Their results can be summarized as:

$$t_{ig}(gas) = \left(1 - 0.00246\dot{q}''_e\right) \times t_{ig}(spark)$$

Thus, for example, at a flux of 50 kW m^{-2}, a gas pilot might be expected to produce 12% shorter ignition times. In a parallel study[80], the same investigators noted that the minimum flux for ignition did *not* decrease when a gas pilot was substituted for the electric spark and that, in the majority of cases it very slightly increased. The reason for this is not clear. The same investigators also compared the ignition times for autoignition and spark ignition, and their results can be expressed as:

$$t_{ig}(autoignition) = \left(2.86 - 0.0172\dot{q}''_e\right) \times t_{ig}(spark)$$

In this case, at a flux of 50 kW m^{-2}, if no pilot is used, ignition times can be expected to be 2.0× those for the spark-ignition case. Additional studies on piloting details and their effects on ignition have been reported by Amos[194].

The results from several of the studies discussed imply that a gas pilot can apply significant local heating to a specimen, even when it is positioned in a 'non-impinging' location. This was early recognized, and was the reason for the arrangement in the ISO 5657 test (see below) whereby a pilot is only periodically swung into position. Such an arrangement minimizes heating, but adds an uncertainty to the ignition time determination. Since part of a pilot flame's heat flux is imposed through radiation, a non-luminous flame, e.g., hydrogen, would be expected to minimize local heating. Thomson[2] explored the effects of a hydrogen pilot. She operated the pilot in two modes—located at a single spot, and hand-circled above the specimen. Her results for PMMA are shown in Table 26. It can be assumed that an electric spark imposes negligibly small heating on the specimen. Thus, even with a non-luminous hydrogen flame located a substantial distance above the face of the specimen, it is evident that when the pilot is fixed at a single location, local heating effects greatly perturb the measured ignition time. By contrast, when the hydrogen pilot is circled around, the ignition times no longer differ statistically from the spark ignition case. Since it is easy to set up spark ignition, but more difficult to carefully circle a hydrogen pilot flame at a fixed height, the recommendation is clear: *standardized piloted-ignition testing should use a spark and not a gas pilot.*

Table 26 Ignition times for 6 mm thick PMMA exposed to a heat flux of 25 kW m^{-2}

Pilot type	Ignition time (s) for height above specimen		
	5 mm	10 mm	20 mm
spark	116 4	112 6	135 5
moving pilot	110 6	105 5	124 8
fixed pilot	68 9	95 4	118 8

ORIENTATION

While materials can be arranged in highly diverse ways, most ignitability testing is done for samples which are either oriented horizontally, face-up, or else vertically. The convective environment for the two conditions is substantively different. For a horizontal specimen, air is entrained from all sides, and a relatively constant surface temperature is found across the face. For a vertical sample, a boundary layer is established, with the bulk of the flow being bottom-up. If the specimen is located in an ambient atmosphere of ambient temperature and is heated with a radiant heater, the air flowing by the face of the specimen will be of ambient temperature at the bottom, and will progressively warm up towards the top. This causes the face temperature of the specimen to be higher at the top than at the bottom; consequently, in some cases of marginal ignition it will be found that a flame will only go down partway on the sample.

During two Cone Calorimeter roundrobins, data on the effect of orientation on ignitability were obtained. Figure 52 shows this relationship, where the results can be correlated as:

$$t_{ig}(V) = 1.20\, t_{ig}(H)$$

There was no irradiance effect, since, if analyzed separately, the 25 kW m^{-2} tests showed a scaling factor of

1.19±0.09, while the ones at 50 kW m^{-2} scaled using 1.26±0.07. Shields et al.[195] also reported results on this point, but based only on tests carried out in a single laboratory and only on cellulosic materials. In their work, the vertical/horizontal ratio comes out to about 1.4. The fact that ignition times should be greater in the vertical orientation is not surprising, if we consider the relevant pyrolysate streams which are igniting. In the case of the horizontal specimen, there exists a roughly-pyramidal volume of pyrolysis gases, and a small electric spark located above the specimen's centerpoint can be situated in a region where a flammable mixture is easily established. In the case of the vertical specimen, a very thin sheet of pyrolysis products flows upwards along the surface. This may require a higher energy concentration due to its thinness, and it may also wander away from the fixed place of the igniter.

If a specimen is exposed in the horizontal, face-down orientation, the environment is somewhat stably stratified. It would be fully stable if the problem were 1-dimensional, but gases heated at the surface will flow across the face, and 'fall off the edge upwards.' A stratified environment does not allow ready mixing of fuel and oxygen, thus ignition should be much delayed. This is exactly what Shields et al. found in using the ISO 5657 apparatus upside-down. The ignition times in the face-down orientation were typically about 3× longer than those found for the face-up orientation. The minimum flux for ignition also rose increased about 3 – 4× compared to that for the face-up orientation. Thus, wood products which can normally be ignited at ca. 12 kW m^{-2}, were requiring around 45 kW m^{-2} for ignition. However, an opposite result was obtained by Moulen and Grubits[196]. They also used the ISO 5657 apparatus, but found ignition times for the face-down orientation to be somewhat *shorter* (Figure 53). Since these are the only two test series reported where these comparisons were made, it is hard to reconcile the opposing conclusions.

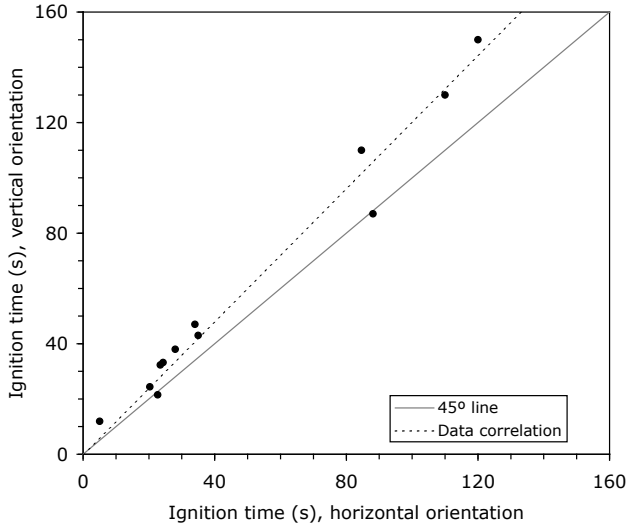

Figure 52 Relation between ignition times in the horizontal and in the vertical orientations, as determined from two Cone Calorimeter round robins

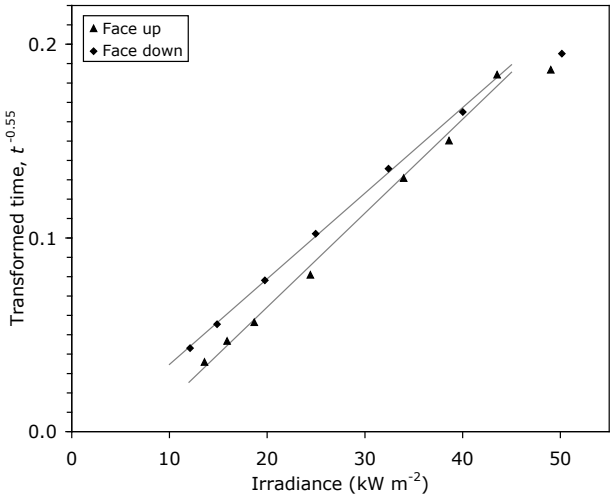

Figure 53 Results of Moulen and Grubits on the effect of orientation for the piloted ignition of hardboard

Materials may, of course, be exposed at angles which are not just multiples of 90º. Results were reported[197] wherein the ignition of PMMA was studied at various angular orientations, not just horizontal and vertical. The minimum ignition time was found to occur at an intermediate orientation (Figure 55). While an effect of irradiance is also seen, nonetheless the average ignition time in the vertical orientation is about 1.2 times that in the horizontal, which is exactly the same conclusion as found in the Cone Calorimeter round robin discussed above. The reason for the 30º position giving the fastest ignition times is presumably related to the details of the boundary layer that is formed above the specimen.

EXPOSED AREA SIZE

For vertical panels exposed in air to radiant heat flux, initially the panel will be at the room temperature and there will be no convective effect. As the face temperature rises, a difference in temperature between the room and specimen will arise, and this will result in a convective flow being induced past the face. The convective heat flux is not uniform along the height. The boundary layer that is formed is progressively thicker towards the top, so the cooling effect is progressively smaller. According to this effect, a tall panel will ignite first at the top, and a taller panel will ignite earlier than a shorter one. A convective effect will be absent entirely if the heat flux is so high that ignition is achieved before the boundary layer attains a steady state. For a specimen of 0.1 m height, it has been estimated that only at irradiance values > 200 kW m^{-2} will the convective effect be totally absent[39].

Apart from the problems of very small specimens or specimens heated only over small portions of their face, the

effects of size ought to be predictable from theory. Long et al.[46] noted that the only scale-dependent term in basic ignition theory is the convective heat transfer coefficient, h_c, which varies with size L according to $h_c \propto \frac{1}{L^{1/4}}$. The effect on ignition time is much smaller than the change in h_c, since heat losses are dominated by radiation. Long et al. estimated that for PMMA reducing the size by a factor of 3 would increase the total heat loss by about 4%. The slight increase in t_{ig} is counteracted by an increase in effectiveness of mixing fuel vapors into the air, since the mass transfer coefficient for this process also varies as $1/L^{1/4}$.

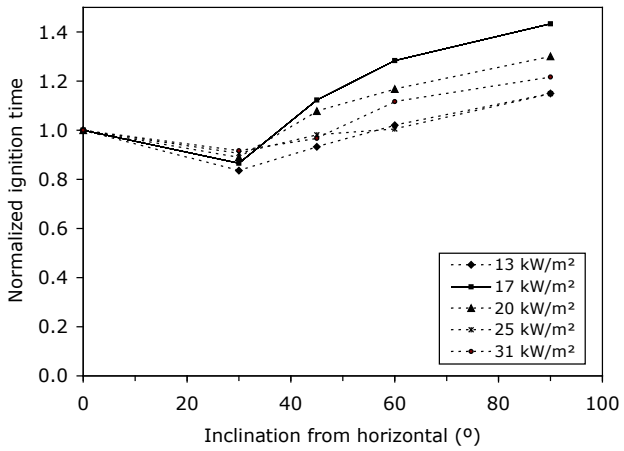

Figure 54 The effect of the angle of inclination on the ignition of 6 mm PMMA slabs

In practice, experimental results indicate that, provided minuscule sample sizes are not being considered, the convective effect is rather small. For example, Kashiwagi[115] examined the effect for PMMA and red oak at an irradiance of 60 kW m^{-2}. A slight decrease in ignition times was found for 150 × 150 mm samples, compared to 75 × 75 mm samples, but the effect was probably within the data scatter. Thomson[2] found that PMMA samples which were heated over a 19 × 19 mm area showed a T_{ig} of 338ºC, compared to 312ºC for samples heated over their entire 65 × 65 mm face area.

Simms et al.[198] showed that for large irradiance values, when the irradiated area was 3 cm^2 on a large-area specimen, the ignition times needed to be increased by 24% over those found when the total specimen face was irradiated. When the absorbed radiation (incident radiation × surface absorptivity) fell below 120 kW m^{-2}, the correction needed increased as shown in Table 27. Data at irradiances lower than 67 kW m^{-2} were not collected. For a 25 cm^2 irradiated area, and an irradiance of 120 kW m^{-2} or higher, the multiplying factor was only 1.03. For an absorbed radiation of 50 kW m^{-2}, the multiplying factor was 1.67. The values quoted are all mean values, and individual materials showed significant deviations from these values, especially for smaller values of absorbed radiation. A general-purpose correction scheme which would take into account the heat flux, the irradiated area, and the material thermophysical properties did not emerge from Simms' study. Also, an explanation did not emerge why the intensity of radiation should be a variable that affects the correction factor.

Hu and Clark[199] tested horizontally-oriented specimens in the ISO 5657 apparatus, using both the standard exposed specimen area of 0.0154 m^2 and a reduced area of 0.0016 m^2, in other words, an area reduced by about a factor of 10. Ignition times for the smaller-specimen size were consistently about 1.14× the values for the standard-size specimens. The 16 cm^2 smaller size is, of course, much larger than the 3 cm^2 areas examined at FRS.

A study with indirect findings was conducted at FRS in connection with ignitability of carpets[200]: actual ignitability was not measured, only onset of specimen melting. Two conditions were examined: a substantial irradiated area of 3000 mm^2, and a tiny area of 10 mm^2. At a given irradiance, it was found that the time to melting was 5 – 6 times longer when the tiny area was exposed, in comparison to the larger one.

Another exploratory study on the same topic was done by Clark[201]. He explored only one value of irradiance, 17 kW m^{-2}. In his arrangement, square specimens, located horizontally, face-up, were embedded in a sand layer. Investigation of heat flows showed that the sand layer adequately simulated samples of larger area, but only pyrolyzing over the actual given face area. In his tests, he first attempted spark ignition. If the spark ignition was unsuccessful after 10 min, a flame was applied at the surface. The results are shown in Table 27. For spark ignition of large irradiated samples, the value of $\dot{q}''_{min}$ for PMMA is about 8 kW m^{-2}; thus, Clark's tests were at about double that. Standard Cone Calorimeter PMMA samples will ignite at about 280 s at an irradiance of 17 kW m^{-2}. Thus, Clark's average value of 311 s is only slightly high. The 10×10 mm sample, however, while showing a modestly raised ignition time, is clearly borderline non-ignition, since 1 out of 3 specimens did not ignite. Thus, for 10×10 mm samples the $\dot{q}''_{min}$ is presumably around 16 kW m^{-2}. While the data are too few to draw general conclusions, the experimental results on wood can be of direct utility in application to fire investigations. If a wood item is thermally-thick, is at least 10 × 10 mm in

size, and is receiving at least 17 kW m^{-2} irradiance, then in the presence of a flame, ignition will occur.

Mikkola[191] compared ignition times in the Cone Calorimeter (100 100 mm specimens) to the ISO 5657 test (specimen exposed diameter = 150 mm). His results (Figure 55) show a heat-flux dependent relationship. There is a wide scatter of data, but for heat fluxes below 50 – 60 kW m^{-2}, the best-fit line is $\frac{t_{ig(ISO5560)}}{t_{ig(ISO5657)}} = 1.34 - 0.0052\dot{q}''_e$. The data would suggest that at larger heat fluxes the ratio becomes close to unity.

In a similar series of experiments, Nussbaum and Östman[202] tested 13 building products in the Cone Calorimeter and in a specially-constructed version of the Cone Calorimeter which was twice in scale, i.e., specimens of 200 × 200 mm were tested. Their results showed a different trend, as given in Table 29. The values at 75 kW m^{-2} are probably subject to more error than suggested by the standard deviation, since most products ignited in 6 s or less, and a shield was not used.

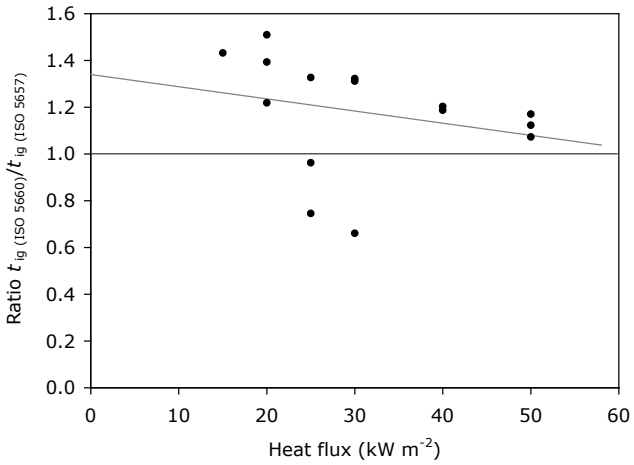

Figure 55 The relation between ignition time in the Cone Calorimeter and in the ISO 5657 apparatus

Table 29 Comparison between ignition times in the Cone Calorimeter and in a similar apparatus using larger, 200×200 mm specimens

Heat flux	Ratio of ignition times, small/large specimens
25	1.32 ± 0.57
50	1.35 ± 0.25
75	1.51 ± 0.34

For *thermally-thin* materials, very little information is available on the area effect. One study[203] concluded that for paper tissues irradiated with a tungsten-lamp source over a 6.5 cm^2 area, the minimum flux for ignition rose 14% from that needed for a large-area exposure.

AIR FLOW RATE

The role of air movement past an ignition specimen is complex. The simplest arrangement to consider is where a specimen is radiatively heated, and convectively cooled. In that case, increased air velocity past the specimen increases convective cooling and shows up directly as a heat loss term. But additional effects are: (1) increased air flow velocity can affect mixing and local concentrations of fuel and oxidizer in the gas stream; (2) for substances which ignite in a glowing mode, air velocity will directly affect the reaction rate in that process. Several studies exist where the effect has been investigated, and these are summarized below. The general guidance is that high velocities inevitably make ignition more difficult. A somewhat different situation pertains to the case of purely-convective heating, where the only source of heat to the specimen is a hot-air stream. This exposure condition was considered above.

In a crude early study, Lullin[204] measured the ignition temperatures of wood samples using a horizontal tube furnace. He found that an optimum flow velocity of 0.4 m s^{-1} existed, with smaller or higher velocities resulting in a higher reported T_{ig}. The specimens were heated at a low enough temperature that ignition of wood was a 2-step process, with an initial glowing ignition followed shortly by flaming. In similar, but better-controlled experiments, Graf[36] later tested a number of materials and found, for some materials, an optimum flow velocity of ca. 0.175 m s^{-1}. There was a great deal of scatter, and some material showed relatively constant T_{ig} values for all velocities below about 0.2 m s^{-1}, down to 0.04 m s^{-1}, which was the lowest velocity used. For velocities significantly greater than 0.2 m s^{-1}, T_{ig} values invariably increased. Bowes[205] used a vertical tube furnace to ignite sawdust and grass meal. Varying velocity over the range 0.003 to 0.03 m s^{-1}, he found no velocity

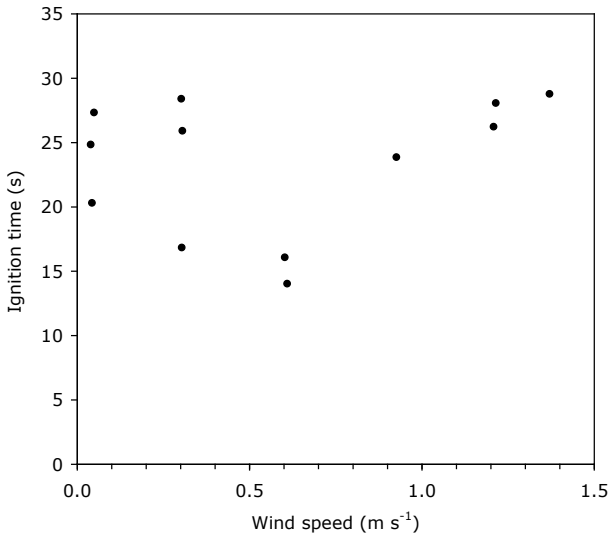

Figure 56 Effect of wind speed on autoignition of horizontally-oriented white pine specimens exposed to radiation from a solar furnace

effect. In a more typical radiant test arrangement, Atreya and Abu-Zaid[20] exposed wood specimens in a horizontal, face-up orientation. Increasing the wind speed from 0.1 m s^{-1} to 1.0 m s^{-1} raised the effective T_{ig} by about 40ºC (Figure 4).

Simms[206] measured the effect of a small draft on the autoignition of wood specimens. The draft did not change the ignition times, but did change the $\dot{q}''_{min}$. For blackened oak and cedar specimens, he found the minimum was 116 kW m^{-2} without a draft, but 100 kW m^{-2} with a draft for oak and 76 kW m^{-2} for cedar. The peculiarities of the experimental rig are unclear, however, since modern researchers have found minimum flux values several-fold smaller than 76 kW m^{-2}. Similarly, Kashiwagi[117] noted that ignition times were longer in still air than in a drafty room. Janssens[75] reported that effects of drafts can alter the results obtained in the ISO 5657 test for horizontally oriented specimens, but quantitative information was not provided.

Weatherford and Sheppard[8] used a test apparatus which subjects specimens to convective heating, efforts having been taken to minimize radiative contribution. In their rig, they found no effect on ignition time when varying air flow velocities over the range of 0.1 to 0.7 m s^{-1}. Muir[207] investigated the effects of air flow on the piloted ignition of vertically oriented samples. Wind speeds greater than 0.75 – 1.0 m s^{-1} led to substantial increases in ignition times. For smaller velocities, the effect was trivial, although at low irradiances (but not at high) he found a statistically-significant but shallow minimum. In one set of results, velocities of 0.2 – 0.3 m s^{-1} gave a slightly lower t_{ig} than did a zero velocity. Ulrich and Butcher[208] reported autoignition measurements on white pine (Figure 56) showing a similar shallow minimum which, in their case, was at around 0.6 m s^{-1}.

Bilbao et al.[209] studied the ignition of 19 mm thick pine specimens in an apparatus somewhat resembling the Cone Calorimeter, but using high velocities of air. The data plotted (Figure 57) all represent flaming, piloted ignition times; the authors also found that at non-zero velocities some flaming ignitions were preceded by a glowing ignition. The effect of an imposed velocity is to increase the convective transfer coefficient, h_c, which in turn raises the value of h_{eff}. The consequence is that increasing the velocity u (m s^{-1}) leads to (a) an increase in $\dot{q}''_{cr}$, and (b) an increase in B_{ig}. Unfortunately, no simplified technique has been developed for directly relating these changes to values of u.

Several studies of air through-flow have been reported for the Cone Calorimeter. In a NIST study[101], three exhaust-system flow rates were used: none, 24 L s^{-1}, and 41 L s^{-1}. Both horizontal and vertical orientations were examined for PMMA and redwood. No systematic effects were found of air flow rate over this range. In the above study, the normal open-air specimen configuration was used. No-exhaust conditions do not indicate zero air flow, since the cone heater alone creates a natural-convection flow, but no attempt was made to quantify this flow. In a similar vein, Thomson[2] examined the effect of whether an extract fan was or was not used with an experimental radiant ignition rig. Using PMMA and polypropylene samples, she also concluded that no effect could be found. Petrella[214] used a special fully-enclosed version of the Cone Calorimeter and again found no effect over the range of 9 – 24 L s^{-1}. Two studies have also been done by VTT on this subject. In the first study[215], no systematic difference was seen for data obtained at 24 L s^{-1} (in open air), as compared to 3 to 6 L s^{-1} (in an enclosed apparatus). In the second study[210], using flow rates of 0.67 – 6 L s^{-1}, longer ignition times were generally found with higher air flow rates, although the data showed a great deal of scatter. Combining results for nylon and polypropylene and excluding some evident outliers, a trend of the following kind can be seen:

$$t_{ig} \approx t_{ig,o}\left(1 + 0.094\dot{V}\right)$$

where $t_{ig,o}$ is a normalizing constant obtained by extrapolation to zero air flow and $\dot{V}$ = air flow rate (L s^{-1}). Thus, for example, a specimen which showed a t_{ig} of 200 s at a flow rate of 6 L s^{-1}, would be likely to show $t_{ig} \approx 140$ s at a flow rate of 1 L s^{-1}.

The OSU Apparatus performs rather differently. In that apparatus[101], PMMA specimens exposed at 35 kW m^{-2} ignited at 209 s with 12 L s^{-1} flow rate and at 403 s with 24 L s^{-1}. Chen[211] reported limited results with a modified ISO 5657 apparatus that used electric spark ignition and found that imposing an air velocity greater than 0.5 m s^{-1} led to longer ignition times than quiescent (< 0.2 m s^{-1}) conditions. Cordova and Fernandez-Pello[212] measured the effect

of an imposed flow velocity on the piloted ignition of PMMA using a wind tunnel apparatus. At zero imposed velocity, ignition took place when a mass loss rate of 1.8 g m^{-2} s^{-1} was reached, while imposing a velocity of 2.5 m s^{-1} doubled the required mass loss rate; at intermediate flow velocities there was a linear relationship between velocity and mass loss rate.

Even though the above list of studies is fairly long, it is difficult to establish firm trends. For velocities greater than about 0.5 m s^{-1}, it is evident that increasing velocity increases cooling and delays ignition. But for small velocities, reported effects are very diverse. The magnitude of the effects in this regime is generally not large, so a practical conclusion might be that velocities < 0.5 m^{-1} do not significantly affect the outcome.

OXYGEN CONCENTRATION

Piloted ignition of a solid might very roughly be considered as occurring when the LFL of a pyrolysate/air mixture is first reached, while autoignition of a solid might be considered to involve the autoignition of pyrolysates. Thus, the effect of oxygen concentration could be anticipated to be different in the two cases.

Both modes of ignition may, in principle, be affected if surface oxidation of the solid is involved. As discussed above, for most materials it is considered appropriate to use an inert-heating model of the solid. The pyrolysates may be generated at a faster rate than expected if oxidation of the solid material is appreciable. The effect is small for most substances, but if the material is capable of glowing combustion (e.g., wood), then the role of oxygen concentration on its pyrolysis rate may have to be considered. For white pine, Kashiwagi et al.[213] showed that, heated at a flux of 40 kW m^{-2}, it showed a peak MLR of 12 g m^{-2} s^{-1} in at O_2 = 21%, 9.5 g m^{-2} s^{-1} at O_2 = 10.5%, and 6.2 g m^{-2} s^{-1} at O_2 = 0.

PILOTED IGNITION

Since the LFL of gases is normally unaffected by varying oxygen concentration over a wide range, it might also be expected that oxygen concentration is not an important variable affecting the piloted ignition of solids. Petrella[214] tested polystyrene and PMMA in the Cone Calorimeter and found that t_{ig} was independent of oxygen concentration. Using an early-identical apparatus, Mikkola[215] tested 6 different materials at 21% and 15% oxygen with a heat flux of 50 kW m^{-2}. Apart from PVC, an average ignition time of 24% higher was found at 15% O_2, compared to values at 21% O_2. PVC was clearly very much affected by O_2 concentration, since the ignition time at 15% O_2 was some 3× as long as at 21% O_2. Interestingly, the results for wood particleboard were essentially identical to those for nylon, polystyrene, and other thermoplastics—a modest rise only. A follow-on study at the same institution[210] examined nylon and polypropylene in more detail and gave the results

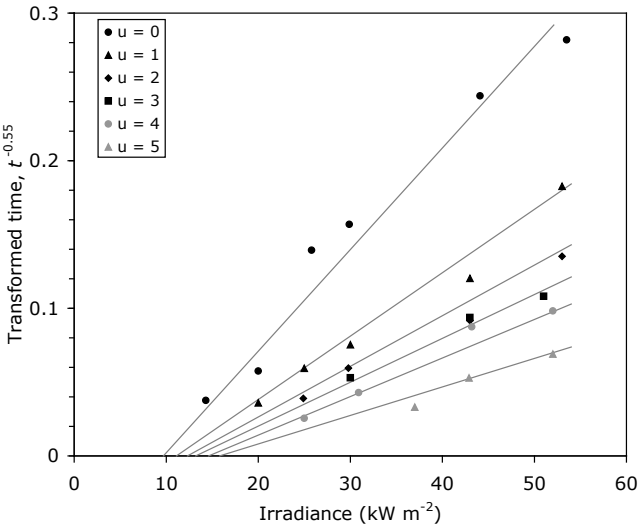

Figure 57 Effect of wind speed on the ignition time of pine

shown in Figure 58. Data obtained by Hirsch et al.[216] on a PVC/acrylic copolymer and on an intumescent FR PUR foam again showed that there is nearly no effect until oxygen concentration approaches its MOC value, at which point ignition times increase precipitously. PMMA shows little variation, down to the lowest flux (15 kW m^{-2}) examined[217]. Results on silicone elastomers[218] showed similar results. Additional data have been collected in a NASA report[219].

AUTOIGNITION

If autoignition of pyrolyzing solids is viewed as occurring when that AIT is first attained for a volume of pyrolysate gas mixed with oxygen, the same relations should hold as

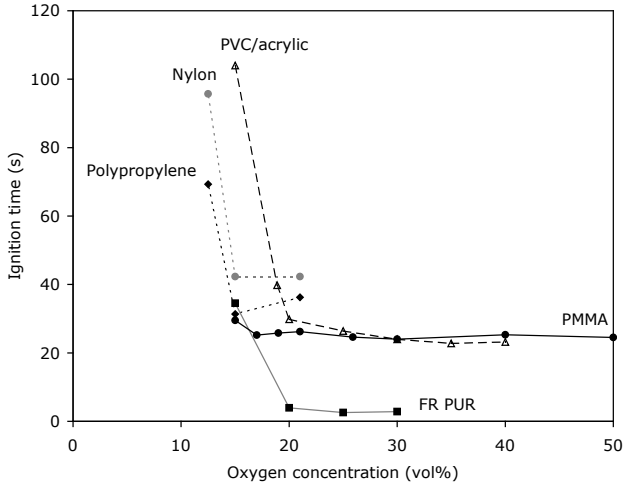

Figure 58 Effect of oxygen concentration on the piloted ignition of several plastics tested at a heat flux of 50 kW m^{-2}

for the AIT of gases. Unfortunately, as seen in Chapter 4, there is a wide spread of results on this point. If it is further assumed that ignition will not involve cool flames or two-stage ignitions, then

$$t_{ig} \propto \frac{\text{constant}}{Y_{O_2}^n}$$

where Y_{O_2} = oxygen mass fraction, and the exponent n is probably somewhat less than 1.0.

Kashiwagi's early model of radiant autoignition[51] predicted a minimum value for the mass fraction of oxygen, Y_{O_2}. This minimum depended on the exact problem being solved, but was often in the vicinity of 0.15. For Y_{O_2} just slightly higher than this minimum value, there was a very narrow range, where ignition time went from infinite to a modest value, as Y_{O_2} was raised slightly. For further increases in Y_{O_2}, the ignition time varied as:

$$t_{ig} \propto Y_{O_2}^{-0.068}$$

Because this dependence on Y_{O_2} is very slight, the result was that the ignition time dropped only about 15% as Y_{O_2} went from 0.23 to 1.00. Alvares[27,220] found a similar behavior in experimental studies on thin cellulose sheets. His results (Figure 59) show that for a partial pressure greater than about 0.18 atm (i.e., from just below ambient) there is a slight effect going as $t_{ig} \propto P_{O_2}^{-1/4}$. However, if the oxygen partial pressure is decreased below about 0.18 atm, ignition times become drastically prolonged and ignition becomes impossible once the partial pressure drops below about 0.16 atm. Nakamura et al.[60] computed the ignition behavior of the same material using a sophisticated axisymmetric, 2-dimensional numerical model, but their results were only qualitatively in line with Alvares' experimental findings.

Ohlemiller and Summerfield[221] examined the ignition of epoxy using enormous (800 – 4000 kW m^{-2}) heat fluxes from a laser. At the low end of this heat flux range (< 1600 kW m^{-2}) ignition time at an oxygen concentration of 43% were slightly longer—but barely more so than the data scatter—as compared to times at 100% oxygen. On the other hand, also using a laser source, Beckel and Matthews[222] found that increasing oxygen fraction over the range of 20 – 100% had a strong effect in reducing the ignition time.

FRS studied the ignition of blocks of wood and sawdust in a tube furnace which incorporated a forced air stream[223]. For 10 mm cubes of wood, they reported that T_{ig} at autoignition dropped from 380ºC to 270ºC when air was replaced with pure oxygen. On the other hand, for sawdust cubes the drop was much smaller, from 310ºC to 280ºC. Moghtaderi[224] showed that for wood, over the range of 14 – 21% O_2, increased oxygen concentration led to shorter ignition times; furthermore, the effect was more pronounced for pre-charred samples. For plastics, the reported effects are inconsistent. Marzani[234] found that changing from an air atmosphere to one of pure O_2 has a negligible effect (5 – 10ºC) on the AIT. On the other hand, Paciorek et al.[225] investigated the difference between AIT values for several materials in air, versus in oxygen, and their results, summarized in Table 30, show large differences. Delfosse[226] examined the autoignition of PVC and found that T_{ig} dropped from 600ºC at 21% to 475ºC at 50% oxygen.

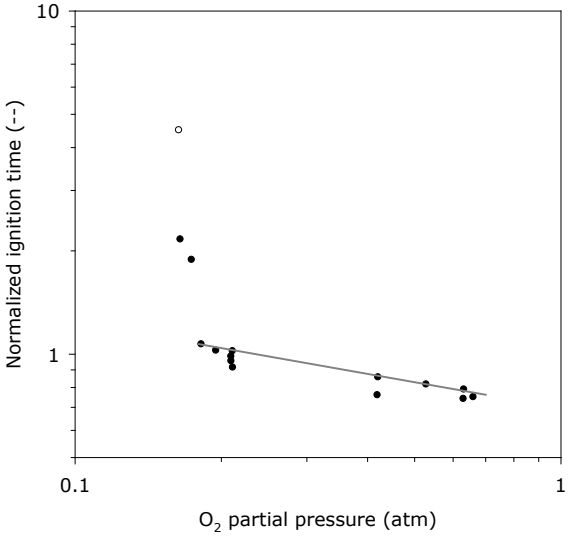

Figure 59 Effect of O_2 partial pressure on the autoignition of cellulose

CHEMICAL COMPOSITION OF DILUENTS

Accidental ignitions in oxygen/nitrogen atmospheres can readily be encountered where the O_2 concentration is not 21%, as discussed above. On rare occasions, accidental ignitions may take place in atmospheres where the diluent is not nitrogen, or is not wholly nitrogen, for example, CO_2 or helium. This has been of some interest to NASA and a review paper is available on this topic[227].

TOTAL PRESSURE

The total pressure affects gas-phase reactions, and it lowers both the AIT and MIE of gases (see Chapter 4). Thus, these same effects may also be expected to manifest themselves in the ignition of fuel vapor/air mixtures pyrolyzed from

Table 30 Effect of oxygen concentration on the AIT of several materials studied by NASA

Material	AIT (ºC)	
	In 21%	In 100%
Fluorel KF 2140	630	400
paint 45B3	495	365
polyisocyanurate foam	> 600	350
PTFE	575	510
Refset	> 610	380

solids. In addition, the total pressure may affect the autoignition of a material indirectly by its effect on the lower flammable limit, but for many materials, over a fairly wide range of pressures, the lower flammable limit is not significantly affected by total pressure[228].

Hermance[229] presented a theoretical model for the autoignition of polymers where the pressure effect is included. His numerically-computed results indicated that $t_{ig} \propto P^{-1/2}$. He did not present any experimental data to validate his theory, but there does exist a limited number of experiments on the effect of pressure for common solids. Kishore and Sankaralingam[230] studied the autoignition of polymers using a DTA apparatus, which is not the best equipment for the task. They found a modest decrease in T_{ig} with pressure, for example, a PVC specimen that ignited at 469ºC at 1 atm, ignited at 394ºC at 21 atm. Wharton et al.[231] also used a DTA technique and obtained similar results for several materials but the opposite result for Neoprene—for this material, raising the pressure increased the T_{ig}.

Attwood and Allen[232] tested 60 mg samples of nylon 6,6 in pure oxygen atmospheres at total pressures of 11 and 131 atm. The ignition temperature at 11 atm was 350ºC, dropping to 300ºC at 131 atm. For several silicone elastomeric materials, however, the order was reversed, with specimens showing a higher T_{ig} at the higher pressure. Wolf et al.[233] studied the ignition of PVC in a pure-oxygen atmosphere and found a marked decrease in T_{ig} with increasing pressure, but they did not quantify their results. Marzani[234] ignited several plastics in a heated bomb at various pressures and using both air and pure O_2. For polyethylene in air, the AIT dropped from 193ºC at 68 atm to 182ºC at 170 atm. But at a pressure of 34 atm or lower, no ignition occurred, up to a maximum bomb temperature of 426ºC. In an O_2 atmosphere, the AIT dropped from 185ºC at 13.6 atm, down to 179ºC at 102 atm, and no ignition was achieved at 6.8 atm or lower. These temperature differences within the 'ignitable range' are trivial, but the existence of a 'non-ignitable range' of pressures is noteworthy. Marzani did not conduct ambient-pressure ignition tests, but the data in Chapter 15 show AIT values in the neighborhood of 400ºC. Thus, it appears that at a certain elevated pressure the AIT drops precipitously by roughly 200ºC. Kuzminskii[235] studied the effect of pressure on the ignition of rubbers in O_2 atmospheres. The AIT for natural rubber dropped from 161ºC at 5 atm to 142ºC at 120 atm. For various synthetic rubber types produced in Russia, the effect was similar or somewhat smaller. Pippen and Stradling[236] tested a number of solid aerospace materials in a flash point tester designed for high pressures and 100% oxygen concentration. The flash point typically dropped 100 – 200ºC as the pressure was raised from 1 atm to 100 atm. Changes in fire point were also quite similar, although a number of the materials did not show sustained burning at all until 1.6 to 3.4 atm was reached.

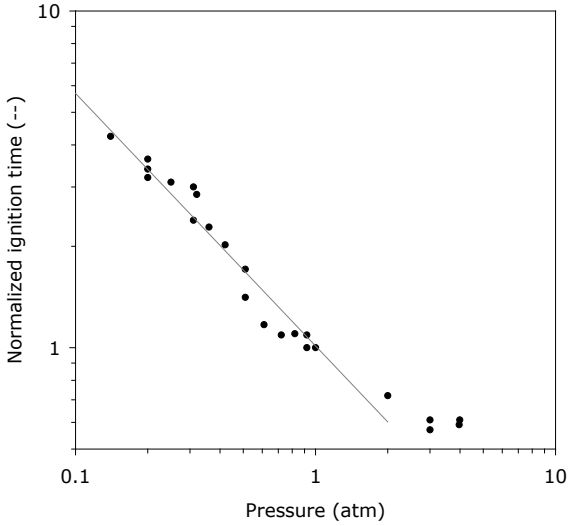

Figure 60 Effect of total pressure on the autoignition of cellulose

Bolod'yan et al.[237] studied the piloted ignition (using a glow coil) and subsequent flame spread of various fabrics in atmospheres of elevated pressure. Plain cotton (and for PMMA) fully burned up at oxygen concentrations below 21% and over the entire pressure range used, 0.1 – 10 MPa. But FR fabrics, including FR cotton and carbon-fiber, and aramid, showed an inverse relationship between pressure and needed oxygen concentration. At ambient pressure, concentrations ca. 40% were needed, but the needed concentration dropped to 15 – 18% as pressure was raised to 10 MPa. In a similar vein, Hirsch and Bunker[238] found that materials such as PTFE and Kel-F which, when ignited with a glow wire but not provided with external heat flux,

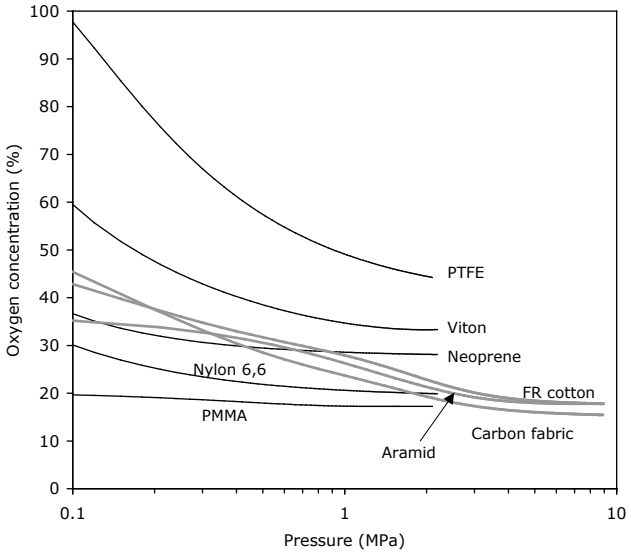

Figure 61 Relation between oxygen concentration and pressure needed for sustained flaming of several materials; data of Benning shown in black, Bolod'yan in gray.

do not burn in 100% O_2 at ambient pressure, do burn in an oxygen atmosphere at 7 MPa. Benning[239] presented similar data for Neoprene, nylon 6,6, PMMA, PTFE, and Viton over the range 0.1 – 2.0 MPa. A summary of trends is shown in Figure 61.

Alvares[220] used an arc furnace to ignite sheets of cellulose at various pressures. His ignition time results, normalized to ignition time at 1 atm, are shown in Figure 60. The fitted line represents $t_{ig} \propto P^{-3/4}$ and is seen to give a good fit for pressures less than 1 atm. At higher pressures, the effect becomes much smaller and it appears that by 3 or 4 atm the effect may be nil.

The topic has been more extensively researched (although not yielding up simple answers) in connection with the ignition of propellants, and this is taken up in Chapter 10. But propellants are not commonly studied in a piloted ignition mode, and there do not appear to be any studies on pressure effects for the piloted ignition of common solids.

MOISTURE AND RELATIVE HUMIDITY

Moisture content could simply be measured as the percent of the total mass of a specimen that is comprised of water. This is done in certain trades and industries, but most commonly, moisture content (MC) is measured on a dry basis. Thus,

$$MC = \frac{\left(W_{wet} - W_{dry}\right) \times 100}{W_{dry}}$$

where W_{wet} = mass wet and W_{dry} = mass dry. This requires using a standard procedure for drying the sample. Typically[240] the specimen is dried in an oven at 103±2ºC until it equilibrates to a constant mass; for specimens of modest size, a 24 h period often suffices. Results are occasionally cited as "xx% ODW," where ODW makes explicit that oven-dry weight was used as the basis. MC values may be greater than 100%, and living vegetation commonly shows values over 100%.

Yuen et al.[241] presented a theory for pressure effects on autoignition of thin materials, but it involves solely a glowing ignition mode.

In 1956, the US Forest Service conducted a study[242] where they examined the relation between the frequency of building fires and moisture, the latter assessed as the equilibrium moisture content of fine fuels. The results (Figure 62) show a very strong effect, with frequency, on the average, being 2 – 6 times greater during the driest periods than the wettest. If the study were repeated today, most likely the effect would be found to be less, since during the study period in the 1940s, a majority of the combustibles were cellulosic; today, a sizable fraction of the fuel load is comprised of man-made polymers, and the majority of these are not hygroscopic. It should also be kept in mind that intervening variables (e.g., use of heating during certain times of year)

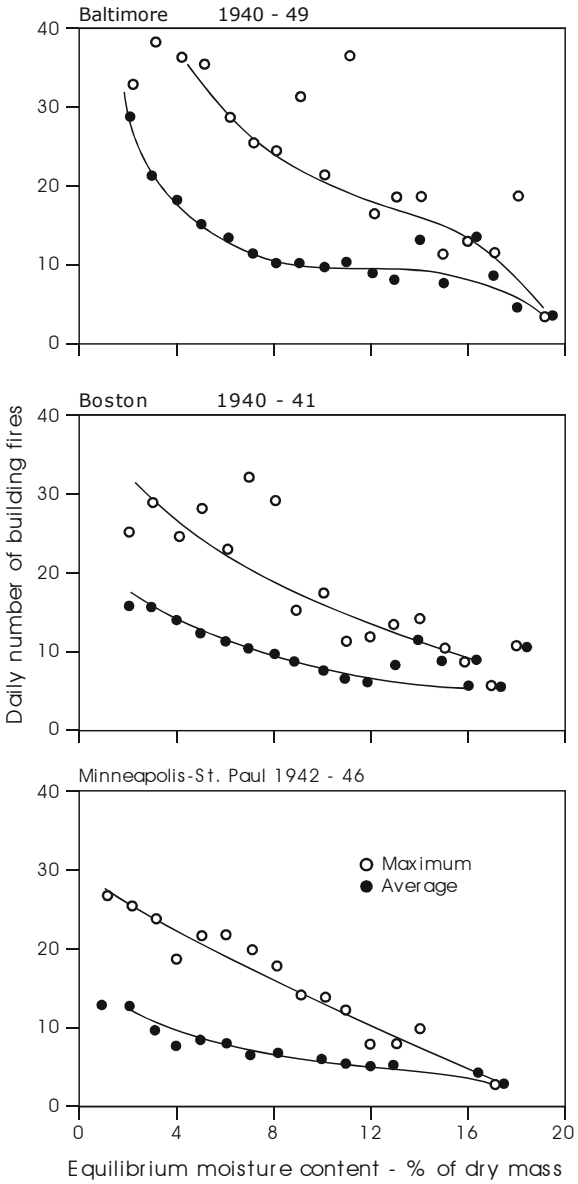

Figure 62 Relation between frequency of building fires and equilibrium moisture content of fine fuels

were not accounted for. Finally, whether a building fire gets reported is influence by flame spread and not by ignition alone. Nonetheless, the trends are striking and suggest that moisture effects should not be overlooked.

The effect of RH on ignition is mostly due to the effect of humidity on the equilibrium moisture content of solid ignitable materials. Few synthetic materials are so affected ('hygroscopic'), but many natural materials of significant interest are hygroscopic: wood and various agricultural products being the most notable examples. The relation between relative humidity and equilibrium moisture content is complex and non-linear; in addition, hysteresis is involved, that is, the adsorption curve is not identical to the desorption curve. These curves are different for various

substances, but for rough purposes, it has been proposed[242] that most cellulosic materials can be roughly represented by a single curve (Figure 64).

The average equilibrium values of moisture in different regions of the US are shown in Figure 63[243]. There is gross variation of about 2:1 between the 'wet' and the 'dry' regions. In addition to the gross climatic differences, there are seasonal differences and smaller-area variations. For example, Peck[244] found moisture contents during the summer of 4% in Salt Lake City and 13.5% in New Orleans. Lumber *outdoors* equilibrates to 12 – 18% MC. *Green wood* is at 50 – 150% MC, depending on the species and on whether heartwood or sapwood is considered. Paints and varnishes applied to wood, even if applied on all sides, delay effects of environmental RH, but do not significantly alter the moisture content to which the piece of wood will equilibrate[244].

The effects of moisture on the ignition of solids can be both in the solid phase and in the gas phase. If a substance is exposed to a high heat flux, so that ignition takes place while moisture still exists in the interior, some of the moisture will be driven out along with the pyrolysates (but some will leave through the back face). This will dilute the fuel vapors and consequently make it more difficult to reach a flammable mixture, but the effect is likely to be small compared to solid-phase effects. Within the material, moisture affects the thermal conductivity and the heat capacity, consequently raising the $\lambda\rho C$. In addition, the endothermic contribution of the heat of vaporization must be considered. This is all possible to track with models that are based on a porous, moist body concept, such as those of Yuen[56] or Moghtaderi[245]. These models require extensive numerical calculations and do not lend themselves to any simplified solutions.

Experimentally, it is found that increasing the moisture content tends to raise the ignition temperature, based on the few available studies. Abu-Zaid[67] found that the autoignition temperature of wood rises was 40ºC higher for MC = 17% specimens, compared to oven-dried ones. Janssens[76] concluded that the piloted ignition T_{ig} of wood rises by 2ºC

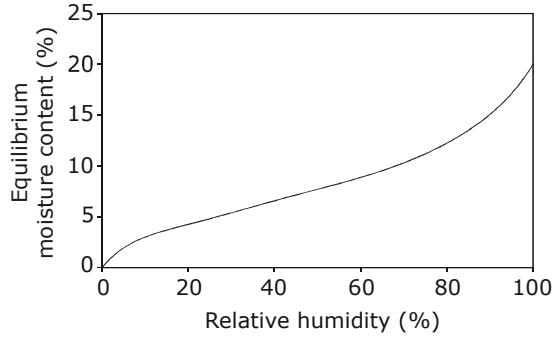

Figure 64 Approximate relation between relative humidity and equilibrium moisture content for fine, cellulosic fuels at room temperature

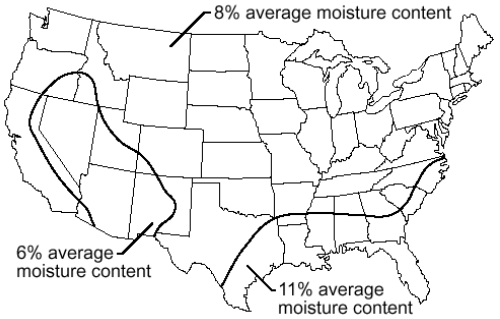

Figure 63 Average equilibrium moisture content of wood indoors, as a function of geographic location in the United States; the southern California coast, up to the San Francisco Bay region, is also at approximately 11% average moisture content.

for each percent of moisture content increase. Both these studies involved fluxes high enough that the specimens were presumably not fully dried out by the time of ignition. At low enough heat fluxes, there should not be a moisture effect since the moisture will be all gone by the time of ignition.

For the ignition of thermally-thin materials, Pickard and Wraight[246] proposed that the MC effect be approximated as an additive term to the ignition time:

$$t_{ig} = t_{ig(dry)} + \frac{\Delta h_{vap} L \rho_o MC}{\alpha_s \dot{q}''_e}$$

where L = thickness (m), ρ_o = dry density (kg m^{-3}), h_{vap} = heat of vaporization of water (kJ kg^{-1}). In tests on cellulose paper, the authors found that the relation was well obeyed for very thin specimens, but less so for specimens greater than about 0.5 mm. Duvvuri[247] showed that for thermally-thick materials, the increase in ignition time also depends on the same variables. But clearly the entire thickness will not be desiccated prior to ignition if a fairly high heat flux is applied. Thus, it may be reasonable to replace h_{vap} with some as-yet unknown parameter a:

$$t_{ig} = t_{ig(dry)} + \frac{aL\rho_o MC}{\alpha_s \dot{q}''_e}$$

Duvvuri's data did not span a wide enough heat flux range to test the above equation, but experimental data from Moghtaderi et al.[21] on intermediate thickness (9 mm) wood specimens show (Table 31) that a is not a constant, but rather decreases strongly with flux. This is not surprising, since at higher fluxes the thermal penetration depth at the time of ignition is smaller, consequently less material needs to be dried out. Agreement with experimental results can be obtained if the following form is taken for a:

Table 31 Piloted ignition times of Monterey pine as a function of moisture content

Heat flux (kW m^{-2})	Ignition time (s)			
	0% MC	15% MC	22% MC	30% MC
20	179	295	420	540
30	19	52	67	93
40	9	18	30	36
50	5	11	11	19
60	3	7	9	11

$$a = 33{,}200\left(\dot{q}''_e\right)^{-2} - 8.7$$

Moghtaderi[248] himself proposed a simpler equation:

$$\frac{t_{ig}}{t_{ig}(dry)} = \left[1 + 0.035MC\right]^2$$

which gives predictions accurate to about a factor of 2. Neither equation has been tested against other materials, so a wider applicability must not be assumed. Simms and Law[249] reported some results on the effect of moisture on the ignition times of wood, both piloted and autoignition. But their heat flux range used was very small, making trends difficult to quantify. Examination of a large set of Cone Calorimeter piloted ignition results showed that differences between ignition times at 0% and at 12% MC are small enough that they are swamped by data scatter[37].

At high heat fluxes, it has been demonstrated for wood[245] that no significant drying occurs at heat fluxes greater than about 35 kW m^{-2}. Conversely, near the minimum flux, the material has very substantially dried out prior to ignition. The latter fact leads to the conclusion that the minimum heat flux should be independent of MC. The sole existing study on topic, by Simms and Law[249], however, produced contrary findings. In their study, $\dot{q}''_{\min}$ for piloted ignition was higher by about 20% for wood with MC = 40%, as compared to oven-dry wood; for autoignition it was higher by about 28%, with the increases being roughly linearly proportional to MC. But these findings would appear to be an experimental artifact due to their short test duration, it being known[287] that some very long test times are needed to reach a true value of $\dot{q}''_{\min}$.

Apart from a few studies on wood, there is very little data on moisture effects. The effect of RH—rather than MC directly—on the ignition of fabrics has been studied[250]. For a 94 g m^{-2} 100% cotton T-shirt fabric, lowering the RH from 90% to 10% dropped the ignition time from 5.4 to 3.1 s under a radiant flux of 23 kW m^{-2}. For an 97 g m^{-2} cotton flannel, however, the change was smaller, going from 5.4 to 4.2 s. For a polyester/cotton blend, there was no significant effect on ignition.

INITIAL TEMPERATURE OF SPECIMEN

Fons[9] examined the effect of varying initial temperature between 10 and 66ºC on the ignition time of ponderosa pine when subjected to thermal immersion testing by insertion into a hot oven. The effect was found not to be significant.

When electric wires and cables are in use, they will generally operate at some temperature above the ambient. Standards bodies such as UL and IEC consider that electrical insulation materials that are used for wires, cables, and other similar applications have an insulation rating temperature, which is the maximum temperature to which the insulation can be exposed for an extended period of time. Since this temperature may be substantially above room temperature, it may be hypothesized that ignitability behavior would be different for specimens at the in-use temperature than at 20º – 25ºC. Lupton et al.[251] conducted a study to determine the effect that running tests at a wire's rating temperature would have on results from testing with a small open flame. They found cases where materials which did not spread flame upwards at ambient temperature did so at the rating temperature; however, the investigation was only exploratory and general guidance could not be evolved. In a similar study, Rodak et al.[252] tested wires used in NASA applications with a small-flame exposure, and found that ignition times decreased when specimens were preheated to elevated temperatures. Again, the study was only exploratory and no systematic guidance resulted.

Baer and Ryan[253] studied the radiant ignition of a propellant comprised primarily of ammonium perchlorate and polysulfide. For heat fluxes in the range 75 – 420 kW m^{-2}, they found that ignition times fell by 50%, as the initial sample temperature rose from –60ºC to +60ºC.

ACCELERATION OF GRAVITY

Older experiments have suggested that the ignitability of a material is not significantly affected by a lowered gravity or by micro-gravity conditions[254]. This is in agreement with the findings of Strehlow and Reuss[255], who concluded that gravity has but a minor effect on the LFL. However, more recently it has been reported[256] that autoignition of paper occurs more readily in micro-gravity. This is understood to be because, in the absence of significant gravity, pyrolysis products are not swept away by convection from the face of the specimen and, thus, a flammable concentration can build up earlier[257]. A recent theoretical study[60] on thin, horizontally-oriented fuels concludes that lowering the acceleration of gravity has a slight effect on promoting autoignition.

SURFACE ABSORPTIVITY, MATERIAL TRANSPARENCY, SURFACE COATINGS, AND SPECTRAL CHARACTERISTICS OF THE RADIANT SOURCE

When a radiant heat flux is incident upon the face of a material, in the general case, the heat flux is apportioned into three ways:

1. absorbed by the material
2. reflected from the face

3. transmitted through the material

Only the portion of the flux which is absorbed by the material can be used to raising its temperature. Thus, most theoretical models are formulated in terms of absorbed, rather than incident heat flux. To know the portion of heat flux which is absorbed requires knowing the material's surface absorptivity. This is not a constant and, rather, depends on the wavelength of the radiation. All radiant sources, apart from lasers, emit radiation at a variety of wavelengths, but the wavelength distribution is controlled both by the temperature of the source and by other factors (e.g., whether the source is a flame or a solid substance heated to a high temperature). Thus, to know the percent of incident flux absorbed requires knowing both the spectral energy distribution of the source and the material's absorptivity, as a function of wavelength.

Thermal radiation in accidental fires comes primarily from two sources: (1) molecular and soot radiation from flames; and (2) radiation from solid surfaces (e.g., walls) that have been heated by fire. The latter radiate similarly to a black body at the given temperature, although they will not be fully black, that is, the emissivity will be less than 1.0. Two black body sources and an exemplar fire source, hexane pool flames, are shown in Figure 66. Room fires with ordinary combustibles will normally not exceed about 1200ºC. Much higher temperatures are found only for fires of metals, in pure-oxygen systems, and other specialized applications.

Considering now the effect of surface absorptivity α_s, a material will have an absorptivity between 0 and 1. For opaque materials other than shiny metals, the value will normally be much closer to 1 than to 0. The absorptivity is a function of the wavelength of the absorbed radiation, and most real substances show a curve which is quite non-uniform. The fact that a substance has a white color only indicates that its absorptivity *in the visible portion of the spectrum* is quite low. For real fires (as contrasted to arc lamps and similar sources), the emitted radiation is primarily in the infrared, not the visible, part of the spectrum. Most 'white' materials are, in fact, of rather high absorptivity in the infrared. Hallman[71] measured the spectral absorptivity of a wide array of plastics and some other commodities. An example is shown for different types of PMMA in Figure 65. For all grades, the absorptivity at wavelengths greater than 2.4 μm is essentially constant at about 0.93. But over the visible spectrum (0.4 to 0.7 μm), the three color types differ greatly. Black PMMA shows an absorptivity of about 0.95, white about 0.3, and clear ≈ 0.

To obtain the integrated value of the absorptivity, Hallman integrated the values of the spectral absorptivity of the materials over the emissive power curves of several sources, as given in Table 32. The results, not surprisingly, show that the absorptivities are nearly identical for the 1000 K black body and the hexane flames, but grossly different for the 3000 K black body. The 3000 K temperature is similar to the temperature of tungsten lamps, so those results could be used to assess experimental studies done with tungsten lamps.

The surface absorptivity of woods was studied by Wesson et al.[105]. For a wide variety of wood species, they found that $\alpha_s = 0.76$ when the source radiation is that of flames. For tungsten lamps operating at 2500 K, Wesson's α_s values ranged from 0.41 to 0.56, with most species being 0.44 to 0.49. Spectrophotometer measurements which are made at room temperature cannot reflect the actual situation of a pyrolyzing solid being degraded in the process of igniting. A number of materials, especially wood, change from a light color to a dark one prior to ignition. This means that the actual absorptivity is dependent on the temperature of the surface which, in turn, depends on the time. For numeric analysis purposes, the effective value will be some value intermediate between the one at room temperature and the one at ignition. Janssens[75] concluded that $\alpha_s = 0.88$ tends to characterize well most woods as they are raised from room temperature to ignition by being heated from a heater having spectral characteristics similar to that of fires.

It is not necessary to know α_s in order to accurately and realistically measure the radiant ignitability of a specimen, provided that the heater in the test apparatus has radiant emission characteristics roughly similar to those of real fires. With this consideration in mind, most fire test equipment designed in the last few decades have used heat sources which are either actual flames, or else are electrical heaters running at 1200ºC or less. During the 1950s and '60s, however, many research studies, especially for the military, were done with apparatuses using tungsten/quartz lamps (effective temperatures ca. 3000 K) or with arc sources, which have an even higher effective temperature. These sources radiate primarily in the visible portion of the spectrum, not in the infrared.

If a test exposure is conducted using an apparatus radiating primarily in the visible portion of the spectrum and it is desired to apply the results to building fires, then one of two things must be done: (1) blacken the surface; or (2) determine the value of α_s pertinent to the spectrum of the heater and correct to a value pertinent to the spectrum of fire. Blackening the surface is not without its drawbacks, since it is not feasible to make a surface black without changing its other characteristics. Typically, blackening is done by applying a coating of some type of soot. Black paint is rarely suitable, since its organic components may contribute to the ignition process. To be effective, the soot layer has to have some minimal thickness, but this then means that there has now been placed an intervening layer in front of the specimen's surface. The intervening layer may change the effective thermal inertia of the substrate.

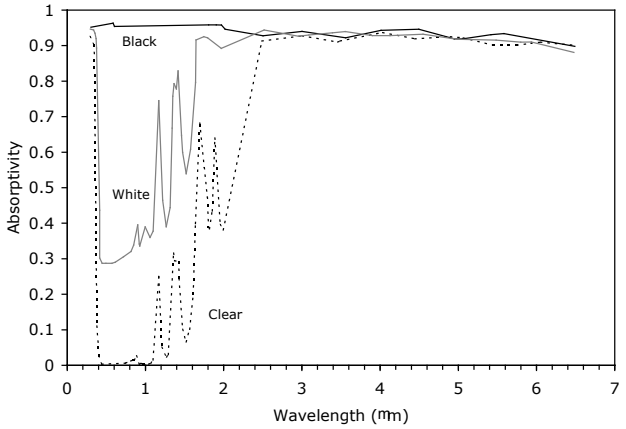

Figure 65 Spectral absorptivity of different types of PMMA

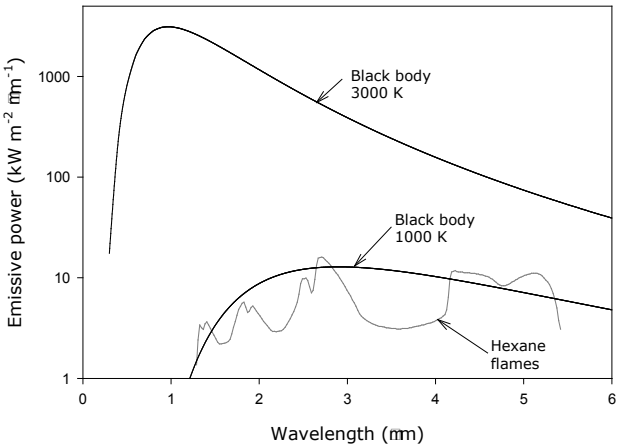

Figure 66 The spectral emissive power of various sources

Issues of surface conditions become important when considering data from the FMRC Flammability Apparatus (see below). In that apparatus, the heat is produced by tungsten/quartz lamps which reach up to ca. 2200ºC. This is much higher than fire temperatures, and in addition, the quartz envelope cuts off all radiation beyond about 4 μm. To address the problem of a spectral distribution strongly biased away from the infrared and towards the visible, FMRC adopted a test protocol of coating the specimen face with a thin layer of graphite powder. The layer of graphite is assumed to have an emissivity very close to 1.0 over the entire radiant spectrum. To examine the effect of a graphite coating, FMRC obtained data[258] comparing the ignition of 25 mm thick black PMMA with identical samples which were coated with graphite (Figure 67). The data show that the uncoated results fall very close to a straight line on a $t^{-0.55}$ plot. The coated results, however, are substantially lower at fluxes over 20 kW m^{-2}, and do not follow one straight line. The FMRC authors' explanation is that the effect is due to the fact that black, but uncoated PMMA specimens are not perfectly opaque, but absorb radiation in depth. However, since all other studies indicate that diathermancy *increases*, not decreases, the time to ignition, this explanation is not plausible. A more credible explanation is that the surface coating of graphite is not of negligible thermal effect, but creates an insulating layer, thereby increasing ignition times at higher irradiances. For comparative purposes, data obtained at NIST on the Cone Calorimeter are also given. These specimens were uncoated and were exposed to a radiant heat source operating at fire temperatures (below 1000ºC). These data points fall along the same line as the FMRC uncoated specimens. In Figure 67, at an irradiance of 60 kW m^{-2}, the ignition times for FMRC's coated specimens are 2.5 times greater than for the coated ones. If the coating associated with FMRC's standard test protocol always leads to such anomalous results, then unconservative errors of up to 250% may be involved in using the coated-specimen protocol.

Most solids are opaque, that is, the fraction of the incident radiant energy which is transmitted through the material is zero. However, some materials show *diathermancy*, that is, they are partially transparent, at least at certain wavelengths. When diathermanous materials are subjected to radiant heating, they absorb radiation in depth, not just at surface. The effect of this partial transparency is to increase the ignition time[221], since the radiant energy is no longer being optimally deposited for raising the surface temperature. Very thin materials, such as paper or facial tissue, are substantially diathermanous, and with these, a portion of the incident energy simply leaves the back face directly, without heating the specimen. When dealing with these materials, Martin et al.[203] pointed out that a factor of $1/(1-\exp(\beta L))$ should theoretically be used to multiply the values of $\dot{q}''_{\min}$ determined on the basis of neglecting diathermancy, where β = extinction coefficient (m^{-1}) and L = specimen thickness (m). However, actual data were not particularly well correlated by this factor, and they concluded that scattering of radiation would also have to be accounted for in order to provide a better fit.

The interaction between the source temperature and the material's diathermancy has been illustrated experimentally by Thomson[2]. She exposed 6 mm thick slabs of PMMA, both black and clear, to an electrical heater which radiates as a gray body. Her results are shown in Table 33. Since the black material has an absorptivity which is essentially independent of wavelength, the operating temperature of the heater does not influence its ignition time. But the absorptivity of clear PMMA progressively drops below about 2.5 μm, thus a smaller fraction of radiation is absorbed as the temperature of the radiant source is increased (and its peak wavelength of radiation correspondingly decreased). Thus, higher heater temperatures produce longer ignition times.

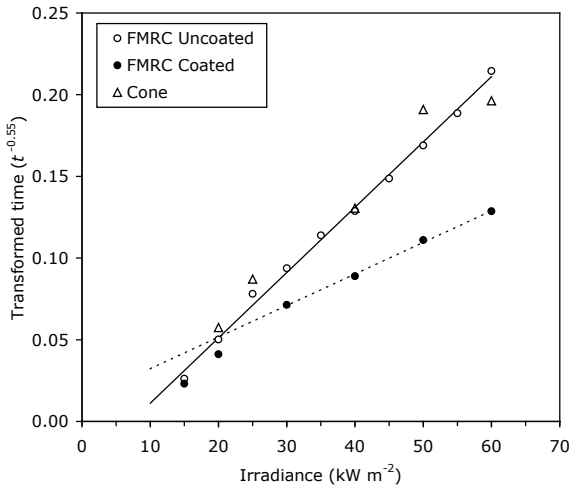

Figure 67 Comparative results on 25 mm thick black PMMA

A question commonly asked is the effect of *paint* on the ignition characteristics of a surface. Paint applied in thick, multiple layers will strongly affect the ignition characteristics of material. The FMRC results discussed above imply that even surface coatings which are applied in quite thin layers may have a measurable effect. In many cases, however, if the thickness is not excessive, a coat of paint may not appreciably affect the ignition results. Moysey and Muir[259] demonstrated this for a number of common paints applied to cedar panels. Vovelle et al.[260] examined three paints on a particleboard surface and found a protective effect with two (ignition times increased by 20 – 65%) and an adverse effect from the third (ignition times decreased by 20 – 26%). In rare cases (e.g., nuclear weapons), ignition from radiation sources having a peak in the visible, rather than infrared, portion of the spectrum must be considered. Then, not surprisingly, painting darker-colored materials with a white paint increases the time to ignition[261]. See also in Chapter 14: *Gypsum wallboard*; *Paints, dyes and related substances*; and *Wood and wood products*.

Table 33 Effect of diathermancy for PMMA specimens exposed to an incident heat flux of 25 kW m^{-2}

Temperature of heater (ºC)	Ignition time (s)	
	Black	Clear
450	124	128
643	120	146
740	134	155
795	128	163

Some products, notably certain thermal insulations, are manufactured with a shiny aluminum facing. The absorptivity of shiny aluminum is around 0.07 to 0.1 in the near infrared. By contrast, most other common building materials show an infrared absorptivity of around 0.7 – 0.8. If the surface truly maintains an absorptivity below 0.1, then ignition of any combustibles underneath is unlikely, except if flashover conditions develop. However, in fires it is common for copious soot to be produced, and for the soot to deposit on a nearby surface. The absorptivity of a black soot coating is around 0.98. Thus, the same product that might be 'ignition-resistant' originally, may ignite readily once sooted up. This situation has some implications for the ignitability testing of aluminum-faced products. Since one can generally have no assurance that a fire would be soot-free, it is prudent to only do ignitability testing on such products either by blackening their face or by first removing the aluminum facing. If the facing is removed, this will also change the pyrolyzing characteristics of the product. Since aluminum is impervious to vapor flow, if a faced product is heated, the vapors will be retained for a short amount of time; subsequently, the facing will split or delaminate as pressure builds up. This propensity has not been studied in any detail, so it is not

known whether blackening the facing or removing it would result in more realistic testing.

POLYMER STRUCTURE

The main properties of polymer which control the ignition time are the thermal inertia, the surface absorptivity, and the ignition temperature. But chemical details of the polymer, such as its molar mass, can also affect the results. Kashiwagi et al.[262] examined the ignition of two different makes of clear, 12 mm thick PMMA—Plexiglas (Rohm & Haas) and Lucite (DuPont). PMMA is ideal for this type of study, since the material has a simple chemistry and the commercial product is nearly a pure polymer. For piloted ignition of vertical samples at a heat flux of 18 kW m^{-2}, they found nearly identical T_{ig} (275ºC), but the Plexiglas sample's ignition time (255 s) was about 15% shorter than the Lucite's (300 s). The samples had nearly identical values of thermal inertia and are presumed to have had very similar absorptivities. The molar masses were 402,000 for Plexiglas and 179,000 for Lucite. If this were the only difference, however, higher molar mass would lead to longer ignition times. But TGA measurements showed that Plexiglas starts to decompose at lower temperatures. The materials have different activation energies, both in nitrogen and in air, and Plexiglas was also found to be more sensitive to oxygen effects. The measured differences might be due to different ways of manufacturing, impurities, and the very small amount of additives that are contained in the polymers, but a direct explanation is not available.

POROSITY

Piles of forest materials, agricultural products, fibers, dusts, etc., are highly porous assemblies that can be packed to a variety of porosities. Thus, porosity becomes a problem variable. Porosity is a dimensionless quantity defined as:

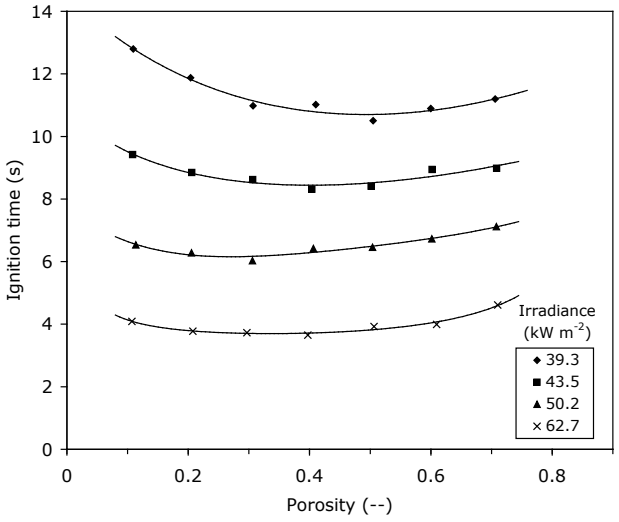

Figure 68 The effect of porosity on piloted ignition of excelsior at MC = 6.7%

$$\varepsilon = \frac{\text{volume of voids}}{\text{gross volume}}$$

Garg and Steward[263] examined the effect of porosity on the ignition of excelsior (Figure 69). Calculations with this model showed that there is negligible effect on ignition time for ε less than about 0.5. The accompanying experiments (piloted ignition conditions) indicated similar trends, but with a pronounced minimum value of t_{ig} at around ε = 0.4 – 0.5. At low irradiance values, assuming the t_{ig} is identical for the porous body as for a solid one could be in substantial error, although at high irradiances this assumption could be reasonable. The authors also tried to model the effect by using an inert-substance model where the thermal properties were modified by substituting $\lambda(1- \varepsilon)$ for λ and $\rho C(1- \varepsilon)$ for ρC, but the predictions of the model did not closely follow the data trends. Similar experiments were also conducted by Varma and Steward[264], but their data showed such high scatter that distinct trends did not emerge

FIRE RETARDANTS

Fire retardants can be of various types. An inert, 'filler' type of retardant, for example, calcium carbonate ($CaCO_3$), functions solely by removing combustible mass fraction and raising the effective thermal inertia. Semi-inert FR agents, for example, alumina trihydrate, $Al(OH)_3$, or magnesium hydroxide, $Mg(OH)_2$, confer the advantages of inert retardants, but also interfere with ignitability and combustion by endothermic decomposition, producing water as the decomposition product. Both of these FR agents tend to be used in high concentrations, possibly as much as 50% of the mass. Such FR agents will change all of the chemical and physical (e.g., thermal inertia) properties of polymer. Other FR agents, however, exist which act to interfere with gas-phase combustion. Most retardants which are halogenated fall into this category. These are normally used in small enough quantities to not change appreciably thermophysical properties such as thermal inertia, but they do raise the ignition temperature of the material. For example, Drysdale and Thomson[265] examined the effect on ignition of a number of polymers, with and without FR agent (Table 34). The FR agents also raised the minimum heat flux for ignition and increased the ignition time at any given heat flux. They also examined inert fillers and found that calcium carbonate did not affect T_{ig}, while alumina trihydrate gave a modest increase in T_{ig}. Large loadings (40 – 50%) of inert fillers raised the minimum flux for ignition. Inert fillers are much denser than the base polymer, so adding the filler causes an increase in the product density. Drysdale and Thomson found that increased times to ignition when adding inert fillers could largely be accounted by the increased specimen density. Hirschler concluded that, since alumina trihydrate is inexpensive and commonly in high loadings, it tends to be the most effective FR agent for improving radiant-flux ignitability performance[266]. The improvement, however, is highly variable and not readily predictable.

Table 34 The effect of halogenated FR agents on the ignition temperature

Material	T_{ig} without FR (°C)	T_{ig}, with FR (°C)
PMMA	306 – 312	370 – 376
polypropylene	320 – 332	392 – 407
polystyrene	360 – 370	430 – 445

The use of FR agents may cause the earliest signs of ignition to occur earlier than for the non-FR material. Grand[267] showed that in most cases the time to sustained flaming either remains the same for the FR material, or else becomes up to several-fold longer. But non-FR polymers which do not exhibit flashing sometimes show a flashing ignition when an FR agent is added, and this flashing ignition comes before the non-FR material would have shown sustained-flaming ignition (Table 35).

Table 35 Effect of FR agents on ignition of some polymers, as tested for piloted ignition in the Cone Calorimeter at a heat flux of 50 kW m^{-2}

Polymer	Flashing time (s)		Sustained flaming (s)	
	Non-FR	FR	Non-FR	FR
ABS	none	27	38	34
HIPS	none	40	52	106
PC/ABS	none	51	49	53
unsaturated polyester	40	150	42	159
XPE	61	33	37	63

Nelson et al.[268] conducted a theoretical study on thermally-thin polymers where they examined the effect of an inert additive. In one example case calculated, when sufficient additive was added so that the mass fraction of resin in the sample dropped to 50%, the critical heat flux for ignition rose from 27.2 to 31.0 kW m^{-2}. This is a modest rise and suggests that very large fractions of inert additive would be needed for the critical heat flux to be raised by a sizeable amount. In general, inert fillers are used for improved arc-tracking performance, to meet the UL 94 HB ratings, and to reduce HRR and smoke, but not normally for improving ignition resistance under radiant heating conditions.

A number of polymer families exist which either intrinsically produce a significant amount of char, or else char-forming can be promoted by additives or chemical modifications. A theoretical paper[269] has recently put forth the thesis that for these polymers there may exist a critical 'jump' at a certain char yield. If the viewpoint is taken that—all else held constant—ignition corresponds to a fixed mass loss rate of combustible volatiles first being attained, then clearly production of char detracts from the ability to produce volatiles. The authors considered the common case where the $\dot{m}''$ versus time curve is double-humped, with the second peak representing the condition that sufficient mass has been lost so that the specimen becomes effectively thermally thin. If with modest char yield the critical value of $\dot{m}''$ is attained prior to reaching the first peak, then when increased charring decreases the volatile production rate, the critical value may only be attained near the second peak—this can correspond to either a large increase in ignition time, or if the second peak is not high enough, no ignition at all.

The compounding of fire-retarded plastics is a highly specialized industrial activity and is generally outside the scope of this Handbook. Current information can be found in the patent literature and in regular conference series of three organizations:

- Fire Retardant Chemicals Association, Lancaster PA. This society of fire-retardant chemical manufacturers holds semiannual technical conferences.
- British Plastics Federation. This society holds biennial conferences. Recent proceedings have been published by Interscience Communications Ltd., London.
- Business Communications Co., Inc., Norwalk CT. This commercial group holds an annual conference on fire retardants.

The above discussion was predicated on the assumption that the substance being treated with FR agents is a synthetic polymer. Entirely different types of FR agents and mechanisms are encountered with wood or other lignocellulosic materials. See *Cellulose insulation* and *Wood and wood products* in Chapter 14.

MOVEMENT OF THE SURFACE

Any material that ignites and burns will eventually show a change of the location of its surface, with respect to its original location. But numerous materials also show movement prior to ignition, and this can affect their ignitability. Plastics can show both swelling and shrinking tendencies. When exposed in the Cone Calorimeter to a uniform radiant flux, many grades of PVC expand considerably. Because the heater is fixed a short distance above the specimen, this would cause them to receive a slightly higher heat flux (the increase is not large, since the movement increases the view factor, but the view factor is already near-maximum). In testing, either wire grids to hold back the surface are used, or else techniques have been adopted where the swelling specimen is tested at a greater than standard distance below the heater. There are no known studies where this phenomenon would have been examined systematically in real fires.

A number of thermoplastic foam materials shrink when exposed to heat. The most notable example is polystyrene foam, although polyethylene foam behaves very similarly. Ignition of polystyrene foams normally does not take place in the solid phase[270]. The material melts at a low enough

temperature so that by the time a sufficient temperature has been reached for ignition, it is in the form of a liquid film.

At present there are no useful quantitative techniques to predict the behavior or the ignitability effects of surface movement. In addition, in certain geometries some materials will undergo a gross movement which is melting and falling out of their original position. This behavior enables them to pass certain unsophisticated fire tests and, on occasion, may represent exactly what happens in real life. In other cases, however, falling down may be precluded and the same material may show rapid ignition.

Intumescent coatings are coatings which are applied over surfaces and whose primary property is rapid, voluminous swelling when exposed to heat. The protective action takes place because the coatings are of limited combustibility, thus, even though they move closer to the source of the heat, the net effect of a successful intumescent coating is to delay ignition and reduce or delay the heat release from the material.

SURFACE ROUGHNESS

If a solid's surface is not smooth, then there can, in principle, be protuberances of lower thermal inertia that are able to ignite more readily than the bulk material. This issue has not been explored, however, in any depth. Akita's study on the radiant ignition of thick wood samples showed that there was no difference in ignition time for smooth-surface, versus rough-sawn, wood boards[271]. On the other hand, Heskestad's[272] work showed that when fabrics are ignited by a small flame and the two sides are dissimilar, there can be a substantial difference in ignition times. But not enough specimens were tested in either study to be able to draw broad-based conclusions.

IGNITABILITY OF AGED, DEGRADED, OR CHARRED MATERIALS

When a solid material is aged, thermally degraded, or charred, a number of physico-chemical changes can occur which may affect its ignitability:

1) lighter fractions (e.g., residual solvents) can vaporize
2) the molar mass can decrease due to scissions, local oxidation, free-radical attack, and other factors
3) water-soluble fire retardant agents may be leached out
4) density may drop, especially if pronounced charring occurs
5) electrical conductivity may decrease due to charring
6) most materials that are not already dark will darken, causing an increase in the radiative absorptivity.

There is a vast body of literature on the degradation of combustible materials, but very few studies have focused on the effects on ignitability.

An aging program was conducted at SP[273] using a variety of products. The test program consisted of exposure in a 70ºC oven for 7 weeks; this was deemed to approximate a 4-year exposure under actual use conditions. Ignition tests were conducted in the Cone Calorimeter at a 50 kW m^{-2} heat flux. Ignition times were unchanged after aging for a wide variety of products (roofing materials, wall coverings, curtains, foam polystyrene, counter-top laminate). Only for an FR paint was there a significant change, but that product improved its performance with aging, going from a t_{ig} of 300 s to 480 s after aging. In another SP program[274], high-impact polystyrene (HIPS) material, of the kind used for making television enclosures, was subject to testing before and after aging. The aging program consisted of 1200 hours at 80ºC, simulating 8 years of normal service life. Two types of samples were tested, non-FR and an FR grade using decabromodiphenylether. The latter showed V0 performance in the UL 94 test both before and after aging. The non-FR material however gave HB results prior to aging, but failed HB classification after aging. Attwood and Allen[232] found an aging effect in ignition of nylon 6,6 in pure-oxygen, hyperbaric atmospheres, with 7-year old material sometimes igniting at greatly lower temperatures than virgin material.

Wood has been the material whose degradation aspects have been studied the most. Details are presented in Chapter 14 under: *Wood and related products*. Briefly, for ignition from external heating, weathering and pre-charring make wood harder to ignite; rotting makes ignition easier. Degradation of electrical wiring insulation is considered in Chapter 14 under *Electric wires and cables.*

WETTING BY WATER

One of the functions of water used in fire extinguishment is to pre-wet surfaces to reduce the potential for further ignitions. A study of this was reported by Josler[275], who tested vertically-orientation wood siding panels in the Cone Calorimeter at an irradiance of 30 kW m^{-2}. Both raw and stained siding boards were examined. In addition to dry control specimens, specimens were wetted with water and with four different fire-fighting 'wetting' additives, i.e., proprietary surfactants. The unstained siding which showed an ignition time of 100 s dry, showed $t_{ig} \approx 140$ s when tested right after wetting with water or with any of the additive systems. The stained siding ignition time rose from 75 s to 90 – 95 s. Tests were also run at 3 h and 6 h after the panels were wetted. The plain-water results showed no improvement over the unwetted controls. However, the best additive system retained nearly full effectiveness after 6 h. The worst one, however, decreased to unwetted-specimen performance. Also explored were the same additives incorporated into a compressed-air foam extinguishing arrangement. A very wide scatter of results was seen for these specimens. Without aging, the best specimen showed $t_{ig} \approx$ 190 s for the unstained siding and $t_{ig} \approx 125$ s for the stained siding. In general, most of the additives did better in the foamed condition than when sprayed from nozzles without foaming. Preliminary testing had indicated that such beneficial results are only obtainable for hydrophilic materials.

Building materials, such as PVC, which are not wetted by water would not show any improvement.

A related issue is *re-ignition*. The question here is: If a fuel was extinguished by applying water, how long will it take before it re-ignites, given a specified irradiance, mass-burned percent, material properties, and amount of water applied? This question has been addressed by some detailed numerical modeling[276], but, due to the large number of variables involved, is difficult to treat in closed form. A limited amount of experimental data has also been published[277,278], but not enough to lead to general guidance. The best illustrations of general trends and magnitude of effects are in papers by Moghtaderi et al.[279,280]. They generally found that, for a given water application rate, re-ignition time decreases linearly with increasing irradiance and with increasing sample porosity. For the samples studied, re-ignition time was also inversely proportional to specimen thickness.

TYPE OF APPARATUS

Even though ignition test apparatuses using a controlled radiant flux should, in principle, give identical results, in practice no two engineering test methods will usually give identical results. Figure 29 shows a comparison of two PMMA materials tested in the Edinburgh University (EU) apparatus and in the ISO 5657 apparatus. At around 20 kW m^{-2}, both apparatuses give identical results. For higher heat fluxes, the EU apparatus gives shorter ignition times, while the converse is true at 10 – 15 kW m^{-2}. Results for two different types of PVC materials tested in the EU apparatus and in the Cone Calorimeter showed shorter times in the Cone Calorimeter at higher fluxes[281]. Of greater interest perhaps is that one grade of PVC showed $\dot{q}''_{\min} \approx 35$ kW m^{-2} in the EU apparatus, but less than 20 kW m^{-2} in the Cone Calorimeter. The samples tested in the EU apparatus were 60 mm diameter, as contrasted to 100 mm squares in the Cone. Also, the EU apparatus used a hydrogen pilot, compared to an electric spark in the Cone.

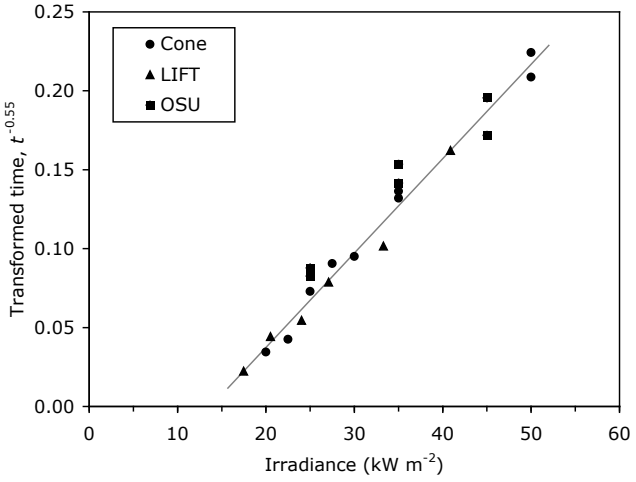

Figure 69 Ignition results for Douglas fir in three different test apparatuses

In other comparisons, however, little systematic difference could be found. Tran et al.[282] tested Douglas fir in three different apparatuses. Figure 69 shows little, if any, systematic difference between the three apparatuses. In Tran's comparison, the minimum flux for ignition was not established, and that might have shown non-trivial differences. Earlier, Quintiere et al.[283] reported on tests of aircraft sandwich panels, tested in the Cone Calorimeter, the LIFT, and the FM Flammability apparatus. There was a great deal of scatter in the results, and any systematic deviations were generally smaller than the data scatter.

MASS OF SAMPLE

The mass of sample does not significantly affect the ignition temperature, except in apparatuses which use minuscule specimen sizes. In a special thermal analysis setup[284] which was equipped with a spark ignition facility (for obtaining real, and not imputed, ignition temperatures), it was found that cotton fabric had an ignition temperature of 270ºC if tested in quantities of at least 350 – 400 mg. For smaller masses, the ignition temperature recorded rose with dropping mass, reaching 300ºC for 50 mg samples. Ignition proved impossible to achieve for samples smaller than 50 mg. Exploring the low end of the mass scale, Davies et al.[285] studied the autoignition of cellulose obtained from cotton using a DTA apparatus. They found an ignition temperature of 349ºC for a 1 mg specimen, and 353ºC for a 15 mg specimen, with intermediate masses also showing essentially identical ignition temperatures. Morimoto et al.[286] reported test results on a wide variety of plastics using a custom-designed test apparatus which was roughly similar to the Setchkin furnace, except that a specimen mass of only 200 mg was used. Their resulting T_{ig} values were much higher than those determined by other workers in the Setchkin furnace. Graf[36] studied the autoignition of wood, paper, and other lignocellulosic materials using a horizontal tube furnace. Over the range explored—0.5 to 10 g—he found that decreasing the specimen mass produced a monotonically increasing T_{ig}. There was a combined effect with air flow rate, and higher air flow rates led to a greater effect of specimen mass. The T_{ig} value for 0.5 g specimens was about 5ºC higher than for 5 g specimens with a reasonably small air flow rate, but at higher air flow rates the difference rose to about 30ºC.

LONG-TERM RADIANT EXPOSURES

Most radiant ignition tests are conducted for periods of 10 – 30 minutes. In one case, Shoub and Bender[287] undertook longer-term exposures using vertical specimens of size 0.92 × 0.92 m. The heat source was an electric radiant panel operating at an effective black-body face temperature of 273ºC and producing a heat flux of 4.3 kW m^{-2} at the center of the specimen, with lower heat fluxes at the edges. Specimens were mounted in two different ways—either onto

Table 36 Ignitions obtained by Shoub and Bender for various materials at a heat flux of 4.3 kW m^{-2}

Specimen	Back	Ignition time (h)	Temperature at ignition (ºC)	
			Face	Back
fiberboard, bagasse (13 mm, 290 kg m^{-3})	a	0.92	260	158
hardboard (6 mm, 960 kg m^{-3})	m	3.93	386	374
paperboard, laminated, primed (10 mm, 560 kg m^{-3})	a	0.58	270	96
paperboard, laminated, painted (10 mm, 560 kg m^{-3})	m	4.75	280	198
plywood (13 mm, 630 kg m^{-3})	a	5.17	254	254
a – air space m – millboard				

furring strips attached to a wall, or directly onto 25 mm thick asbestos millboard. A spark ignition system was installed at ceiling level, far above the specimens. However, all ignitions were observed to take place directly at the specimen and without the help of the igniter; thus, the results represent autoignition and not piloted ignition conditions. Their main results are given in Table 36. No ignitions were obtained for:

- acoustical tile, 12 mm, screwed onto millboard
- polystyrene wall tile, 1.7 mm, cemented onto gypsum wallboard
- wood veneer laminated onto gypsum wallboard
- vinyl-faced gypsum wallboard

The results indicate that self-heating was contributing, at least for some specimens. In the absence of self-heating, the face temperatures of the specimens could not exceed 273ºC, the temperature of the radiant source, and would actually have to be significantly less. A significant amount of convective cooling had to be present since the bottom of the specimens was raised 0.2 m off the floor, and even more cooling in the case of those specimens mounted with an open air space in back. The experimental facility set up by Shoub and Bender was rather crude and it would be important to obtain corroboration by other workers before their results are considered reliable.

Arcing across a carbonized path

Many electrical fire ignitions are due to arcing across a carbonized path. If a carbonized path is created where current may potentially flow, arcing may then occur along this path, possibly leading to ignition either of the combustible insulator itself, or some other nearby fuel. A carbonized path can be created in at least three ways[288]:

(1) arc tracking;
(2) overheating (by electrical overcurrent, external radiant heating, etc.);
(3) impingement of fire upon the insulation.

NFPA 921[289] considers ignitions from arc tracking and from arcing-through-char to be different phenomena, but they are not. A carbonized path need not be created by arc tracking, as discussed in detail below, but by one of the other two mechanisms. The outcome in all cases, however, irrespective of how the carbonized path was created, can be manifested as arcing-through-char.

Systematic research knowledge, what little there is of it, is almost wholly confined to arc tracking. Creation of a carbonized path by overheating is considered in Chapter 14 under *Electric wires and cables*. The existence of arc tracking has been known for a long time, even though details are poorly understood. A German textbook[290] discussed it in 1937, and an ASTM standard was already published in 1948[291]. Arc tracking is a progressive creation by *electrical* means of a carbonized path along the surface of in insulator that separates two current-carrying conductors. Moisture and contaminants are generally responsible for causing arc tracking, although dry tracking also can occur. The electric conductivity of pure water is very low, but when ionic contaminants are dissolved in water, its conductivity increases and it becomes possible to create current flow if the layer of moisture has access to circuit conductors somewhere. The flow of current then has a drying effect on the moisture layer. The drying is non-uniform, and eventually dry patches start to be formed along the current path. The first overt electrical discharges occur as faint, purple-colored *corona discharges* across the dry patches[292]. With buildup of carbonization along the path, small electrical discharges, called *scintillations*, can then occur. These are red or orange-colored. Since part of the current flow is through an electrolyte of significant resistance, these scintillations represent a very small current flow (less than 50 – 100 mA in one series of tests[293]) and would not trip any overcurrent devices. Surprisingly, temperatures up to 1000ºC can be generated by such surface leakage discharges. These elevated temperatures then continue the process of polymer carbonization. Thus, in the tracking process, a carbon track is laid down along the surface, and that track has a low enough resistivity that current can subsequently start to flow along the carbonized track, which, in turn, causes more carbonization and more heating. A runaway situation can then develop. The tracks which occur due to repeated wetting and drying often propagate in a tree-like fashion, thus the condition is sometimes referred to as *treeing*. However, the term 'dielectric treeing' usually refers to microscopic cracks induced by an electric field, not necessarily to the carbonized track of concern here. There has been a large variety of theories[294] attempting to explain the causes and mechanisms of dielectric treeing (sometimes subdivided into electrical trees and water trees).

Eventually, an arc discharge may occur along a carbonized path between the two metal conductors. To create an electric arc in this way requires a vastly lower voltage than does simple breakdown in air between two electrodes. For

example, with many plastics, Yoshimura et al.[292] found that 600 VAC was sufficient to cause an arc discharge across a 4 mm gap. By contrast, breakdown across a 4 mm gap in air requires about 10,000 VAC (see Chapter 11). On cables, arc tracking will normally not be initiated unless a conductive moisture film exists that has electrical contact to two conductors that have a voltage difference between them. This may happen if a cable is mechanically damaged, so that two current-carrying conductors are exposed. Moisture then collects on the damaged area, and pollutants are present which ionize the layer. But on some materials, arc tracking does not require a direct contact between an electrode and the surface of the insulator; tracking over phenolic and melamine surfaces could be initiated even when the electrodes were separated by gaps of about 0.25 mm from the insulator surface.

The process as described above is sometimes referred to as 'wet-tracking' or 'wet fire.' In high-voltage applications it is also common to encounter 'dry-tracking.' This occurs without the presence of moisture or surface contaminants. Instead, it is sufficient that an electric arc occur close to a polymeric surface. If the process continues, the high temperatures create a charred track along the surface of the polymer. In low-voltage circuits, a carbonized path is less likely to be created by an arc near the surface of an insulator. Instead, a carbonized path may be created by a glowing connection or other source of locally-elevated temperatures. These causes are discussed in more detail in Chapters 11 and 14.

In DC circuits, tracking usually starts at the anode, chars a local area right at the anode, then meanders, rather than progressing along the shortest path to the cathode[295]. Similarly, in AC circuits growth of the track occurs mainly from the electrode that is instantaneously acting as the anode. Arcing does not continue unless the conducting path is poor. Thus, in phenolics it was found that arcing very quickly establishes a highly-conductive path, and afterwards arcing is no longer observed. A much lower value of resistance is established along a path which has arc-tracked, in comparison to one which was only thermally charred[295].

Oba[296] conducted experiments where he damaged the insulation on Japanese type VVF power cable (which has two 2-mm solid copper conductors*) to expose the conductors, then sprayed electrolyte onto the area to initiate arc tracking. By varying the AC voltage supplied to the cord, he obtained a char length relation as a function of voltage (Figure 70). Below 50 V, progress of charring was very limited. He repeated the experiments by depositing powdered carbon onto the damaged area and found, in that case, for arc tracking to occur, the applied voltage had to exceed 24 V. Below 50 V, small incandescent spots could

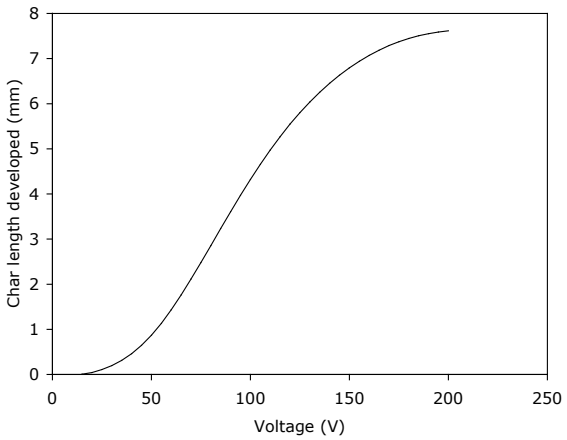

Figure 70 Char length developed after 70 h in the wet arc-tracking experiments of Oba

be produced, but not flaming ignition. Flaming ignition was readily possible for voltages of 100 – 150 V. Above 200 V, flaming ignition readily occurred, but increased char lengths were not obtained since the events were explosively forceful and blew off the carbonized material and the melted conductor portions. Under other conditions, much less than 24 V is sufficient to cause arc tracking. Bernstein[297] reports that arc tracking can occur in 6 V battery circuits, provided the battery has sufficient current capacity to sustain the arc.

In an early theoretical study into the arc tracking problem[298], it was found that the molecular structure of the polymer is the main determinant of arcing propensity. Aliphatic polymers (e.g., polyethylene, PTFE) tend not to undergo arc tracking, while aromatic ones or ones containing alternating double bonds (e.g., phenolic, polyethylene terephthalate, polystyrene) do. This is because the latter, when pyrolyzed, leave residues which are electrically conductive or semi-conductive. Also tending to exhibit arc tracking are polymers which, while lacking aromatic rings or double bonds originally, form rings or double bonds during thermal degradation; PVC and polyacrylonitrile are examples of this. It was also found out that oxygen is not a requisite for the formation of arc tracks, and that materials can be made to arc track in a nitrogen atmosphere. To simplify matters greatly, it can be said that arc tracking can only happen if a polymer can char, since if the degradation product is gaseous rather than a char, a conductive track cannot be established. Practical difficulties arise because charring is not an absolute property of polymers but, rather, is conditional. Despite a black appearance, the track is *not* graphitic carbon, but rather an organic semiconductor[298]. Arc tracking is not necessarily confined to the surface, but may involve subsurface layers, especially if the insulator is heterogeneous, i.e., fiber-reinforced[299].

* The original paper contains a misprint – the conductors were 2 mm diameter, not 2 mm^2 area.

A comparative experimental study[300] using the IEC 60112 test method showed that styrene-butadiene rubber (SBR) readily exhibited arc tracking even in the dry state. This is partly attributed to the use of carbon black in the formulation, but Neoprene samples with a similar loading of carbon black did not exhibit dry arc tracking. Neoprene, however, did show the worst performance in moist tracking. For most polymers, it was shown that the impressed voltage has a significant effect, but that raising the ambient temperature by 100ºC does not. The authors provided data on a large number of other wire insulation polymers.

Wilkins and Billings[301] did some fundamental research on arc tracking propensity and found that each material capable of arc tracking has a minimum current which must be available for arc tracking to occur. Their experimental results were: PVC 0.15 – 0.20 mA, PVA 0.3 mA, Ebonite (butadiene/methylstyrene rubber) 1.1 mA, phenolic/paper 1.15 mA, polycarbonate 1.2 mA, and PTFE 2.3 mA. A thermal model was evolved that could predict this behavior. A minimum current is necessary so that the material could achieve a r equired local breakdown temperature; these values ranged from 186ºC for PVC to 446ºC for PTFE. The breakdown temperature is controlled by the thermal decomposition of the material, and was found to be correlated to TGA results for each material, thus the minimum current could be correlated to the T_{90} in the TGA test, which is the temperature at which 10% of the mass is lost. They also found that materials which show zero residue upon completion of a TGA test are only prone to arc *erosion*, but not arc tracking. Simple thermoplastics are materials which pyrolyze completely in a TGA test. Residual material remains (and therefore arc tracking is possible) either if the polymer innately chars, or else if additives are used which cause residual weight to remain. Materials with a high residual weight fraction are ones which are often thermally resistant and are selected to resist radiant or flame ignition. Thus, the requirements for such resistance versus arc tracking performance can be conflicting. However, alumina trihydrate ($Al_2O_3 \cdot 3H_2O$), a common filler for many polymers, was found to be highly effective in reducing the arc tracking propensity in certain polymers[302,303].

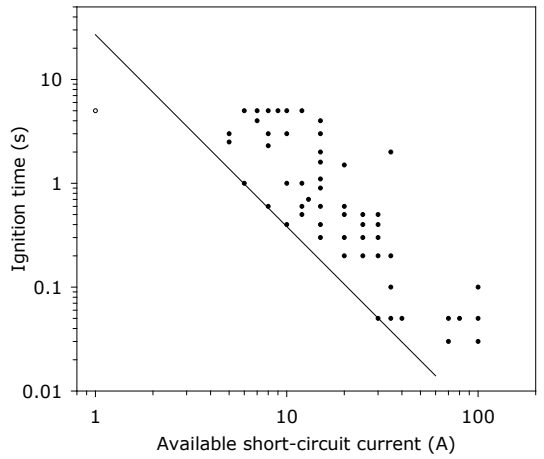

Figure 71 Ignition of electric cords with carbonized section from plugging into branch circuits having various available short-circuit current capacities

In design, the resistance to arc tracking is controlled by two means: (1) selection of well-performing insulation materials; and (2) observing adequate *creepage* distances. The latter concept is illustrated in Figure 72. For arcing from metal to metal, the governing distance is called the clearance distance, d_1. But since arc tracking proceeds only along solid surfaces, the distance across which arc tracking must travel, if failure is to occur, is called the creepage distance, d_2. Creepage distances are set down in numerous military and industrial specifications, but the rationale is usually empirical and not much scientific research is available on the topic. Day and Stonard[304] conducted tests where time to wet arc-tracking failure was measured as a function of creepage distance. With highly aggressive contaminants used, after 20 min most specimens still had not reached ultimate limits, but rank-order differences, not surprisingly, were the same as found in comparative tracking index test results on the materials.

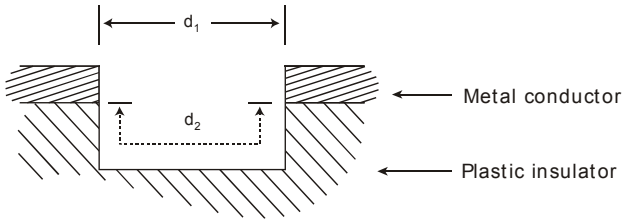

Figure 72 Simplified view illustrating clearance and creepage distances

In an interesting study[305], UL simulated ignitions due to arc tracking in the laboratory. In their tests, they created a carbonized track by faulting a length of 16 AWG cord containing 24 copper strands and insulated with PVC. Insulation was partially scraped off the cord to reveal the two conductors. The path across the now-exposed conductors was wrapped with PVC electrical tape, which presumably is more prone to arc tracking than is bulk PVC cord insulation. The construction was over-wrapped with fiberglass tape and carbonization was initiated by connecting a neon transformer across the cord connections. Ignitions were then examined using the carbonized cord by plugging it into branch circuits having various available short-circuit currents. Surgical cotton was wrapped around the specimen to serve as ignition target. The results are indicated in Figure 71. Apart from one data point, the lower bound to the results can be described by:

$$t_{ig} = 27 A^{-1.83}$$

where t_{ig} = ignition time (s) and A = available short-circuit current (A).

Glowing ignition

When a solid is pyrolyzed by the application of heat, two things happen: (1) gaseous products are liberated; and (2) the solid-phase material is changed. The solid-phase material may respond by either melting or charring, although occasionally both occur. Significantly higher temperatures are normally reached on charring solids than on melting ones. Because of the high surface temperatures, direct surface reactions sometimes become dominant in the case of charring materials. A surface that undergoes rapid oxidation is described as having reached glowing ignition. In an experiment where the surface temperature of the sample is monitored, when glowing ignition occurs, a jump of several hundred degrees Celsius in the surface temperature over the span of a few seconds is registered.

Many charring substances respond when subject to high heat fluxes by igniting with a flame, with the flame first appearing some distance away from the specimen surface in the plume of pyrolysates. The same substances when presented with a low heat flux often ignite by first exhibiting glowing at the surface, and possibly later erupting in flaming. Examples of such substances include wood[19,306], charring fabrics[307], and oats dust[308]. In the case of fabrics, it was observed that minor impurities in the fabric had a strong effect in determining whether, at a given heat flux level, ignition will be glowing or flaming. One type of PVC material was shown to exhibit a glowing ignition when the smoke-suppressant additive ferrocene was added, but not for the virgin material[309].

Glowing ignition has received very little systematic study. Since glowing ignition involves the direct surface oxidation of a material (heterogeneous reaction), Baer and Ryan[253] suggested that the simplest model is:

$$\frac{\partial T}{\partial t} = \frac{\lambda}{\rho C}\frac{\partial^2 T}{\partial x^2}$$

with the boundary condition:

$$-\lambda \left.\frac{\partial T}{\partial x}\right|_{x=0} = \dot{q}_e'' + B_s Q_s \exp(-E_s / RT)$$

where T = temperature, t = time, λ = thermal conductivity, ρ = density, C = heat capacity, $\dot{q}_e''$ = irradiance, B_s = pre-exponential factor, Q_s = heat of reaction, E_s = activation energy for surface reaction, and R = universal gas constant. Based on this, Lengellé et al.[310] proposed an approximate scheme which is essentially a perturbation on the inert solution. They assumed that ignition corresponds to the instant at which the surface temperature rise due to the exothermicity first equals a fraction b of the incident heat flux:

$$B_s Q_s \exp\left(-E_s / RT_{ig}\right) = b\,\dot{q}_e''$$

In a system where E_s, B_sQ_s, and b are known, the above equation can then be solved for $T_{ig}(\dot{q}_e'')$, giving:

$$T_{ig} = \frac{E_s}{R}\left[\ln\left(\frac{B_s Q_s}{b\,\dot{q}_e''}\right)\right]^{-1}$$

where b = non-dimensional temperature rise associated with ignition. The b factor serves as an ignition criterion and they found empirically that $b \approx 0.15$ corresponds to ignition. The equation predicts that T_{ig} decreases with decreasing irradiance. In the Lengellé scheme, plots of t_{ig}^{-n} against $\dot{q}_e''$ give straight lines, just as with the inert solution; the physical meaning of the slope of the line, however, is altered. For ignition of substances other than propellants, where the exothermicity stems from reaction with atmospheric oxygen, the concentration of oxygen can be expected to play a role, that is $B_s \propto C_{ox,\infty}^m$, where $C_{ox,\infty}$ = oxygen concentration far away from the fuel surface, and m = reaction order. Suuberg et al.[311] examined experimental data for a number of chars and concluded that m = 0.68±0.08; a more recent survey[312] suggests that m may range from about 0.6 to 1.0 Thus, glowing ignition sensibly ought to become more difficult as the oxygen concentration drops. All of the experimental data discussed by these authors come from industrial combustion studies with little similarity to accidental ignition scenarios, so the application to fire safety scenarios can only be speculative.

Smoldering ignition

Smoldering can be defined as a propagating, self-sustained exothermic reaction wave deriving its principal heat from heterogeneous oxidation of a solid fuel. As discussed in Chapter 3, heterogeneous oxidation means that the reaction occurs on the surface of the fuel. Since flames are a manifestation of a homogeneous (dispersed within a volume; not at the surface) reaction, flames are not seen in connection with smoldering. This technical meaning is much narrower and more specific than the layman's view of smoldering. The layman often applies 'smoldering' to fires which show small (as opposed to larger) flames, or to situations where an external heat source is charring or pyrolyzing a substance. In this book, we use the term 'smoldering' according to the technical definition given above, unless made clear otherwise. If the smoldering reaction achieves temperatures high enough to exhibit a visible glow, the combustion is often referred to as *glowing* combustion. But glowing combustion can also be caused by applying an external source of heat, rather than as an outcome of smoldering.

Most combustible solids do not smolder. Generally, smoldering is only common with porous or granular materials that can char and that have limited, if any, tendencies to melt. In addition, the char structure must be porous and not clogged by molten material[313]. Common materials which are known, under some circumstances, to smolder include:

- wood and cellulosic products in finely divided form (chips, low-density fiberboard, etc.)
- paper

- leather
- cotton, in the form of batting, fabric, or string
- carbon
- forest duff, peat, and organic soils
- various agricultural products
- latex foam
- some types of polyurethane, polyisocyanurate and phenol formaldehyde foams; open-cell (flexible) foams are more likely to smolder than closed-cell (rigid) foams.
- coal, charcoal, coke, cigarettes, and incense sticks—these are among the few materials which are used to produce *wanted* smoldering.
- dust layers of various sorts.

A very wide variety of organic substances can smolder when arranged into a layer of dust or powder. Examples include coal, cocoa, lycopodium, and sawdust. Powdered iron sulfite can also smolder[314]. Metal powders or dusts (e.g., magnesium [314], brass[315]) can also be made to smolder. For the case of magnesium, however, since the temperatures registered in the process were ca. 1300ºC, it does not entirely appear appropriate to use the term 'smoldering'; for brass, by contrast, 'smolder' temperatures of ca. 400ºC were found.

Under some conditions, certain cellulosic substances—paper, solid wood—can smolder that do not appear to be porous. Cigarette paper, is of course porous, but on a scale too small to be seen with the naked eye. Most other cases of paper smoldering appear to involve layers of paper, where air access is between sheets. Solid wood has limited porosity, and its smolderability is discussed in Chapter 14.

In the end-use environment, porous material is likely to exist in layers or in heaps. The air flow and heat flow which prevail during a smoldering ignition are highly 3-dimensional and analysis is difficult. For this reason, many laboratory studies have been conducted in simplified geometries, where a long, narrow pile is created with impervious barriers on all except the two ends; air is then forced into one open end and exits the other. Under such conditions, a 1-dimensional smolder geometry can be created. If the end facing the wind is ignited, then the mode of smolder is called *forward smolder* since the air flow direction and the direction of smolder-front movement are the same. This mode is also, somewhat confusingly, called counter-current smolder*. If the opposite end is ignited, then the condition is one of *reverse smolder*. In that case, the smolder front moves in the opposite direction from the air movement. The latter mode is also called concurrent smolder, or opposed-flow smolder. Figure 73 is Sato's illustration of the two cases[316]. Laboratory studies done under such conditions have been helpful in understanding the physics of smolder. Nonetheless, it must be remembered that rather different conditions usually prevail in the case of real fires, so numeric data obtained in 1-dimensional laboratory studies cannot be directly applied if the fire conditions involve a 3-dimensional problem.

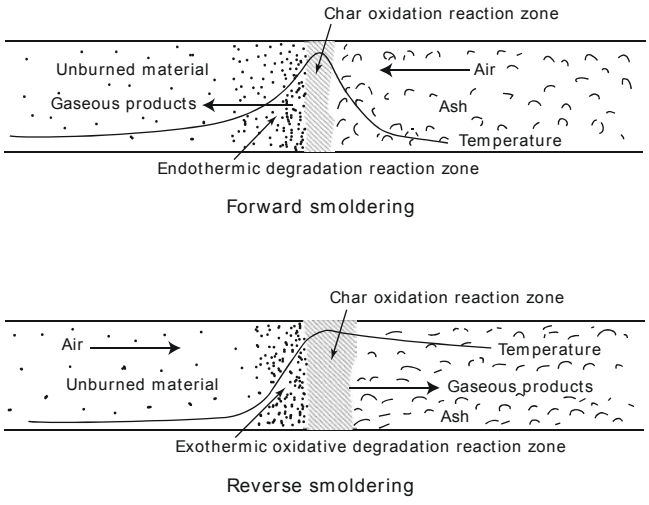

Figure 73 Two types of 1-dimensional smoldering

Forward and reverse smolder geometries differ fundamentally in the nature of the air that is supplied to the smolder front. In the case of forward smolder, the air must travel through the already burned portion. It arrives at the smolder front preheated, but also depleted of oxygen, since some of the oxygen already gets used for reactions in the partly-burned region. In reverse smolder, the air arrives at the smolder front without preheating and without depletion of oxygen. Thus, reverse smolder can establish a steady-state smolder velocity. For forward smolder, the continued transport of heat in a direction to preheat the fuel causes the reaction to continually accelerate. In the smolder wave, the smolder velocity is limited by the influx of oxygen, rather than by the fuel or by the chemical kinetics. The critical role of oxygen supply in opposed-flow smolder can be noted experimentally[317] in the fact that at the end of the smolder zone, oxygen concentration drops to zero; fuel concentration, by contrast, does not. The *rate* of smolder is normally higher for reverse smolder than for forward smolder. Evidently, the oxygen depletion that occurs in forward smoldering is more effective toward decreasing the reaction rate, than is preheating as a means of raising reaction rate.

* 'Forward' denotes that wind and smolder front velocity are both in the same direction; 'counter-current' denotes that the air and the fuel are fed from opposite directions into the smolder front. In the opposite situation, 'reverse' denotes that wind and smolder front velocities are in opposite directions, while 'concurrent' denotes that the air and the fuel are fed from the same direction into the smolder front.

In addition to the fluid mechanics, the chemistry of combustion often differs between forward and opposed-flow smolder. Oxidative pyrolysis of virgin material tends to dominate in reverse smolder, while char oxidation becomes of importance in forward smolder.

Many laboratory studies of smoldering used a flat, thin 'pancake' heater as the external source of heat. The pancake heater can be characterized either by its surface temperature or by the heat flux at its surface. In such studies, it has been found that to create a self-sustained 1-dimensional smolder reaction, the external heat source must be able to raise temperatures to a sufficient value at a distance away from the heater representing a *minimum char thickness*. For forward smolder of flexible polyurethane foam, the minimum char thickness has been experimentally found to be ca. 50 mm; for reverse smolder, the minimum is ca. 100 mm[318]. In terms of 'external' variables, a minimum heat flux exists, below which ignition will not occur, since a steady state temperature will be established in the vicinity of the heater which is below the minimum necessary to create a self-sustained smolder reaction. In the same manner as for radiant ignition of the front face of a solid combustible, the heat flux alone does not characterize the response, but the time of application must also be considered. The heat flux/time relationship necessary for reverse smolder ignition is shown in Figure 74, where comparison to experiment indicates a rough agreement, at least for longer time periods. For forward smolder, the heating times are less.

While a minimum ignition temperature does not exist in general for a substance to sustain smoldering, in 1-dimensional studies it is commonly found that a higher igniter temperature is needed for reverse smolder to occur than for forward smolder. For polyurethane foam in an atmosphere at ambient oxygen concentration, in one experimental rig[318] it was found that T_{min} = 290ºC for forward smolder, but 385ºC for reverse smolder. For forward smolder conditions, changing the oxygen concentration does not change the minimum temperature, but for reverse smolder, decreasing the oxygen concentration raises the minimum needed temperature.

Kellogg et al.[319] ignited heavy cotton fabrics in a smolder mode by pressing an electric cartridge heater onto the fabric surface. They found that a minimum heat flux around 15 kW m^{-2} was needed for ignition and that this did not vary with the basis weight (g m^{-2}) of the fabric. Lowering the oxygen concentration to 14.7% raised the minimum flux to 17.5 kW m^{-2}. The time to ignition, at a given heat flux, however was strongly dependent on the basis weight. Except for heat fluxes barely above the minimum needed for ignition, their data could be represented by a straight line of $1/t_{ig}$ versus (heat flux/basis weight):

$$\frac{1}{t_{ig}} = 0.79\left(\frac{\dot{q}_e''}{W}\right) - 0.0119$$

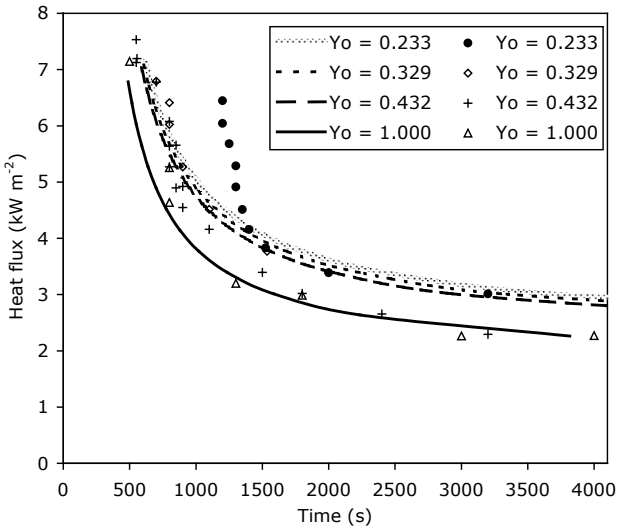

Figure 74 The heat flux needed for reverse smolder ignition of polyurethane foam[318]
(Copyright Elsevier Science, used by permission)

where t_{ig} = ignition time (s), $\dot{q}_e''$ = heat flux (kW m^{-2}), and W = basis weight (g m^{-2}).

Minimum conditions for ignition of smolder-retardant-treated loose-fill cellulose insulation in a smoldering mode were investigated by Ohlemiller[164]. He found, not surprisingly, that larger hot surfaces required a lower temperature. A wire of 4.8 mm diameter required 380 – 385ºC, while an 0.2 0.2 m plate only 255 – 266ºC. The effect of the smolder retardant was judged to be very small, and untreated specimens required only slightly lower temperatures.

There are very few data on smolder started by external radiant heating, as opposed to a heat source which is in contact with the material. In one study[320] on flexible polyurethane foam using a Cone Calorimeter as the heat source, it was found smoldering ignition could only be sustained over the very narrow flux range of 6.1 to 6.8 kW m^{-2}. For heat fluxes less than 6.1 kW m^{-2}, the heat was not sufficient to cause a char zone to propagate. For heat fluxes higher than 6.8 kW m^{-2}, surface melting occurred. This caused the surface to become non-porous, stopping the possibility of smolder. A critical temperature of 300 – 325ºC was found for a self-sustained smolder front. The authors also found that a mass loss rate of 0.8 g s^{-1} m^{-2} was the minimum rate needed for smoldering ignition.

Reproducibility of smoldering-ignition tests is commonly poor, partly because the process is inordinately sensitive to *air flow*. Honeycutt[321] documented in a series of tests on cigarette ignition of upholstered furniture that a velocity of 0.0005 m s^{-1} had no effect, but velocities as small as 0.035 m s^{-1} already detectably affected the results. In most cases, moderate velocities increase the propensity to smoldering ignition. It was also found that the warmth of a person

sitting down on a chair can induce velocities on the order of 0.01 m s^{-1}.

The *velocity* of smolder, once ignition has occurred, is very slow. For a wide variety of smolderable materials[322,323], it was found that smoldering rates encompassed the range between 0.5 mm min^{-1} and 6 mm min^{-1}. For coal dust[324], the range is reported as 0.83 to 8.3 mm min^{-1}. For cellulose insulation, a velocity of 3.1 mm min^{-1} has been reported[164]. For cellulose insulation treated with fire retardant agents, values in the range of 1.3 to 1.75 mm min^{-1} were found. The presence of even high loadings of smolder-retardant agent does not drop the smolder velocity to zero. Denser materials smolder more slowly, and Palmer[325] has suggested that, for a variety of materials, the product (density × smolder velocity) is roughly constant. According to this approximation,

$$v = k / \rho$$

where v = smolder velocity (mm min^{-1}); k = 300 to 670; and ρ = density (kg m^{-3}). Matters become more complex to evaluate when the smolder front has a strongly 3-dimensional aspect. In one interesting experiment[326], a cube of air-dried sawdust, 0.91 × 0.91 × 0.91 m, was assembled with a lit cigarette placed into the center. For 7 days there was no external evidence of combustion, but thereafter the surface slumped slightly and acrid smoke first appeared. By the 12th day, the cube was evidently in active combustion.

Blowing air over a smoldering product increases the smoldering velocity. In a study[327] on grain 'screenings' (small particles) it was found that blowing air at a velocity of 4 m s^{-1} increased the smolder velocity by about a factor of 10. Raising the ambient temperature increases the smolder velocity. For a number of products[323,328], it was found that raising the temperature from 20 to 100ºC roughly doubles the smolder velocity.

The *smoke* emitted from smoldering has not been much studied. For smoldering oil shale dust, it was found[329] that the smoke contained a high enough percentage of flammable gases that a lighted match would ignite the smoke.

THEORY

For cases where a smolderable material is ignited by a large hot surface, the same ignition theory can be used as is used for self-heating of dust layers (see Chapter 9). A successful example of such application to cellulose attic insulation has been published[164]. For small, hot sources, however, it was found that the theory becomes problematic to apply and, of course, it could not be applied at all to smoldering initiated with a flame. A number of theories have been proposed for smolder velocity, but ones based on credible physics[330,331] have so far not led to solutions of practical applicability.

EFFECT OF LAYER THICKNESS

Smoldering cannot be sustained unless the smolderable material has a minimum layer thickness[332]. The amount of practical guidance on this point is limited. Palmer[333] studied layers of several dust types, and his results are shown in Figure 75. For particle sizes below 0.4 mm, the results show a linear dependence on particle diameter. For cork dust, sustained smoldering was possible down to about 1 mm layer thickness, provided very fine dusts were used. Palmer also investigated large diameters of cork dust and found a depth around 50 mm for 2 mm particles; for larger particle sizes, the minimum required layer depth decreased instead of further increasing. In addition, Palmer examined dry grass dust of < 0.065 mm sieve size. This dust was able to smolder in a 2 mm thick layer.

Ohlemiller and Rogers[334] examined the minimum layer depth needed for sustained smoldering of cellulose insulation. For untreated material, a depth of 35 mm was found, while for insulation treated with 20% boric acid, the depth increased to 65 mm. The material is fibrous in nature, so particle diameter is not a meaningful measure. No theoretical treatment of the problem is available, but Ohlemiller considers it likely that physical properties, especially packing density, are the most important in controlling the process[335]. A scale effect was also documented for flexible polyurethane foam[336].

EFFECT OF PACKING DENSITY OR POROSITY

For the smoldering process to be sustained, porosity must neither be so low that access of oxygen is too difficult, nor so high that excessive heat losses, especially from radiation, occur to the external atmosphere. Lawson[337] explored the effect of density on the smoldering ignition of cellulose insulation by a cigarette. He found that material which was resistant to smoldering ignition at a lower density, generally started to smolder if the insulation was packed tighter. In the case of one material, he also found that further increases in density led to non-ignitions, indicating the existence of an optimum density for ignition. Palmer also reported that a maximum density exists beyond which smoldering will not propagate[333]. Pyne et al.[338] suggested that fuel beds will not smolder if porosity is greater than 90%.

SMOLDER PROMOTERS AND SMOLDER INHIBITORS

Experiments, primarily by McCarter[339-341] indicated that certain inorganic impurities often found in wood products, natural-fiber textile, and other substances of lignocellulosic origin are strong promoters of smoldering. These impurities include salts and hydroxides of monovalent metals (e.g., NaCl, NaOH, KCl, etc.), and salts of iron, chromium, and lead (e.g., $FeCl_3 \cdot 4H_2O$, $CrCl_3 \cdot 6H_2O$). The latter group of compounds induced a more complete smolder combustion and McCarter associated this with catalytic activity of these metals. Potassium was the most potent metal found with respect to facilitating smolder. Unfortunately, it is also the

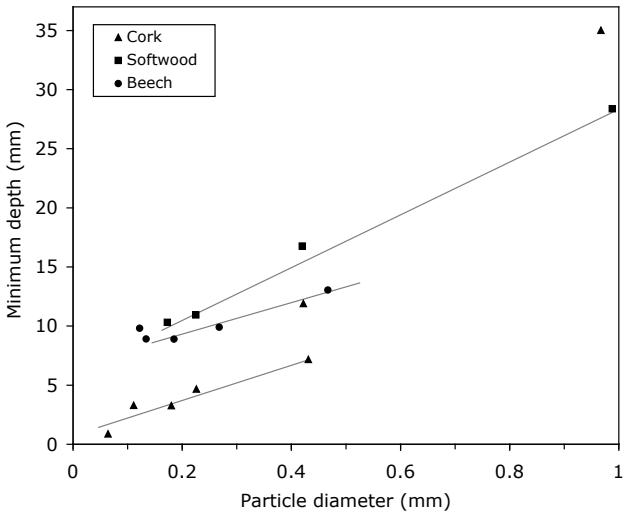

Figure 75 Minimum layer depth for smoldering of several dust types

most dominant inorganic cation found in natural cotton and possibly other lignocellulosics. Smolder was not facilitated by aluminum, antimony, barium, calcium, cobalt, copper, magnesium, molybdenum, nickel, tin, or zinc compounds examined.

With certain materials such as cotton, it is possible to suppress the smolder tendency by thorough washing, since this removes the metal-ion impurities. Kellogg et al.[319] found that untreated cotton fabric had about 6000 ppm potassium ion content. Washing the fabric to the extent of lowering it to 2000 ppm had little effect; reducing to 1000 ppm substantially prolonged the time needed for smoldering ignition, while washing so that only 150 ppm remained made smoldering ignition impossible. Smolder can be inhibited by the application of sulfur (S_8) or compounds containing boron or phosphorus. The most useful of the latter are boric acid (H_3BO_3), and the ammonium phosphates. A number of multivalent metal chloride compounds were also found to be effective, but these have generally not been found commercially viable. The mechanism of action of sulfur is unique[342], in that it entails a reaction of sulfur vapors with carbonaceous radicals, thereby interfering with combustion at the smolder front. The remaining substances commonly used as smolder inhibitors have long been studied as flame-retardants for wood. These work largely by altering the normal pyrolysis chemistry of the material, that is, they act solely in the solid phase; in addition, boron-based compounds may create a glassy film at elevated temperatures which can present a physical barrier to combustion[343]. The early history of smolder-inhibitor compounds and their modes of action was comprehensively reviewed by Browne[344], with a later review by Le Van[345]. Smolder inhibitors are generally developed empirically and theoretical guidance on identifying optimum candidates is non-existent.

Unlike for cotton, washing does not work as a technique for removing smolder-promoters from wood fibers, since these are not water-soluble in wood[340]. Calcium and magnesium were found to be the primary elements serving a smolder-promoter role in wood fibers. These are strictly not inorganic impurities, since they are bound into the carboxyl groups of the cellulose. Removal is possible, however, by the use of an acid wash. Other chemical reactions that replace these metal cations with hydrogen, ammonium, or aluminum cations were also judged likely to reduce the smolderability of wood fibers.

TRANSITION FROM SMOLDERING TO FLAMING IGNITION

The conditions governing when and if a transition to flaming will occur has been the subject of theoretical investigations and of laboratory studies, using simplified geometries. Smoldering to flaming transition can occur in conditions where the material sits in stagnant air[164]. Real-life smoldering in layers of porous material is complex, because heat and mass transfer are not 1-dimensional and because edge conditions may play a crucial role. Smoldering materials are often found to break out into flaming when the smolder front encounters a change of media[346]. For example, smoldering cellulose loose-fill insulation tends to break out in flaming when the smolder front reaches a wood framing member[347]. The mechanism of this has been studied[349], and it was found that the smoldering insulation shrinks and creates a gap between itself and the adjacent wood member. This gap allows a flow of air to develop, which oxidizes the char formed on the cellulose insulation and raises it to a high glowing temperature. The glowing char has a good view factor to the adjoining wood surface and ignites it radiatively.

The time required for a smoldering fire to break out into flaming can be surprisingly long. A case is reported of a smoldering initiation in a Russian grain silo which took 2 years to reach a flaming state, at which point an explosion occurred[348].

Because of the geometric complexities of studying layers of material sitting in stagnant air, many laboratory studies focused on creating flow conditions where air can enter the combustion zone only along one direction, and the conditions are so set up that either reverse or forward smoldering is exhibited. For reverse smolder, a simple theoretical treatment suggests that the smolder velocity will be constant and transition to flaming ignition will not occur. This is based upon a 1-dimensional idealization of material far away from boundaries, and does not necessarily imply that flaming cannot break out when an edge is reached. If the smolder is forward smolder, however, then as smolder velocity increases with time, transition to flaming can be directly anticipated. Laboratory studies, however, prove that transition to flaming is also possible for reverse smolder,

although the minimum air velocity that must flow through the material for this to occur is about doubled[349]. In the laboratory study cited, this meant a doubling from 2 to 4 m s^{-1}, but it is not clear whether in real-life smoldering situations identical velocities (due to wind, or induced by natural convection in some manner) would apply to the transition point. In a study using a more realistic geometry of 2-dimensional, forward smoldering it was learned that transition to flaming is most likely to occur if there is a velocity of 0.25 – 2.0 m s^{-1} across the specimen face[336]. Higher velocities are more likely to lead to extinguishment rather than a transition to flaming. For dusts or powders, the particle size also influences the likelihood of transition to flaming. An old FRS study[326] reported that dust layers with larger particle sizes are more likely to transition but did not provide numerical data.

Even if a sufficient velocity is provided for a transition to flaming to occur, the process takes time. The time to flaming[350] has been found to (a) increase sharply with increasing density of material; and (b) decrease with increasing air velocity. These experimental times ranged from 5 to 75 min, although no general relations were obtained.

The effect of FR or smolder-inhibiting agents has been found to be mixed[349]. Borax or boric acid suppressed smoldering-to-flaming transitions from occurring in the bulk material at air velocities up to 5 m s^{-1}. However, when the smolder front reached a wood framing member, the effect of borax was found to be minimal on the transition to flaming. For boric acid treatment, the air velocity needed for transition to flaming during forward-flaming was raised from 2 m s^{-1} to about 3.7 m s^{-1}.

INDICATORS OF SMOLDERING

In many situations it is useful to establish when signs of a smoldering fire might first have been detectable. The first research paper on this topic appeared recently. Mizuno et al.[351] conducted experiments where smoke was introduced to unexpecting experiment subjects. It took less than 10 mg of combustion products distributed into a medium-sized room to elicit a 100% response, but individual response times were extremely varied (< 1 min to over 30 min). Most subjects (80%) first noted a smell and not visible smoke. Some subjects smelled smoke when the quantity smoldered was less than 0.1 mg.

Tests for ignition properties of solids

There are basically two types of testing strategies that are used for determining the flaming ignition of solids: (1) to create a test exposure which directly mimics an expected fire exposure. This is the strategy used for examining the ignition of substances from small flames. No theory or analysis is used, with credibility resting solely on the fact that the test flame is considered to be very similar to the flame in the actual fire. (2) Testing using highly controlled, simple exposure conditions. These conditions are not necessarily viewed as representing the real environment, except in isolated occasions. Instead, the test results form the input data into some analysis scheme which can predict ignition. For this purpose, radiant heating is inevitably used. Heaters can be designed which impose a uniform radiant heat flux upon a test specimen and which present only a tiny fraction of heat transfer by means of convection. Convective heating is normally not used in tests, since, according to fundamental heat transfer theory, it can be seen that it is very difficult to create conditions on a flat specimen face whereby heat transfer rates do not vary greatly between the leading edge and the trailing edge. Furthermore, it is also not readily feasible to eliminate radiant heating, so there is little hope of creating a tractable convective heating environment. Consequently, test methods can be divided into flame tests, radiant heat tests, and some miscellaneous types.

The listings below summarize the features of the most widely used tests for ignition of solids. An ASTM index[352] is available which lists large numbers of additional fire tests according to end-use application; many of these tests have procedures where ignitability is examined. Some less-commonly used ASTM, ISO, and IEC tests have been examined by Hirschler and Grayson[353]. A wide variety of other test methods are described by Pál[354] and Troitzsch[355]; these references are especially useful for locating foreign and obsolete standards. Because of the enormous variety of publications that IEC has issued on flame ignition tests, it has also published a report[356] providing a history of the development and use of some of the various test flames incorporated in their standards.

FLAME IGNITION TESTS

There is a wide assortment of tests which entail the use of a small flame placed against a test specimen. The most widely used of those are reviewed in this Section. As will be seen below, the objectives for these tests generally go beyond a straightforward issue of ignitability. There are, in fact, very few tests where the test result is simply whether a flame was able to ignite a specimen, and if so, the number of seconds that this took. Most tests in use measure some combination of ignitability and flame spread—specimens pass if flame spread no further than a given criterion. A large fraction of these tests also measure *afterflame* or *afterglow*. As discussed above, whether a substance, once ignited, will or will not continue burning once the ignition source is removed, can be an important question. The afterflame concept is an empirical expression of this performance. Thus, while the information is intended to address a distinct need, the main limitation of such measurements is their lack of generality—it may be that a specimen passes, given a certain exposure flame, but it is impossible to tell what will happen with a different flame or with a different arrangement of the specimen. The concept of afterglow is somewhat more difficult to justify. Apart from issues associated with smoldering or self-heating (which are not ad-

dressed by these tests), it is rarely the case that a hazard will be created if the surface of something continues to glow after having been exposed to flames. After all, flames already existed in the environment and the test article failed to propagate flames.

All of the standard tests for small-flame ignition are conducted at room temperature. But for some products, e.g., electric wire and cable, the normal operating conditions involve a temperature distinctly above ambient. Elevated temperature effects are discussed above under *Variables affecting ignition of solids: Ambient temperature*.

ASTM D 2859 METHENAMINE PILL TEST

The smallest flame used in a standard fire test method is the methenamine pill used in the ASTM D 2859 test[357] for carpets. Methenamine ($C_6H_{12}N_4$) is a subliming, non-melting solid which is commonly used as a urinary antibacterial agent. In the test, an 0.149 g pill is ignited with a match on its top surface and placed upon the carpet. On top of the carpet is placed a steel plate having a 205 mm opening in the middle; the tablet is centered in the middle of this hole. The pill burns about 2 min and produces a heat flux of about 4 – 4.5 kW m^{-2} during the peak burning time[358]. To pass the test, 7 out of 8 specimens must not burn closer than 25 mm to the edge of steel plate's opening. According to CPSC regulations, carpeting sold in the US must pass the methenamine pill test, and an essentially identical description of the test method is contained in the Federal Regulations[359]. In the CPSC scenario, the methenamine pill is intended to simulate a burning particle being ejected from a fireplace and landing on a carpet. It is important to realize that the test simulates a very tiny, flaming object. If ignition from small, incandescent (i.e., non-flaming) objects is to be tested, than there is no assurance that data from the methenamine pill could be used. Apart from strict ignitability issues, when small particles land on lightweight, fluffy, or porous materials, there is a complex reaction of the target which can include melting, shrinking, and charring. Even if a small flaming object and a small incandescent object are the same size, it cannot be concluded, in general, that this type of surface response will be similar and that, therefore, ignitability propensity will be similar.

Methenamine pills have also been used to test other products. In one series of tests on mattresses[360], it was found out that while the methenamine pill may present the smallest flame, it is not always the least-strenuous flame source. When compared to a 20 s application of a butane flame, most test specimens either passed or failed both ignition sources. But 2 out of 20 specimens failed the methenamine test, while passing the butane flame test. Conversely, 2 other specimens passed the methenamine test but failed the butane flame test. The occasional odd results are probably due to the fact that the burning pill can recede into the surface as the flaming progresses.

CS 191-53 (16 CFR 1610) FLAMMABLE FABRICS TEST

The general apparel flammability test was developed in the late 1940s after a series of tragic fires involving highly flammable fuzzy rayon sweaters, evening gowns, and children's cowboy chaps. The development of the test method has been reviewed by Bonnet[361]. The political background for the test, along with its limitations, has been given by Patton[362]. All clothing and clothing fabrics sold in the US must meet this test requirement[363]. The test method clamps a 152 × 51 mm specimen in a metal edge frame and this is placed at a 45º angle inside a test cabinet. A hypodermic needle is used as a butane burner to impose a 16 mm long flame for 1 s to the upper surface of the specimen at 25 mm from the lower end. Burn time is indicated by burn-through of a cotton thread trip cord placed 127 mm upstream of the ignition point, which triggers a timer. There are many other numerous details of preparing and conditioning specimens for test, and these are described in a CPSC manual[364]. ASTM D 1230[365] is somewhat similar, but it is rarely used.

The criteria for the standard are shown in Table 37. They are especially convoluted, since the blatantly political motivations of Congress were apparently not appreciated by the enforcing agency, so they added a footnote without changing the original wording of the standard. Also, the meaningfulness of three classes is obscure, since they are not utilized in regulation.

Table 37 Criteria applicable to the CS 191-53 test standard

Class	Flat-weave fabrics	Raised-fiber fabrics
1	trip time 4 s *	trip time > 7 s; or any trip time is permitted, if specimen only shows a surface flash and base fabric does not ignite or fuse
2	(not used)	4 s trip time 7 s, and base fabric ignites or fuses
3	trip time < 4 s *	trip time < 4 s and base fabric ignites or fuses

* changed to 3.5 s by US Congress.

Because of the extraordinarily brief flame exposure and the lenient criteria, this test method is exceptionally easy to pass. A majority of fabrics weighing more than about 70 g m^{-2} does not even ignite from the flame exposure used in the test. Of fabrics which would functionally be suitable for making apparel, only very lightweight, gauzy fabrics or ones with a highly flammable nap would likely fail. Apart from these types, most other apparel fabrics requires more than 1 s of flame exposure to ignite[366]. Data on ignition times of fabrics are compiled in Chapter 14. CPSC recognized the fact that heavier weight fabrics do not fail the test

by exempting plain-weave fabrics heavier than 2.6 oz/yard (88 g m^{-2}) from testing.

FF-3-71 (16 CFR 1615) AND FF-5-74 (16 CFR 1616) CHILDREN'S SLEEPWEAR TESTS

A standard for the flammability of children's sleepwear was originally issued by the Dept. of Commerce in 1971 as DOC FF-3-71 and was enforced by the Federal Trade Commission. The method comprises a small test cabinet in which fabric specimens 89 mm wide by 254 mm high are clamped in a vertically-suspended metal frame. A special tube burner applies a 38 mm long methane flame at a 25º angle for 3 s to the surface of the specimen, at the bottom edge. The test passes if the average char length for 5 specimens does not exceed 178 mm and if no single specimen burns the full vertical length if 254 mm.

Upon creation of CPSC in 1973, this standard passed into their jurisdiction. Initially, sleepwear manufacturers found that the easiest way to meet the standard was to use polyester fabric and to treat it with the FR agent 'tris,' which is *tris*(2,3-dibromopropyl)phosphate. A major furore arose in the mid-70s when the claim was made that this FR agent was carcinogenic. Despite the fact that (1) no human injuries had been reported from the chemical, and (2) many alternatives were available for producing complying fabrics, CPSC responded by modifying the test method[367] to eliminate the afterflame requirement which was originally a part of the test criteria. Using the modified test method, polyester and nylon fabrics can generally pass without any chemical treatment. The FF-3-71 test method is called out for children's sizes 0 – 6X; the same test, but with different regulatory requirements is called out for children's sizes 7 – 14 as FF-5-74.

CPSC 16 CFR 1500.44 FLAMMABLE SOLIDS TEST

CPSC maintains two definitions for the flammability of solids. (1) *Extremely flammable solid*—Means a solid substance that ignites and burns at an ambient temperature of [26.7ºC] or less when subjected to friction, percussion, or electrical spark. (2) *Flammable solid*—Means a solid substance that, when tested by the method described in § 1500.44, ignites and burns with a self-sustained flame at a rate greater than [2.54 mm s^{-1}] along its major axis. There is no test method associated with "extremely flammable solid." For "flammable solid," the CPSC test method involves holding a burning paraffin candle of at least 25 mm diameter with flame in contact of the specimen surface for 5 s, or less if the specimen ignites in < 5 s. The specimen passes if it does not ignite during the 5 s exposure, or if the fire propagation rate is less than the criterion value. The test requires that the flame be touching the sample "at the end of the major axis." This has been criticized by NIST[368], in that many substances do not have an identifiable major axis and that packing density is not specified for substances which are in loose form. In addition, problems were found in identifying the "substance" when flammable trim of otherwise non-flammable solids was concerned. To solve the difficulties attendant to the testing of several classes of products, NIST developed improved test methods, but these were not adopted by CPSC.

The Bureau of Mines[369] proposed a test method for this topic, but this has not met acceptance. The UN test method on this topic is discussed in Chapter 10.

NFPA 701 AND NFPA 705 METHODS

The NFPA 701 test[370] is a fabric test which is generally used in building codes for curtains, scenery, and decorations in schools and places of public assembly. The standard was originally published in 1938, but has been revised at various later times. The traditional large-scale test in NFPA 701 was developed by UL in the 1930s and comprises a tall metal chimney, inside which was hung a 2.97 m long fabric specimen. This was ignited by applying a Bunsen burner flame for 12 s at the bottom edge. The test method was completely changed in 1996 when the large-chimney test was replaced with two tests. Test 1 is for general use and entails a 400 mm long specimen which is hung vertically in an open-face test cabinet and exposed for 45 s to the flame of a Meeker burner held horizontally against the bottom edge. To pass, the afterflame must not last longer than 2 s nor must more than 40% of the specimen mass be lost. Following a research program[371], Test 2 was developed for fabrics with linings and curtains comprising multiple layers. A 1.2 m high specimen is hung inside a metal chimney and exposed for 120 s to flames of a Bunsen burner held at 25º off vertical at the bottom edge. To pass, the afterflame must not last longer than 2 s, nor must the char length exceed 435 mm (or 1050 mm for folded specimens).

The NFPA 701 also used to contain a 'field test' procedure. This test was sometimes misused and applied to plastics, for which it was never intended. Consequently, in 1992, the 'field test' became a separate standard, NFPA 705[372]. In the field test, a kitchen match is applied for 12 s to the bottom of a vertically suspended specimen; to pass, afterflame must not exceed 2 s, and burn length must not exceed 102 mm. The field test is stated not to be correlated to NFPA 701 results, so its value is only as a rough indicator.

ASTM D 1692

This was a small-flame ignition test[373] which used a wing-tip burner to apply a flame to a test specimen positioned horizontally on a wire mesh. Either sheet or foam specimens were used. The unusual feature of this test method was that specimens which did not burn farther than 127 mm were to be reported as "self-extinguishing by this test." This florid language caused the Federal Trade Commission to view the test method as a tool for deceptive marketing of plastics, and was one of the main reasons that the FTC took action against numerous plastics manufacturers and ASTM in 1973[163]. As part of the settlement, the test method was

withdrawn. The identical hardware still exists in the UL 94HB test, but the deprecated term is not used there.

UL 94 TEST SERIES

Perkins published in 1941 a study which was the forerunner to the UL 94 standard[374]. Plastics at that time were coming into more widespread use, as more polymer types were becoming commercialized. Perkins designed a test method using a gas burner flame to simulate the flame of "a common strike-on-the-box match." In the original study, only a vertical orientation was used, with specimen length being 152 mm. Various widths and thicknesses were explored. Perkins only applied the burner flame a single time, but explored flame application durations from 4 to 60 s. On the basis of the results obtained, Perkins classified plastics into 3 groups: Group 1. Cellulose acetate was taken as the benchmark for this group. Cellulose acetate butyrate, PMMA, polystyrene, and one sample of polyvinyl alcohol were also included. Group 2. This group comprised specimens less combustible—for various reasons—than Group 1. Included were a plasticized PVC/PVA copolymer, casein, phenolic, and urea formaldehyde. Group 3. Specimens in this group did not propagate flame after removal of the test flame. Specimens in this group included plasticized PVC, a number of PVC/PVA copolymers, phenol formaldehyde and another sample of PVA. As described below, the UL 94 test (first published in 1972) is substantially different from Perkins' original scheme.

UL 94[375] is actually a series of different tests; thus, a material cannot be described as "passing UL 94," but may be described, for example, as meeting the requirements for V-0. The individual tests and classifications are summarized in Table 38. These only cover the highlights of the testing procedures; the user should consult the standard for actual procedural details. The specimens tested under UL 94 are plastic materials, cut to standard sizes; other UL tests are provided for examining the ignitability of end-use articles.

A majority of the procedures of UL 94 are based on the use of a Bunsen burner, the construction of which is standardized in ASTM D 5025[376]. The use of the burner for the 20 mm and 125 mm flames is described in ASTM D 5207[377]. Both of these test flames involve operating the burner in a premixed mode. IEC standards 60695-11-3[378] and 60695-11-4[379] are functionally equivalent to ASTM D 5207.

The thickness plays a crucial role in UL 94 ratings. Most materials ignite more readily and burn faster or for greater distances if they are thinner. Thus, an actual rating may be described as "V-1 1/8-inch," which denotes that the material is accepted as V-1, but only provided thicknesses of 1/8" or greater are used. The same material may also be rated "V-0 ¼-inch," indicating that at the greater thickness a better rating is obtained.

The mildest tests in the UL 94 series are the ones where the material is oriented horizontally: 94HB and 94HBF. ASTM D 635 test[380] is functionally identical to the 94HB procedure. The 94HBF, 94HF-2, and 94HF-1 tests are used solely for foam materials; these tests are essentially identical to ASTM D 4986[381], which replaced the withdrawn ASTM D 1692 test. The results from the foam series of tests cannot be directly compared to HB ratings, since different test procedures are involved, but all horizontal-burning tests are milder than is any vertical-test rating (e.g., V-2).

The vertical-burn series tests are more strenuous than the horizontal-burn test. ASTM D 3801[382] is similar to the 94V-x procedures. IEC 60695-11-10[383], ISO 1210[384], ISO 9772[385], and ISO 9773[386] standards comprise test procedures which provide equivalents to both HB and V-x methods. The IEC method, which is becoming the most widely used, has a slightly different procedure for obtaining HB ratings. In the IEC scheme, meeting *either* the maximum flame travel distance or the maximum flame spread rate requirement suffices. In addition, the IEC scheme provides for HB40 and HB75 ratings, depending on which flame spread rate (mm min^{-1}) was obtained; there is no limitation as to specific sample thicknesses to be tested.

The 5V designations (5VA and 5VB) come from the fact that the flame used was originally specified as a 5-inch flame. For a 5VA rating, two entirely different sizes of specimens must be tested and pass in order to receive the appropriate rating. ASTM D 5048[387], ISO 10351[388] and IEC 60695-11-20[389] are essentially identical to the 5V portion of UL 94. The 94VTM (Vertical Test Mandrel) tests are used solely for thin materials which deform or burn up to the holding clamp when subjected to the 94V-x test; ASTM D 4804[390] is similar. The RP test is not an ignition test at all, but rather a radiant panel flame spread test. For the main tests, the order of difficulty of qualifying a specimen is: HB (easiest), V-2, V-1, V-0, 5VB, 5VA (hardest). There is no direct comparability of the results of the HF or VTM series to results from HB or V-x series.

The UL 94 series of tests attempts to screen out rapidly-aging components by requiring that certain replicates be subjected to accelerated-aging conditioning for 7 days at 70ºC. It is not clear there is any relation of this conditioning to actual degradation during the service life of the material.

Generally, there are three ways that a UL 94 V-0 rating can be achieved:

1. use of polymers that contain halogen in their basic structure (e.g., PTFE, polychlorotrifluoroethylene, brominated epoxy);

Table 38 Main features of UL 94 small flame tests

Rating	Specimen size			Burner angle	Time flame applied (s)	No. of times flame applied	Burner flame	Specimens tested	Criteria
	Width (mm)	Thick. (mm)	Length (mm)						
HB	13	(1) actual max., 13 mm (2) 3 mm	125	([a])	30	1	20 mm (50 W)	3	• L_b < 100 mm • ([b]) BR ≤ 40 mm min^{-1} • ([c]) BR ≤ 75 mm min^{-1}
HBF	50	(1) actual max., 13 mm (2) actual min.	150	0°	30	1	wingtip burner	5	• L_b < 125 mm • BR 38 mm min^{-1}
HF-1									• L_d ≤ 60 mm • AF ≤ 2 s for 4/5 specimens • AF ≤ 10 s for all specimens • AG ≤ 30 s for all • no cotton ignited below specimen
HF-2									• L_d ≤ 60 mm • AF ≤ 2 s for 4/5 specimens • AF ≤ 10 s for all specimens • AG ≤ 30 s for all
V-0	13	(1) actual max., 13 mm (2) actual min.	125	0° ([c])	10	2	20 mm (50 W)	5	• AF ≤ 10 s per flame application • AF ≤ 50 s total for 5 specimens • (AF + AG) ≤ 30 s for each specimen after 2nd flame application • no AF or AG reaches clamp (at 119 mm) • no cotton ignited below specimen
V-1									• AF ≤ 30 s per flame application • AF ≤ 250 s total for 5 specimens • (AF + AG) ≤ 60 s for each specimen after 2nd flame application • no AF or AG reaches clamp (at 119 mm) • no cotton ignited below specimen
V-2									• AF ≤ 30 s per flame application • AF ≤ 250 s total for 5 specimens • (AF + AG) ≤ 60 s for each specimen after 2nd flame application • no AF or AG reaches clamp (at 119 mm)

Main features of UL 94 small flame tests…continued

Rating	Specimen size			Burner angle	Time flame applied (s)	No. of times flame applied	Burner flame	Specimens tested	Criteria
	Width (mm)	Thick. (mm)	Length (mm)						
VTM-0	50	(1) actual max. (2) actual min.	200 ([e])	0º ([d])	3	2	20 mm (50 W)	5	• AF ≤ 10 s for any application • AF ≤ 50 s total for 2×5 applications • (AF + AG) ≤ 30 s for each specimen after second application • no AF or AG reaches clamp • no cotton ignited below specimen
VTM-1									• AF ≤ 310 s for any application • AF ≤ 250 s total for 2×5 applications • (AF + AG) v 60 s for each specimen after second application • no AF or AG reaches clamp • no cotton ignited below specimen
VTM-2									• AF ≤ 310 s for any application • AF ≤ 250 s total for 2×5 applications • (AF + AG) ≤ 60 s for each specimen after second application • no AF or AG reaches clamp

	150	(1) actual max., 13 mm (2) actual min.	150					3	• no burn-through holes
5VB	13	(1) actual max., 13 mm (2) actual min.	125	20º	5	5	125 mm (500 W)	5	• (AF + AG) ≤ 60 s after 5th application of flame • no cotton ignited below specimen
RP	(see standard for details)								

L_b – burned length
L_d – damaged length
BR – burn rate
AF – duration of afterflame
AG – duration of afterglow

([a]) flame is held vertically; specimen is oriented so that long axis is horizontal, while short axis is tilted 45º with respect to horizontal
([b]) for actual thickness specimen
([c]) for 3.2 mm thick specimen
([d]) angle may be up to 45º if melting/dripping is encountered
([e]) twisted into a modified cylinder shape

2. use of polymers that, upon thermal decomposition, leave more than about 60% of their mass as char (e.g., polyphenylsulfone, polybenzimidazole, or Kevlar);
3. incorporating suitable flame retardants into the formulation.

Lyon and Walters[391] proposed that a V-0 rating will be obtained by materials which show a HRR less than about 250 kW m^{-2}, on the basis of the average HRR determined at an irradiance of 50 kW m^{-2}. Materials which show a HRR > 400 kW m^{-2} are almost certain to be rated no better than HB, with intermediate values giving scattered results. The rule was based on studying only 15 materials, and a later study by Bergendahl et al.[392] show that there is only a modest relationship between performance in the UL 94 test, versus that in radiant heating tests. The latter investigators studied 6 materials in UL 94 and in the Cone Calorimeter and found that, while long ignition times and low HRR tended to correlate to a good UL 94 rating, there were specimens with essentially identical results in the Cone Calorimeter that were classified as HB for one versus V-0 for the other.

The reason for the existence of UL 94 series of tests, presumably, is because they are felt to reflect the propensity of plastics to ignite when presented with small flames. Surprisingly, validation of the tests has rarely been undertaken. The most comprehensive effort so far is discussed in Chapter 14 under *Television sets and computer monitors*. That study indicates significant problems with the test series. The V-2 rating appears to be especially problematic—the range of performance for specimens qualified as V-2 was found to be huge, overlapping both HB and V-0. UL themselves ran a small series of tests[393] on computer monitors where only HB and V-0 specimens were examined. The salient findings were:

- An HB rated monitor ignited readily with a paper match, when held at a corner or underneath. The sides and top could not be ignited with a wooden match. A candle was able to ignite in all configurations except on burning completely down and challenging the underneath surface.
- Four V-0 rated monitors resisted paper matches, wood matches, and candles placed in variety of locations. In one case, however, when the candle flame was next to a ventilation opening, an ignition occurred (due to thickness variations and edge burning), but the monitor eventually self-extinguished without full consumption of test article.
- A burning HB rated monitor placed close to a V-0 rated monitor was able to ignite the latter, with full consumption occurring. This, of course, emphasizes that the V ratings are not intended to reflect behavior when the ignition source is large.
- A monitor which had a HB-rated base, with the remainder being V-0-rated ignited and burned completely when ignited by a candle flame to the base.

V-1 rated materials were not considered in the test work since V-1 ratings are rare. Most materials, if they burn for 10 s, will burn for 30 s. It would be difficult for polymer chemists to produce a V-1 material by design.

As part of an international harmonization effort, the next edition of UL 94 will no longer contain technical provisions, but rather will refer the user to IEC/ISO standards:

- HB ratings: IEC 60695-11-10
- V ratings: IEC 60695-11-10
- 5V ratings: IEC 60695-11-20
- FH ratings: ISO 9772
- VTM ratings: ISO 9773

UL END-PRODUCT TESTS

For many appliances and devices, UL provides that plastics may be qualified in two different ways: (1) by conducting small-flame, arc-tracking, and other tests on the plastic material used; or (2) by subjecting the actual product to fire testing. Thus, UL 746C[394] and UL 1950[*395] prescribe a series of fire tests to be conducted on actual finished products. The decision *where* to apply the flame can be crucial, but this is left up to the discretion of the laboratory. UL 746C in general considers that passing *either* the 12 mm flame test or the 20 mm flame test is equivalent to using an HB-rated plastic.

The *12 mm flame test* ('Needle-flame test') is published as UL 1694[396] but is also separately described in a number of end-use product standards. The test is mainly used by manufacturers of electronic components. It provides for two, 30 s applications of flame (estimated at 45 W) to be made to the item. For this test, the burner is a hypodermic needle of 0.5 mm I.D., with the end cut flat. No air supply is introduced into the burner. Two flame applications are made, with the length of flame exposure being dependent on the specimen volume. Specimens of less than 250 mm^3 are exposed for 5 s, those between 1750 and 2500 mm^3 for 30 s, with intermediate sizes being exposed for 10 or 20 s. The item passes if the afterflame time following each application does not exceed 30 s, if the afterflame plus afterglow time following the second application does not exceed 60 s, if cotton placed below the specimen is not ignited, and if the specimen is not completely consumed. Parts which are made of plastics rated at least V-2 do not need to be tested. This is the mildest test used by UL for general-purpose testing of plastics and it does not have an equivalent in the UL 94 series. Some of its history has been provided by Moltzan and Hall[397]. The IEC equivalent to this test is IEC 60695-2-2[398].

The *20 mm flame test* (50 W; also described as the *¾ inch flame test*) provides for two, 30 s applications of flame to the item. The burner conditions earlier were different, but

[*] Apart from minor deviations, UL 1950 is identical to IEC 60950 and CSA C22.2 No. 950 tests.

currently are standardized to be identical to UL 94. While the test burner used is essentially identical to that employed in the UL 94 V tests, the criteria are more lenient than for V-2: the item passes if afterflame does not exceed 60 s after the 2nd flame application and if the entire object is not consumed. No flame travel limits are set (and, similar to V-2, no limits on molten flaming material). Under UL 746C, parts which are made of plastics rated at least V-2 are presumed to pass the 20 mm test. However, for the purposes of the UL 1950 test, plastics must be rated at least V-1 in order to be presumed to pass the 20 mm flame test.

The *130 mm flame test* (500 W; also described as the *5 inch flame test* and sometimes identified as 125 mm or 127 mm flame test) uses a Bunsen burner with air supply adjusted so the flame has a 38 mm inner blue cone. The test involves the application of a flame 5 times, each time being applied for 5 s then removed for 5 s. The item passes if afterflame does not exceed 60 s after the final flame application, if cotton placed below the specimen does not ignite, and if the specimen is not sufficiently destroyed to reduce the integrity of the device. Parts which are made of plastics rated 5VA do not need to be tested.

In addition to the above tests, UL 746C also describes a test which is conducted on plaques, rather than on the real-scale object. The *746-5VS enclosure flammability test* uses the 5-inch burner flame, but exposes 152 × 152 mm plaques of the material for 60 s. The item passes if neither afterflame nor afterglow exceed 5s, if cotton placed below the specimen does not ignite, and if the plaques do not burn through.

For large plastic enclosure or exterior parts, defined as those having an area > 10 ft^2 (0.93 m^2) or a dimension > 6 ft (1.83 m), UL 746C also requires that the Steiner Tunnel (ASTM E 84) or the radiant panel (ASTM E 162) tests be run. Both of these tests are flame spread tests and do not examine the ignition behavior of the specimen.

The *hot flaming oil test* is prescribed by UL 1950 for the testing of certain full-scale enclosures of electronic equipment. This specialized test is used to examine whether openings in the bottom of an enclosure can set fire to combustibles underneath. A ladle holding 10 mL of burning oil is used to pour the oil into the bottom of the enclosure, and cheesecloth below the enclosure must not ignite.

In addition to flame tests, UL procedures for end-use product testing also include tests for other ignition modes. These are published in UL 746A and are described below under *Arc tracing and arc ignition tests* (the High-Current Arc Ignition Test) and *Other types of tests* (the Glow-Wire Ignition Test and the Hot Wire Ignition Test).

SMALL-FLAME TESTS FOR WIRE AND CABLE

ASTM D 2633

A small-burner flame test for wire specimens is described in Par. 63 of ASTM D 2633[399]. A 560 mm long specimen is used, stretched taut vertically, with a paper flag attached 254 mm above the location at which the flame is applied. The flame is applied from a gas burner which is inclined 20º from vertical. The flame is applied 5 times for 15 s each, with a 15 s interval between applications. Passing results are reported if the flag is not more than 25% burned during test and if cotton placed underneath the specimen does not ignite.

UL 1581

UL standards for various types of wires and cables (e.g., UL 44, UL 62[400], and UL 83) specify the requirement to test the wire/cable according to one or more of small-scale tests* that are delineated in UL 1581[401]. Apart from several narrowly specialized methods, the general-purpose methods for small-scale ignitability testing are the following:

Horizontal flame/FT2 test, Par. 1100. A 254 mm long specimen is supported horizontally, and surgical cotton is placed 241 mm below the specimen. A Tirrill burner positioned at 20º off vertical is used to apply a flame to the center of the specimen for 30 s. The specimen fails if it ignites the cotton or if the total length of char exceeds 100 mm. The "FT2" designation refers to the designation of the test originally promulgated by the Canadian Standards Association.

Vertical flame/FT-1 test, Par. 1060. The method is similar to ASTM D 2633, except that: (a) the specimen length is 457 mm; (b) an additional failure criterion is applied that the specimen shall not flame longer than 60 s after the end of the 5th application of flame; (c) a 4 m^3 test chamber is used.

VW-1 (vertical-wire) test, Par. 1080. The method, which was originally designated the FR-1 test, is identical to the Vertical Flame test, except that: (a) instead of there being a fixed 15 s waiting interval in between flame applications, if the specimen is still flaming after waiting 15 s, the next application of flame does not occur until the specimen's flaming stops; and (b) the afterflame time length criterion is ≤ 60 s after *each* flame application, instead of only after the 5th one. This procedure is tougher for certain specimens than the Par. 1060 test, since it was found that re-applying the flame while the specimen was still burning caused flaming to be extinguished for certain specimens, due to local velocity effects, and the specimen would not re-ignite[402]. ASTM D 3032 describes a test method (Sec. 18, Test Method A) which is similar; this test method is anticipated to be moved into another ASTM standard in the near future. At that time, the procedures will specifically identify the flame as being 500 W.

* Some standards also require large-scale flammability tests to be performed, but these are not primarily tests for ignition.

IEC tests

IEC provides two different small-flame tests for wires or cables, IEC 60332-1 and IEC 60332-2. The test method IEC 60332-1[403] uses a vertical specimen 600 mm long, clamped between two clamps 550 mm apart. A 1000 W burner flame is applied at 45º to the specimen and is placed so that the inner blue cone of the flame is 10 mm from the surface of the specimen and 475 mm below the top clamp. The period of flame application varies with the specimen diameter, being 60 s for specimens ≤ 25 mm, 120 s for specimens of 25 – 50 mm, 240 s for specimens of 50 – 70 mm, and 480 s for specimens > 75 mm. In all cases, the charred area must extend no closer than 50 mm to the top clamp and 10 mm to the bottom clamp. The test method IEC 60332-2[404] uses an identical specimen and clamp arrangement, but the burner flame is specified by a total flame length of 125 mm, not by HRR. The flame is applied for only 20 s, irrespective of specimen size. To pass, the charred area must not extend closer than 50 to the top clamp. There is a separate IEC test for grouped (bunched) cables, but this large-flame test does not have much relation to ignitability.

MVSS 302

The only requirement of the US Federal government for fire behavior of interior materials of automobiles is the extremely lenient MVSS 302 test[405]. A 102 mm × 356 mm (4" ×14") is tested in a maximum thickness of 12.7 mm (½") by being clamped in a metal U-shaped edge frame and exposed to 38 mm high Bunsen burner flame for 15 s. The material passes if it burns for no longer than 45 s after the removal of the flame, or if the flame does not spread farther than 51 mm (2"), or if the flame spread rate does not exceed 1.69 mm s^{-1} (4" min^{-1}). ASTM D 5132[406] and ISO 3795[407] are functionally equivalent to MVSS 302, except that they do not include criteria for passing. The MVSS 302 represents a minimum performance level, even less strenuous than UL 94HB.

FAR BUNSEN BURNER TEST

The Federal Aviation Administration requires various aircraft materials to pass a vertical Bunsen burner test. This test is described in Appendix F of Federal Aviation Regulations (FAR) Part 25. The apparatus originates with a 1951 Federal test, identified as Method 5902. In a 1968 revision, this was replaced by Method 5903, which adds a requirement that "Matheson B-gas" be used as the fuel gas. The latter is a mixture comprising 55% hydrogen, 24% methane, 3% ethane, and 18% carbon monoxide. Its origins date back to the World War II era, when it was desired to standardize a controlled mixture which would be representative of 'manufactured gas' or 'producer gas' which was a common fuel preceding the widespread use of natural gas (which is predominantly methane). An FAA

Table 39 Results from round-robin testing with the ISO 11925-2 small-flame ignition test

Material	Thick. (mm)	Percent reported ignitions[a]			Notes
		Surface location	Bottom edge location	Side edge location	
extruded PS foam, FR	20	57/55	59/59		melted away from flame, but ignited
expanded PS foam, FR	40	16/12	12/24		melted away from flame; only occasional transient ignition
expanded PS foam	60	74/85	88/96		burned completely
PMMA	3	10/70	100/100		bottom edge ignition and 30 s exposure needed for successful ignition
birch plywood	12	10/10	78/78	71/71	no ignition from surface or bottom exposure; occasional ignition w/o flame spread for side edge ignition
PVC	0.1	74/74	46/47		shrank back, sometimes pulled out of holder; ignited and burned, but only for duration of exposure
paper wall covering on gypsum	13	30/47	33/30		rare ignitions; probably occurred where imperfect adhesion to gypsum
pine	19	40/53	89/100		required 30 s exposure to ignite
medium density fiberboard	9	20/30	96/97		no ignition with surface exposure; ignites with bottom edge exposure
PVC coated polyester fabric	0.5	100/100	100/100		shrank away severely, ignited, but ignition not sustained
PUR foam w. aluminum facing	40	80/87	100/100	100/100	flame pierced aluminum and caused rapid burning of foam
PUR foam w. bitumen paper facing	40	59/78 100/100[b]	100/93 100/100	100/100	bitumen facing ignited, but only burned during exposure; when tested with foam side out, burned rapidly

a – first number refers to 15 s exposure, second to 30 s exposure
b – second set of data refers to foam-side exposure

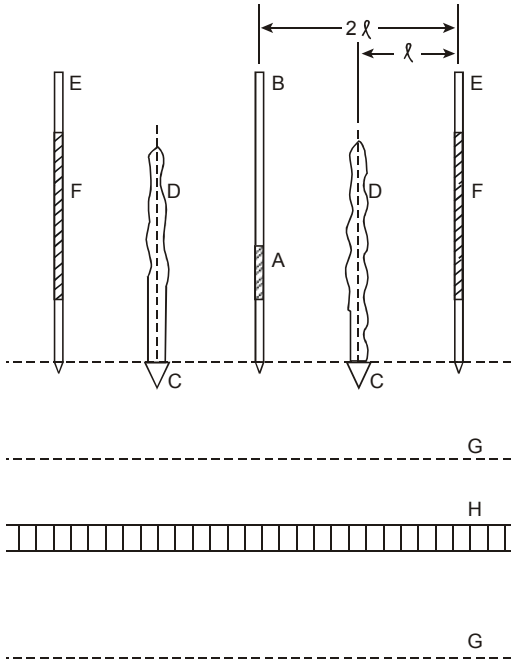

Figure 76 Vertical cross-section through large-flame test used by Koohyar (**A** specimen; **B** specimen holder; **C** liquid pan burners; **D** flame; **E** shroud; **F** viewing ports; **G** screens; **H** honeycomb air diffuser)

study[408], however, found a problem with this gas, in that it tends to give irreproducible flames. This is attributed to iron pentacarbonyl, $Fe(CO)_5$, which is formed when the CO gas component reacts with rust in the gas cylinder. It was determined, by contrast, that 99% purity methane, used as a fuel, did not show any such irreproducibility problems. The same study also examined the influence of thermocouple diameter on measurement of the flame temperature. An inverse relationship between diameter and maximum temperature reading was found.

ISO 11925-2 SMALL FLAME TEST

The ISO small-burner test[409] has mainly derived from the German 'Kleinbrenner' test. An Annex for materials which melt and shrink was developed on the basis of research at the French laboratory LNE. Its basic concept was adopted by the European Commission as one of the test methods for regulating the lower-rated classes of building products. Consequently, the test further evolved under CEN work. A 90 mm wide by 250 mm specimen is mounted vertically in an edge-frame specimen holder. The complicated burner is used to produce a flame of 20 mm height, which is applied at a 45º angle to the specimen. Because of European standardization issues, numerous alternatives and reporting schemes are involved. The burner flame may be applied for 15 or 30 s. Each product is to be tested 6 times by applying the flame to the broad surface and another 6 times by applying the flame to the bottom edge. Multi-layer products over 10 mm are subject to additional testing regimens. Data to be reported include: whether ignition occurs; whether flame spreads as far as 150 mm; if flaming droplets are observed; and if filter paper placed underneath the specimen ignites. If the product shrinks away from the flame without igniting, then an entirely different moving-flame procedure is to be done.

A round-robin with 12 materials was conducted using the 1997 version of this test method[410]. The main results are summarized in Table 39. Despite the seemingly routine nature of the test, it was rare to find 0 or 100% ignitions reported for any material. The Notes in the table refer to typical behavior of specimens.

LARGE-FLAME TESTS

A few flame-ignition test methods have been developed where it is intended to impose a relatively constant heat flux from a flame onto a flat specimen surface. The geometry envisioned is similar to that of the radiant ignition tests, described below. A specimen is used which is much larger in its two face dimensions than it is in the depth. The edges are protected in some manner, so that ignition would not occur at the edges or corner of the specimen. One such test was developed by Koohyar[73]. In his rig, a vertical specimen (100 × 100 mm) was heated by two flames, one on each side, with neither flame touching the specimen (Figure 76). The flames stood upright because combustion air flow to the flames was fed from the bottom and was balanced to be equal from both sides. The heat flux imposed on the specimen was adjusted by varying the spacing distance *l* of the flames. The geometry suggests that the view factor of the flame sheet was quite close to 1.0, so it is not clear how the diminution in heat flux was achieved; perhaps there was a sizable contribution from convection.

Later, Lawson and Parker[411] created a geometry where there was one flame, but two specimens, with the single flame occupying a central position between two specimens spaced 53 mm apart (Figure 77). Unlike in the Khooyar rig,

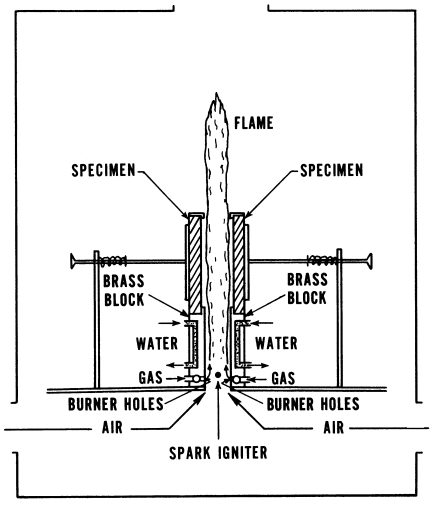

Figure 77 Flame ignition test by Lawson and Parker

a methane burner was used, supplied with fuel at a rate of 8 kW (57 kW m^{-1}, if computed per length of line burner). The flame was positioned relatively close to the specimen face and ignition was declared to occur at the time that the flame 'attached' to the face. The gas flow was set so that the flame would impose an average heat flux of 32 kW m^{-2} to the specimen; unlike in the Khooyar rig, provisions were not made for varying the heat flux.

In both these rigs, it was evident that heat flux uniformity could not have been particularly good, although documentation was not provided on this point. Subsequent test development efforts were generally based on the view that a radiant heat source is much easier to control reproducibly and that it can also simulate an actual large-flame exposure, simply by selecting an appropriate irradiance.

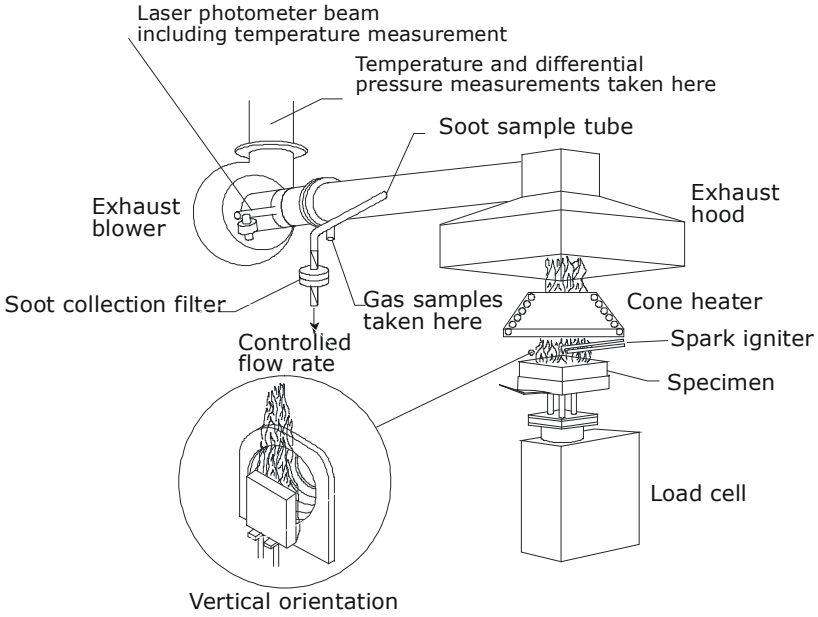

Figure 78 General view of the Cone Calorimeter

RADIANT IGNITION TESTS

THE CONE CALORIMETER

The Cone Calorimeter was developed by Babrauskas[412-414] at NIST during the 1980s as an apparatus primarily for measuring the HRR of small-scale specimens (Figure 78). Until its development, there was not available any standardized test where samples can be heated radiatively with a uniform, feedback-loop stabilized heat flux. The method has been published as ASTM E 1354[415], ISO 5660[416], and in various specialized standards. Because of the uniform exposure provided to specimens, it has become widely used for measuring additional fire properties: mass loss rate, ignitability, smoke production rate, and toxic gas production. Currently it is the most common apparatus used in laboratories worldwide for measuring the radiant ignitability of materials. Babrauskas and Parker[101] described the early ignition testing work with the Cone Calorimeter.

Apart from specialized units that have been constructed to operate in controlled atmospheres[417], specimens are tested in room air. A radiant heater can impose up to 100 kW m^{-2} upon the face of the specimen, which may be horizontally or vertically oriented. Some specimens melt, collapse, or otherwise behave anomalously when in the vertical orientation, thus standard testing is done in the horizontal orientation, with vertical orientation only being used for special research purposes.

The conical heater of the Cone Calorimeter was inspired by the earlier one found in the ISO 5657 test, as described below. The heater in the Cone Calorimeter is not identical, however, since certain improvements were made to enhance reliability and to increase the maximum obtainable heat flux. The emissivity of the heater[418] is approximately 0.99 and the emissivity × view factor product[75] for the cone heater is 0.73, thus the radiant flux going to a cold specimen is:

$$\dot{q}''_e = 0.73\,\sigma\left(T_h^4 - T_o^4\right)$$

where T_h = heater temperature (K) and T_o = room temperature (K). The heater radiates as a grey body operating at a maximum temperature of about 1273 K (1000ºC). Thus, the radiation of the heater falls in the same portion of the spectrum as do most building fires, which are commonly at or below 1000ºC.

Because, in the horizontal orientation, the radiant heater essentially surmounts the pyrolysate plume emerging from the sample, attenuation of radiation by the pyrolysate stream is not as large as it would be in test arrangements where the radiant heat flux arrives straight-down from a remote radiator and has to pass through the thickest part of the plume. In the vertical orientation, the boundary layer of pyrolysates adjacent to the surface is innately thin and the issue does not arise.

In any ignition test where uniform face-heating is provided, effects at the edges must be shown not to be significant. A study was done on samples for the Cone Calorimeter prepared in three different ways: (1) a steel edge frame around the specimen; (2) no edge frame; specimens terminate in a cut edge; (3) an insulated edge frame[419]. For most products, ignition time effects differed only to within the data scatter. For foam plastics, there was a more significant effect, but it is found that many of these cannot be studied in a truly apparatus-independent way.

Figure 78 does not show it, but the current version of the Cone Calorimeter requires the use of a retractable shield between the heater and the specimen. It takes the operator a

finite amount of time to insert the specimen holder into the apparatus and seat it down on the load cell. For products where ignition times are of several minutes duration, small errors in heat flux exposure at the start of the test will not make a d etectable difference. But for specimens which ignite in only a few seconds, uncertainty in starting the test can cause an error. The benefits of using a shield were documented during a research program where extensive testing of upholstered furniture composites was done[420].

ISO 5657

The ISO 5657 test [421] was the first standardized ignition test to be made available which used an electric radiant panel for exposing specimens to a nearly-uniform heat flux. It was originally developed in 1970 by Stephen Grubits[422], at the Experimental Building Station in Australia, now part of CSIRO. Grubits' original version had optional provisions for a spark igniter, or a gas pilot. CSIRO later dropped the gas pilot in favor of a hot wire igniter[196]. Subsequent development of the test in Germany by Peter Topf led to the adoption of the 'dipping duck' pilot. Grubits used the test apparatus in the upright (specimen held face-up), turned sideways (specimen vertical), and upside-down orientations. The ISO version only adopted the face-up orientation.

The most unusual feature of the ISO 5657 test is the 'dipping duck' gas pilot. It was designed to bring a gas pilot close to the specimen surface, yet to avoid imposing a significant amount of added heat flux locally. The pilot is attached to an motorized arm which briefly brings it down once every 4 s, then retracts it to a standby position. It was found that halogenated test specimens tend to extinguish the gas pilot, thus, in the standby position the pilot approaches a r e-igniter flame, which is an auxiliary, non-moving pilot which re-ignites the main pilot if it had been extinguished. The 4-s dipping cycles places a limit on the accuracy, which clearly cannot be better than ±2 s. Another unusual feature is the arrangement whereby a deadweight device presses the specimen up against a masking plate. This device is intended to compensate for specimens which shrink and recede from a heat source, although the squeezing of a test specimen is arguably unreasonable.

The emissivity × view factor product[192] for the apparatus has been determined to be 0.67. The geometry and construction of the conical heater are similar (but not identical) to those on the Cone Calorimeter, thus the value is rather close to the 0.73 obtained for the Cone Calorimeter.

For most testing and research work, ISO 5657 h as been superceded by the Cone Calorimeter, the design of which was inspired by certain features of the ISO 5657 test. Thus, the features of the ISO 5657 test will be described mainly by the differences between it and the Cone Calorimeter, as shown in Table 40. In comparing test results between the two apparatuses, it was found that ignition is typically slightly faster in the ISO 5657 test than in the Cone Calorimeter, although in many cases the differences are no more than the scatter of the data[423]. There may be many reasons for this, but possibly the lack of temperature control on the ISO 5657 equipment is the largest cause.

ASTM E 1321 (LIFT)

This test[424] is primarily designed to obtain material properties pertinent to opposed-flow flame spread. A separate portion of the test is designed for the measurement of ignition times of samples exposed to a nearly-uniform radiant heat flux. Vertically-oriented specimens of 155 × 155 mm are used, with ignition being by an acetylene/air pilot flame. The pilot flame is 180 mm long and horizontally projected about 25 mm above the top edge of the specimen. The gas-fired radiant heat panel is capable of imposing heat fluxes up to 65 kW m^{-2} on the specimen. The ASTM stand-

Table 40 A comparison of features of the ISO 5657 and Cone Calorimeter tests

Feature	ISO 5657 test	Cone Calorimeter
Heating source	electrical element, shaped as truncated cone	electrical element, shaped as truncated cone
Max. power of heater	3000 W	5000 W
Maximum heat flux	50 kW m^{-2}	100 kW m^{-2}
Control of heat flux	set temperature, maintained by servo loop	set temperature, maintained by servo loop
Pilot	propane gas flame, dipping every 4 s	continuous electric spark; optionally, may be tested without pilot
Specimen orientation	horizontal only	horizontal; vertical (optional)
Specimen size	165 165 mm	100 100 mm
Specimen holder	pressure plate forcing specimen against mask plate having a 140 mm circular opening; specimen rests on high density (825 kg m^{-3}) board	horizontal orientation: placed on a pad of low-density (65 kg m^{-3}) ceramic fiber blanket, supported in stainless steel holder vertical orientation: in stainless steel holder, backed by low-density ceramic fiber blanket, supported by calcium silicate board

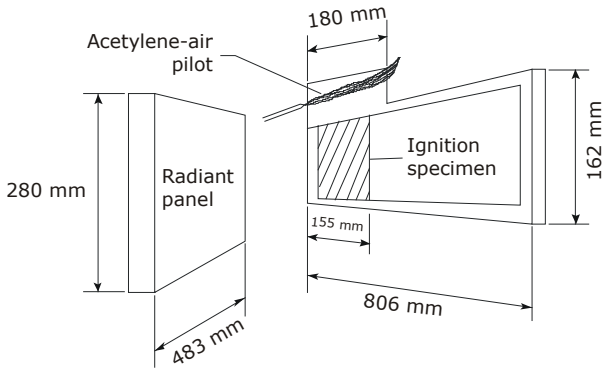

Figure 79 The LIFT test apparatus

ard uses the Quintiere analysis method, which was discussed in detail earlier in this Chapter. The value of $\dot{q}''_{\min}$ is required to be obtained to 2 kW m^{-2} precision in conducting the ignition tests. Due to the nearby presence of the gas-fired heating panel, there is a strong convective flow established across the face of the specimen. Thus, Drysdale[425] has found that values of $\dot{q}''_{\min}$ determined from the LIFT test are consistently higher than those from other apparatuses. In a similar vein, Janssens[75] documented that values of $\dot{q}''_{cr}$ measured in the LIFT test are about 1.0 to 1.5 kW m^{-2} higher than measured in the Cone Calorimeter. He also discovered that systematic errors in measured ignition times occur for heat fluxes > 45 kW m^{-2}; this is because the heater panel is not thermostatically controlled and inserting a cold specimen upsets the panel temperature significantly at higher heat fluxes. Finally, the standard ASTM E 1321 procedure provides for a method for determining an effective value of the thermal inertia, $\lambda\rho C$, but Janssens considers that the values are over-estimated, due to the use of asymptotic approximations.

There have been several variants of this test. The HIFT test[426] involves turning the entire rig around by 90º so that the specimen is in the horizontal plane and melting substances can be tested. The FIST test[427] involves adding a forced air flow of 1 m s^{-1} over the face of the specimen.

FM FIRE PROPAGATION APPARATUS—ASTM E 2058

This apparatus[428] (Figure 80), earlier referred to as the FM Flammability Apparatus, is a specialized test method used by the Factory Mutual system for measuring HRR, ignitability, and flame spread. In many aspects, the apparatus is not too dissimilar to the horizontal orientation of the Cone Calorimeter, but there are two notable peculiarities. (1) The apparatus uses a tungsten/quartz lamp heat source operating at up to a 2200ºC effective radiation temperature, which results in a radiant spectrum much different from the type of heating obtained from flames, room fires, or hot surfaces, which are almost invariably below 1200ºC. The radiation from the FM source is largely in the visible spectrum, where many substances show a much lower absorptivity than in the infrared spectrum. Consequently, the standard procedure with this test involves blackening of the surface to raise what might otherwise be a very low absorptivity. This does not necessarily result in the same amount of radiant flux being absorbed by a specimen as would happen if the surface were not blackened, but radiation from a lower-temperature source were provided. (2) The apparatus can be operated using atmospheres of various oxygen concentrations, but it is normally operated at 40% oxygen instead of at 21%. This is due to a desire to use the HRR data in the context an FM scaling rule which holds that small-scale data collected at 40% oxygen agree better with large-scale data than if this test apparatus were operated at 21% oxygen. Because of the radiant spectrum and the blackening procedure, results from the FM Flammability Apparatus may be systematically different from those obtained in other test methods.

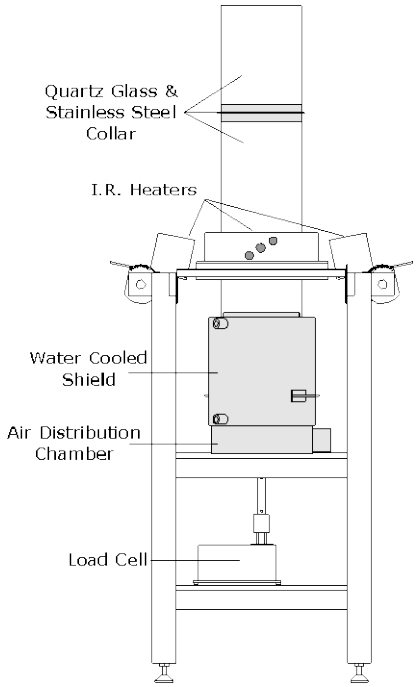

Figure 80 Factory Mutual flammability apparatus

Other differences include a maximum irradiance of 65 kW m^{-2} and an ethylene/air gas pilot. Specimen mounting details in the FM apparatus depend on the particular commodity which is being tested, but wires and cables are commonly tested as single lengths, rather than as a packed array, such as is standard in the Cone Calorimeter. This creates a major difference in response, especially with thinner cables, which are then exposed on all sides and tend to respond in a thermally-thin manner, even if they would respond as thermally-thick in other installations. This was illustrated by Gandhi[429], who tested 9 communications cables in the Cone Calorimeter and in the FM apparatus. Because of these mounting differences, specimens in the FM apparatus ignited much more rapidly (Figure 81) despite

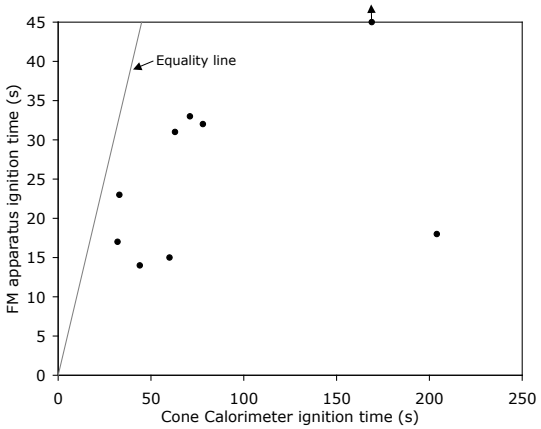

Figure 81 A comparison of piloted ignition times in the FM apparatus and in the Cone Calorimeter for thin communications cables

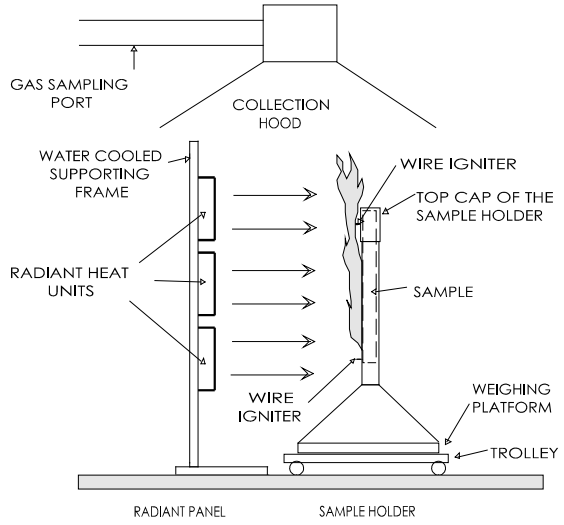

Figure 82 The ICAL apparatus

the fact that both sets of specimens were tested by Gandhi at 21% oxygen. In normal operation, users follow additional testing prescriptions which are given in a large assortment of FM in-house standards; the ASTM standard merely prescribes basic instrument construction and operation principles.

ASTM E 1623 (ICAL)

The ASTM E 1623[430] test is known as the 'ICAL,' which denotes Intermediate-scale CALorimeter. This method (Figure 82) is intended for testing complicated assemblies, where bench-scale testing might not provide sufficiently usable characterization. Vertically-oriented 1.0 × 1.0 m specimens are used, with a thickness of up to 152 mm. Unlike the Cone Calorimeter, heating is by a gas fired panel. Ignitability may be measured at heat fluxes of up to around 60 kW m^{-2}. Piloting is by hot wire igniters, located at both top and bottom of the specimen holder.

Some years after the ICAL was developed, it was noticed that ignition times were consistently longer than in the Cone Calorimeter. This was identified to be due to the greater convective velocity that a large specimen induces[431]. The solution was to mount a ledge below the sample, which has the effect of stopping the boundary layer flow and creating a local eddy, with downward air velocity at the lower portion of the specimen face. The ledge also served a flameholder function once ignition took place and ensured a more steady burning.

ARC TRACKING AND ARC IGNITION TESTS

A 1994 survey[432] identifies 26 different tests which have been published for determining arc tracking resistance, although some of them were drafts rather than formal test methods. A number of the more widely used tests are described below. Others of occasional interest include ASTM D 2132[433], ISO 2678[434], IEC 60587[435], and NASA Handbook NHB 8060 (Test 18)[436].

ASTM D 495

This test[437] creates a high voltage, low current exposure condition and only evaluates arc tracking under dry, clean conditions. Dry tracking can be induced by HV discharges over an insulator's surfaces in real applications, and the test simulates this situation. The method provides a 12,000 V arc across tungsten rod (alternatively, stainless steel strip) electrodes placed on the surface and spaced 6.38 mm apart (Figure 83). The test method is used in UL 746A, and the latter classifies the ASTM D 495 numeric performance into Performance Level Categories (PLC) 0 through 7, with PLC 0 being the best and PLC 7 the worst.

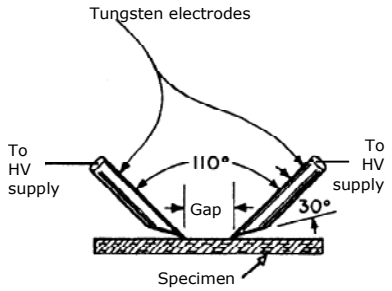

Figure 83 Electrode arrangement of the ASTM D 495 arc tracking test

ASTM D 2303

The method[438], referred to by UL as the Inclined Plane Tracking test, uses a 50 × 130 mm flat specimen where an AC voltage is applied to the surface by two electrodes spaced 50 mm apart, and the surface is continually doused with a stream of liquid contaminant. This rather intricate test can be run in two modes: (1) the initial tracking voltage mode, or (2) the time-to-track mode. For the first case, increasing voltages are applied and the lowest voltage reported which results in progressive tracking during a 1 h exposure. For the time-to-track mode, a desired voltage (up to 6

kV) is applied and the time recorded for progressive tracking to develop.

ASTM D 3032

This ASTM document[439] is a compilation of a large number of different test methods for wire insulation. Three of the methods are directly related to flammability, two being for arc tracking and the third one (see above under UL 1581) being a flame test. Section 26 describes a procedure for damage from dry-arc propagation, wherein a reciprocating guillotine blade slices through a wire bundle to create a short circuit. A specific arrangement of 7 wires is connected to a 3-phase, 400 Hz AC supply circuit, and resistance is inserted in the lines to provide a 1 A current flow. The blade sawing through the assembly initiates an arc, and the test criteria involve the arc-damaged length of wires, both those in contact with the blade and those that are not. The test is considered to be an arc-tracking test, but the connection is tenuous, since no arc-tracking is actually induced. The ASTM D 3032 standard is being reorganized and the VW-1 flame test procedure and some others are being devolved onto a separate test standard.

Section 27 is a wet-arc tracking test. A bundle of seven wires connected in a specified way to a 3-phase, 400 Hz AC supply circuit is used, with resistance being inserted in the lines to provide a 1 A current flow. The insulation is stripped off two of the wires and a 3% NaCl solution is dripped onto the exposed conductors at a rate of 8 – 10 drops per minute. The primary result is the length of wire damaged by arcing.

ASTM D 3638

According to ASTM D 3638[440], the Comparative Tracking Index (CTI) is defined as the voltage which will cause failure by tracking when 50 drops of electrolyte are applied, simulating wet conditions. The maximum test voltage does not exceed 600 VAC. In the procedure, two platinum electrodes are placed on a specimen 4 mm apart; a test voltage is selected and 50 drops of ammonium chloride solution are dispensed into the gap at 30 s intervals. The test method is used in UL 746A, and the latter classifies the ASTM D 3638 numeric performance into Performance Level Categories (PLC) 0 through 5, with PLC 0 being the best and PLC 5 the worst. *IEC 60112*[441] is identical, except that it also describes the Proof Tracking Index, which is a go/no-go test at a single, specified voltage. Research with the IEC 60112 test has been described by Centurioni et al.[442] A roundrobin was conducted in the late 1990s to assess the IEC 60112 test[443]. As a consequence, a number of changes to the procedure are expected to occur. The data collected can also be used to reflect on general categories of materials. For a series of board products (no wire insulation was tested), FR polyamide, non-FR polybutylene terephthalate, and unsaturated polyester gave results of > 600 V. FR polybutylene terephthalate and polycarbonate were ca. 225 V, while phenolic laminate gave ca. 175 V.

MIL-STD-2223

This military standard[444] contains two test methods used by the military for testing of arc-tracking propensity of wires and cables. Test Method 3006 for wet-arc tracking is similar to Section 27 of ASTM D 3032, while Test Method 3007 follows Section 26 of ASTM D 3032 for dry-arc tracking.

UL TESTS

For rating arc-tracking and arc-ignition performance of plastics, the UL 746A standard[445] refers to ASTM D 495 (for D 495 ratings), D 2303 (for inclined-plane tracking) and D 3638 (for CTI ratings) tests. It also establishes three other tests which are not standardized by ASTM. The High-Voltage Arc-Tracking-Rate test applies 5200 V AC across two electrodes onto the specimen surface. The arc is applied multiple times during 2 minutes, and an arc-tracking rate is computed as the length of track established, divided by 2 min. The numeric results (HVTR ratings) are grouped into 5 PLC categories, ranging from PLC 0 to PLC 4.

The High-Voltage Arc Resistance test uses the same power source as the High-Voltage Arc-Tracking-Rate test, but only applies the arc in a single, fixed location for a maximum time of 300 s. The test result is the time that it takes for ignition to occur. The numeric results (HVAR ratings) are grouped into four PLC categories, ranging from PLC 0 to PLC 3.

Finally, in the High-Current Arc Ignition test (HAI), a fixed copper electrode and a movable stainless steel electrode are connected to a 240 VAC power source and an arc is struck between them at the surface of the test specimen, which is a 12.7 × 127 mm bar. Forty arcs per minute are applied, and the primary measurement is the number of arcs it takes to cause ignition. The performance is grouped into 5 PLC categories, ranging from PLC 0 to PLC 4. Middendorf[446,447] describes some of the practical problems with this test method. The UL 1950 standard[395] utilizes HAI ratings for certain equipment. But more commonly, for circuit voltages less than 600 V, UL end-product standards utilize CTI ratings.

Generally, if the manufacturer cannot provide material which qualifies under one or more of the necessary standards, the option is available to perform whole-device tests. The *End-Product Arc Resistance Test* is described in UL 746C[394].

ELECTRIC SPARK OR ARC IGNITION

BUREAU OF MINES ELECTRIC SPARK METHOD

In the 1940s, the Bureau of Mines developed a test method for ignitability of dust layers using an electric spark source[448]. In the method, a 1.6 mm layer of dust is placed on a steel platen, to which one electrode is connected. The

second electrode is a steel needle which is lowered manually onto the dust layer until a spark discharge occurs. The charging voltage for the capacitor is 400 V. Results are reported as MIE values, similar to normal procedures used for gases.

NORDTEST NT FIRE 016 METHOD

The Nordtest method[449] is conceptually very similar to the Bureau of Mines method. A powder or granular sample fills a chrome-steel specimen cup which is 2 mm deep and 12 mm diameter. The second electrode of the spark circuit comprises an 0.5 mm tungsten wire which is brought to within about 1 mm of the specimen's surface. A standard charging circuit is not prescribed, but Eckhoff[450] has described procedures that are implemented at Christian Michelsen Research. Unlike the Bureau of Mines method, the Nordtest method has primarily been used for pyrotechnics and explosives.

NIST ELECTRIC ARC METHOD

Peacock and Vaishnav[368] designed a test method for testing substances that might be highly prone to electric arc ignition on behalf of CPSC, who have a regulation against "extremely flammable" solids. CPSC regulations do not provide a test method and the NIST development work was intended to provide a regulatory test. The apparatus uses a 10 kV (AC) source to create an arc between two copper electrodes placed 5 mm apart and 3 mm above the specimen surface. Black powder and smokeless powder ignited in about 0.1 s, as did human hair. The head of a safety match ignited in 0.2 s, while common consumer goods such as paper, plastic and rubber took about 0.5 to 1.0 s. The authors recommended that an arc application time of 0.3 s would distinguish between the hazardous substances and the normal ones, but noted that common solids, in general, are more readily ignitable by a match than by a small electric arc. Thus, they questioned the need for a regulation specifically based on electric arc ignitability of consumer goods. CPSC did not adopt the proposed method into regulation.

SMOLDERING

Smoldering ignitions can occur due to self-heating or due to external ignition sources. The ignitability of materials from self-heating is considered in Chapter 9. As far as ignition from external sources, there does not exist any test method suitable for all materials. The primary consumer goods for which external-source smoldering ignitions are problematic are cellulose insulation and articles containing resilient padding; tests for these are given below.

Mintz[451] has proposed that the Setchkin furnace be used for examining the smoldering ignition of materials by monitoring the specimen temperature rise and looking for evidence on an exotherm as a point of inflection on the temperature curve. But a s moldering ignition is evidence of self-heating, so it appears to be more desirable to test by one of the methods presented in Chapter 9, which recognize the role of self-heating, rather than adapting a test method designed for another purpose.

CELLULOSE INSULATION

In the US, the smoldering ignitability of loose-fill cellulose insulation is regulated by CPSC[452]. Functionally, ASTM C 739[453] provides the same testing instructions. As part of this test method, a procedure is described whereby the material is used to fill an open-top box, 200 × 200 mm. A lit cigarette is inserted into the center, and flaming or continued smoldering are monitored. The specimen passes if no flaming occurs and if the mass loss does not exceed 15%.

MATTRESS TESTS

The smoldering potential of mattresses is tested according to CPSC regulations[454]. This is a full-scale test, whereby 18 cigarettes are placed on the test mattress and the extent charring is observed. Nine cigarettes are placed on the bare surface and 9 are placed on a b edsheet-covered mattress and then covered by a s econd cotton sheet. To pass, the charring must not extend more than 51 mm from the cigarette in any direction. For initial screening purposes, a bench-scale test is available as ASTM D 5238[455], however, the latter is restricted to cotton batting, whereas the Federal standard applies to all mattress types, including foam types, some of which are susceptible to smoldering.

BURNING BRAND IGNITION

ASTM E 108 ROOF TEST

In the US, roof coverings are normally tested by ASTM E 108[456]. This method originated at UL shortly after 1900 and comprises five different tests, including two which pertain to ignition: the burning brand test and the flying brand test. In each of the tests, a roof deck is constructed at the end of a wind tunnel, with the wind tunnel blowing onto the deck at a speed of 5.36 m s^{-1} (12 mph). In the burning brand test, which simulates the roof-as-victim scenario, wood cribs are used to simulate a brand which has landed upon the test roof. Roof performance is graded into Classes A, B, and C. The test brand for Class A roofs is a 2 kg, 305 × 305 mm crib; for Class B a 500 g, 152 × 152 mm crib (Color Plate 10); and for Class C twenty 9.25 g, 38 × 38 mm cribs (Color Plate 11). The criteria for the test method are given in the parallel UL standard, UL 790[457]. To pass, no flying brands may be generated from the roof assembly during the burning brand exposure, nor may glowing pieces of the deck fall down, nor may there be sustained flaming underneath the deck, nor may the underlying deck (apart from non-combustible decks) become exposed due to failure of the roof covering. In the flying brand test, which simulates the roof-as-source-of-brands scenario, a l arge gas burner and a wind tunnel apply a wind-blown flame to the top side of the roof. To pass, no glowing or burning particles may be produced by the roof. Studies[458] indicated that the 5.36 m s^{-1} wind speed is rough-

ly optimum—doubling or halving its value decreases the likelihood of test failure. The Class A brand is an exceptionally heavy object with respect to the aerodynamic lift that it could create. Thus, it would be unlikely to become airborne for any significant distance—it might more appropriately be viewed as a burning portion falling from a building. In any case, the Class A requirements are remarkably stringent.

OTHER TYPES OF TESTS

CONVECTIVE HEATING TESTS

No standard tests have been developed in this category, although a number of research studies have been reported (described earlier in this Chapter).

HOT WIRE OR BAR IGNITION TESTS

ASTM D 3874 method[459] uses a Nichrome heating wire which is wrapped around a bar-shaped specimen and heated at a rate of 0.26 W mm^{-1}; the actual temperature of the hot wire is not specified. The test result is the length of time that it took for the specimen to ignite. The early development of the method is described by Schwarz[460]. The statement is given in the ASTM Standard that the results from the test are equivalent to those from the IEC 60695-2-20 standard. Hot wire ignition (HWI ratings) from the test are also used in UL 746A[445], which groups performance into six performance categories, PLC 0 (best) through PLC 5 (worst) according to the ignition time. Test on various plastics using the method have been reported by de Aruajo and Wagner[461]. The ignition time was found to generally increase with increasing thickness of the sample. In several cases, the authors found that their measurements disagreed significantly with the manufacturer's reported PLC category.

In the *ASTM D 6194* 'glow-wire' method[462], a 4 mm Nichrome wire is formed into a tongue shape and is held against the specimen at a single point for 30 s. The variable is the temperature of the wire needed to achieve ignition during a 30 s exposure. The reported glow wire ignition temperature is 25ºC higher than the highest temperature which led to no ignitions of three specimens. GWIT ratings (Glow-Wire Ignition Temperature) described in UL 746A[445] are functionally equivalent, as is the IEC 60695-2-13 test[463]. Compared to the ASTM D 3874, the glow-wire test method has more physical significance, since the temperature measured is in some way characteristic of the material, not just an arbitrary performance index. In the IEC test, traditionally, the only test temperatures used were 550, 650, 750, 850, and 960ºC, although recently the test method also permits temperatures in even-100 units. In principle, the GWIT results could be used for any of a wide variety of purposes. In practice, the tests tend to be used for only one purpose: as a part of a test procedure for approval of electric or electronic equipment. In that context, it is expected that electric faults may occur, that the faults may cause gross overheating of wires, and this condition should not lead to a fire hazard from burning plastic parts inside the equipment. Now, most of the wiring will be in copper, which has a melting point of 1085ºC. Electric faults in equipment which does not have special current-limiting features can be expected to melt wiring and to cause even higher temperatures associated with the post-fusion arc. It might possibly be considered that certain types of arcing will be short enough not to be an ignition hazard, but it seems much harder to claim that electric faults cannot cause wires to reach their melting point temperature. Thus, it seems unduly lax that the IEC recipe permits testing at temperatures as low as 550ºC and does not even encompass testing at 1085ºC.

Although the concepts are generally similar, an unpublished UL study[464] indicated that there is no correlation between the PLC ratings obtained in the HWI test and the temperatures reported in the GWIT.

In the 1981 edition of IEC 707[465] test, which has been withdrawn, the *Schramm-Zebrowski incandescent rod test* was described, wherein a 10 × 125 × 4 mm bar-shaped specimen was held horizontally and a glowing silicon carbide rod pressed into its end. The glowing rod was 8 mm dia. and controlled to a temperature of 955ºC. The results were grouped into three classes, depending on whether the specimen did not ignite, ignited but failed to progress a distance of 100 mm, or else spread beyond that. This method was also issued by ASTM as D 757.

The specialized *bad-connection test* of IEC 60695-2-3[466] is specifically intended to simulate the ignition potential of a faulty electrical connection which is glowing due to abnormally high resistance having been formed (see Chapter 11). Only screw connections are tested with this method. A Nichrome heater wire is inserted into the screw connection for 30 min, and it is observed whether or not the test device ignites.

Glow temperature is sometimes tested for. There is a specific Russian test[467] for this property.

HOT RIVET OR NUT TESTS

A hot rivet or nut, if it falls on a combustible material, might start a fire. This thinking led to an old US Navy test where a hot rivet was used to test latex foams. A British test of this nature still exists, BS 4790[468], which is applicable to the testing of carpets. Tests of this type are relatively mild, since the specimen is always oriented horizontally and the heat flux from the hot object drops to zero in a short distance.

SETCHKIN FURNACE, ASTM D 1929

When empirical determinations of 'ignition temperature' are made, the test method used is usually the Setchkin Furnace, ASTM D 1929[167,469,470]. This test method uses a hot-air furnace (Figure 84) wherein a 3 g specimen is placed

into a cup. The furnace is pre-equilibrated to a desired test temperature, and the ignition temperature is determined by a trial-and-error procedure, narrowing the temperature down to within 10ºC. If autoignition ('spontaneous ignition,' or SIT, in the terminology of the method) is to be determined, no pilot is used; if the test is for piloted ignition ('flash ignition' or FIT), then a small propane gas pilot flame located high above the specimen is used. The ignition/no-ignition determination is made at the moment when 10 min have elapsed after insertion of the specimen. An air flow at a velocity of 0.025 m s^{-1} is provided through the specimen cavity. An identical method is published by ISO as ISO 871[471].

The apparatus was developed by Nicholas Setchkin at the National Bureau of Standards and is a further development of the early apparatus of Prince[5]. The same apparatus is also used in the ASTM E 136 t est for 'non-combustibility'[472]. Early versions of ASTM D 1929 included an alternative rising-temperature method and a trial-and-error procedure for determining the optimum air flow velocity. The latter procedure was abandoned since it was discovered that for most materials the 0.025 m s^{-1} velocity provides close to worst-case results[473].

The temperature reported as the 'ignition temperature' is the one registered by thermocouple T_2, which is in the air space, 10 mm below from the specimen pan. The thermocouple actually placed at the specimen surface, T_1, is used only in the context that the standard states: "Flaming or glowing combustion can also be observed by a rapid rise in temperature T_1, as compared to T_2." For materials that shrink or melt, T_1 will probably end up in the gas phase, above the specimen, once heating has progressed.

Just prior to ignition, a specimen usually undergoes some detectable self-heating, thus there is not a fixed relationship between the specimen temperature and the furnace temperature at the instant of ignition. This is true for both the unpiloted and the piloted modes. Yoshida et al.[474] reported a series of results on electric wire/cable materials. Differences of 20 – 40ºC were common, while differences of up to 70ºC were seen occasionally. Even the sign of the difference was seen to be random. The authors also found that, for temperatures above the minimum required for ignition, $1/t_{ig}$ increased linearly with increasing furnace temperature. The reason for this is not entirely clear, since heat flux is not linearly proportional to temperature. In addition to the standard ASTM procedure, the authors also conducted tests where a spark igniter was installed inside the furnace cavity, a short distance above the specimen. For a set of 9 different materials examined, the average specimen temperature at the flash-ignition point using the D 1929 pilot flame was 382ºC, versus 337ºC when using spark ignition. A 45ºC difference is striking. As discussed earlier in this Chapter, ignition by a flame pilot is normally a more strenuous condition than ignition by a spark. The fact that in the

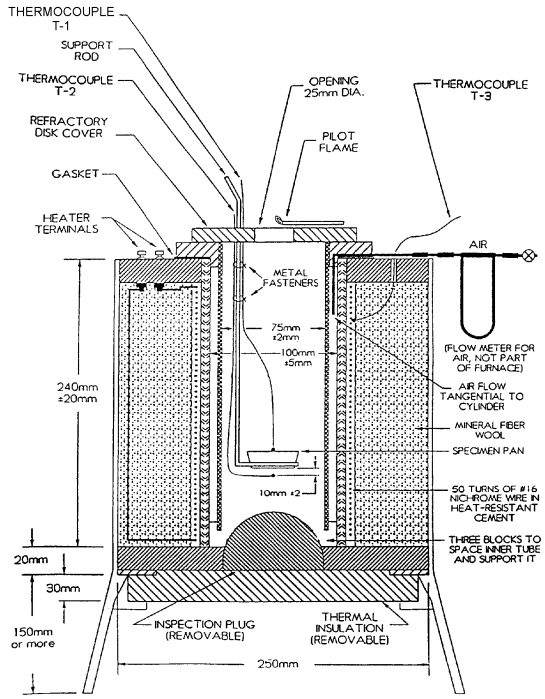

Figure 84 The Setchkin Furnace, ASTM D 1929
(Copyright ASTM International, used by permission)

apparatus a s park igniter is significantly more effective indicates that the pilot flame is very poorly sited. This should not be surprising upon examining the drawing of the test furnace: good practice normally suggests placing a pilot flame close to where combustible gases are being generated, not far downstream. It has been observed[473] that the difference between the autoignition and the piloted ignition temperature, as determined by the standard ASTM D 1929 procedure is generally less than 20ºC. A difference this small again points out the unsatisfactory location for the ignition device in the test apparatus.

Wulff et al.[475] attempted to conduct ignition tests on fabrics in the standard apparatus, but temperature measurements in the vicinity of the specimen indicated unacceptable non-uniformities. They then modified the apparatus by (a) replacing the ceramic cylinder core with one made of steel, which has a much higher thermal conductivity; a nd (b) introducing preheated air into the furnace. It does not appear that any other researchers have considered these particular difficulties of the test method.

Masařík[476] reported on a study using the Czech test method ČSN 64 0149, which is very similar to the Setchkin furnace. He examined three design alternatives for the apparatus:

(1) furnace inner tube: ceramic vs. stainless steel
(2) specimen pan: nickel vs. stainless steel
(3) ignition source: glowing wire vs. pilot flame.

where the underlined alternatives are the ones specified in the Setchkin furnace. Plastics showed little sensitivity to the variables examined. But for wood fiberboard, there were large effects, confounded with reproducibility problems. The piloted ignition temperature obtained ranged from 240 to 380ºC. The combination of nickel specimen pan and glowing wire ignition appeared to cause much higher recorded ignition temperatures in some, but not all laboratories. Since neither of these conditions pertains to the Setchkin furnace, the results suggest that those two variables have been well chosen in the ASTM D 1929 method.

Results of interlaboratory trials ('roundrobins') have been reported on the method. The data (see *Plastics* in Chapter 14) indicate adequate precision, with reproducibility standard deviation of typically 20 – 30ºC. The problem with relying on data from the test method is, thus, not that the reproducibility is poor, but, rather, that the test conditions do not simulate actual fire ignitions very well, and that substantially different results may be obtained in a real end-use environment.

Hilado and Kosola[477] proposed that it makes more sense to measure the air temperature above the specimen, rather than below an impervious specimen pan. They constructed a rig based on a horizontal tube furnace; their results are given in Chapter 15.

LIMITING OXYGEN INDEX (LOI), ASTM D 2863

The oxygen index test, or limiting oxygen index test, ASTM D 2863[478] is commonly used for plastics. The Oxygen Index for a given fuel is defined as:

$$\mathrm{OI} = \frac{X_{O_2}}{X_{O_2} + X_{N_2}}$$

where X denotes the mole (or volume) fraction of a substance. Thus, it is not identical to the oxygen volume fraction X_{O_2}, since the latter is (moles O_2)/(moles total gases), while the OI is (moles O_2)/(moles O_2+N_2). But since the only difference between (moles total gases) and (moles O_2+N_2) is the moles of fuel vapors, and the latter are a small fraction of the total, in fact $\mathrm{OI} \approx X_{O_2}$. The objective of the test is to determine the lowest OI value at which burning (downward flame propagation) can be sustained, thus the test is usually referred to as the limiting oxygen index test.

The concept of LOI testing is based on a plausible, but flawed idea: By testing small cylinders of material in a candle-like configuration, it should be possible to determine whether the material is able or not to sustain burning in an environment of a certain oxygen concentration. The problems with the LOI test are that (1) The results are strongly apparatus-dependent. (2) The apparatus presents a minimally challenging geometry. For example, burning associated with upward flame spread is much more severe than burning in a candle-like geometry. (3) The test is conducted at room temperature. Raising the temperature lowers the oxygen concentration at which burning is sustained, and ignition incidents may occur in connection with overheating of equipment or devices. The test method has also been used for liquids, but it has been shown that the LOI results do not correlate to flash point values[479]. In addition, LOI results for hydrocarbons liquids are typically 15 – 16%, yet limits of flammability testing on these fuels indicate that oxygen must be lowered to around 11 – 14% before upward propagation becomes impossible. Thus, reliance on LOI data would err unconservatively.

Routley[480] and Abbott and Chalabi[481] proposed a heated oxygen index, where the variable reported is a 'temperature index,' defined as the temperature at which the material will burn in air having the ambient oxygen concentration. This is more realistic, since elevated temperatures are common in fire environments, while elevated oxygen levels less so. Nonetheless, the technique fails to overcome the other problems of the LOI test concept.

THERMAL ANALYSIS TESTS

It is occasionally considered that thermal analysis (TGA, DTA, DSC) techniques can be used to determine an ignition temperature of solid materials. Unfortunately, the values of T_{ig} (generally ignition is taken to mean the occurrence of the first significant exotherm) obtained using specimens of a few milligrams exposed to a pre-programmed temperature rise rate in a thermal analysis instrument may not necessarily be related to ignition temperatures of bulk solids igniting under radiant flux or flame-heating exposure. The ignition temperature obtained from such a thermal analysis test will depend on the heating rate of the sample, and there is no particular heating rate that is 'correct.' As an example, for pure cellulose, it was found that the ignition temperature determined in a DTA apparatus[285] increased from 288ºC for a heating rate of 1ºC min^{-1}, to 351ºC when heated at 20ºC min^{-1}. Wharton et al.[231] also documented that the heating rate makes a large difference on the ignition temperatures obtained from DTA tests. For testing in a more realistic scale, as discussed earlier in this chapter, the heat flux does not appreciably affect the T_{ig} for most materials, apart from ones igniting in a glowing mode. On the other hand, Fangrat et al.[88] found a number of instances where the ignition temperature determined in thermal analysis tests was very close to that observed in Cone Calorimeter testing.

Highlights and summary of practical guidance

A substance which is a pure chemical element cannot pyrolyze since it cannot degrade into any simpler structure. Thus, it is impossible for a substance of this kind to thermally degrade, release volatile vapors, and then have these vapors ignite. Elements can ignite and burn, but their mechanisms are unique. Most of ignitable elements are metals, for example, aluminum, magnesium, and iron. Some non-metal elements also ignite and do so by mechanisms similar to metals. Examples of non-metal elements that can ignite include carbon (graphite), boron, phosphorus, and sulfur. Metals are subject to low-temperature oxidation, which means that a pure metal placed in the atmosphere soon becomes coated with a metal oxide on its surface. For most metals, the metal oxide is a solid product and—to a lesser or greater extent—it adheres to the surface. The oxidation of carbon is unique in many ways because the oxides of carbon, CO and CO_2, are gases. Except for those metals capable of pyrophoric behavior, at room temperature the oxidation process is self-limiting, since (a) as a thicker oxide layer builds up, the layer progressively interferes with the metal/oxygen reaction; and (b) the layer itself serves as heat sink. At high temperatures, reactions proceed fast enough that ignition becomes possible, but details of the process vary according to chemical and thermodynamic constants of the metal. Thus, there is not a single theory that is universally applicable. Detailed theoretical models exist, but these are generally limited to a single element. Specific information on various metals and other ignitable elements is given in Chapter 14.

Some elements exhibit pyrophoric behavior when they are in the form of extremely-small particles. As the particle diameter decreases, the volume/surface ratio goes down. Since the heat generated is proportional to the surface area and (ignoring losses) it must all go towards raising the temperature of the particle, the smaller the particle the higher is the temperature attained. The critical sizes are so small (about 0.03 μm or less) that pyrophoric problems arise only in specialized industries.

Ignition of metals

GENERAL PRINCIPLES

Metals are used as fuels in certain rocketry and pyrotechnic applications, because their combination of high heat of combustion and high density means that a great deal of energy can be delivered from a given volume of fuel. Unfortunately, unwanted metal fires tend to be especially severe and problematic, thus, their ignition behavior must be studied.

The vast majority of solid substances encountered in fires initially respond to heat by pyrolyzing, that is, by degrading chemically into substances of smaller molar mass, which are then able to gasify. The ignition event then corresponds to the initial flaming combustion of the gasified vapors. But pure elements, being the simplest chemical arrangement, cannot further break down into smaller, more readily vaporizable fragments; they can only change state. Thus, they can only burn either by a direct surface oxidation reaction (*heterogeneous combustion*) or else they must be raised to such a temperature that the rate of vaporization becomes sufficient to sustain *homogeneous combustion*, that is, combustion which takes place throughout a volume. A normal flame is an example of homogeneous combustion. The most common examples of solids capable of undergoing heterogeneous combustion are certain metals. However, wood and some synthetic polymers also undergo heterogeneous combustion late in a fire, after all of the available components that can gasify have finished gasifying and flaming. The term *glowing combustion* is sometimes applied to charcoal, wood (in its non-flaming stage) and other substances which exhibit medium-temperature heterogeneous combustion. This term is usually not applied to heterogeneous combustion of metals, since they burn white-hot.

For any substance susceptible to exothermic reactions, ignition occurs if a heat balance cannot be established at a low, steady temperature. Thus, before considering any details, it is convenient to establish a qualitative picture of the basic heat flow terms involved in ignition. This is difficult to do when heating and reactivity are spatially highly non-uniform, such as in a pyrolyzing solid or in the gas plume above a liquid pool. But for other types of substances a useful comparison can be made (Table 1). It can be seen that metals are a 'parallel universe' to other substances. Ignition is facilitated for metals when the particles are made smaller. But for a haystack or a beaker of unstable liquid undergoing self-heating, ignition probability is increased when the volume of the material is made larger.

Table 1 The role of volume and surface area in the ignition of substances

Substance	Heat generation	Heat losses
Gases Porous self-heating solids Unstable liquids	Proportional to the volume	Proportional to the outside surface area
Metals	Proportional to the surface area	Proportional to the volume (during the initial heating)

Under the right conditions, most metals can burn except for the noble metals (gold, silver, platinum, etc.). When a metal burns, the product of combustion is its metal oxide (or its metal nitride). For example aluminum:

$$4Al + 3O_2 \rightarrow 2Al_2O_3$$

The situation is complicated by the fact that most metals form a film of the oxide on their surface simply from low temperature oxidation in air. For those metals, surfaces which are not covered in oxide can be created by producing metal particles in an inert atmosphere, but these are highly specialized applications. The oxide film cannot burn, since it already is the product of the metal's oxidation. Before the bulk metal can burn, the oxide skin must be removed in some way. The rupture of the oxide layer plays a critical role in the ignition process, and it is considered that the rupturing is highly influenced by boundary conditions.

One of the rare similarities which metal combustion shares with hydrocarbon combustion is that dissociation occurs. Thus, in the high-temperature zone there is to be found both elemental oxygen and gas-phase elemental metal.

Ignition can be influenced by oxygen solubility in the metal, for those metals where the solubility is relatively high, such as titanium or zirconium.

Bahn[1] proposed that there are three mechanisms for the ignition of small metal particles:

(1) oxidation of a pure metal surface in an oxidizing atmosphere;
(2) reaction between an oxidizing atmosphere and a reactive chemical that has formed on the surface of the metal;
(3) reaction between an oxidizing atmosphere and a metal induced by mechanical energy, e.g., friction or rupture energy.

The third mechanism is often of interest in hyperbaric oxygen systems and is further considered in Chapter 13.

The first major experimental study of the ignition temperatures of metals was by Grosse and Conway[14]. They classified metals into three groups in regards to their ignition characteristics:

(1) Metals that ignite at or below their melting points (barium, calcium, iron, magnesium, molybdenum, strontium, thorium). These metals all have melting points above 650 – 660ºC. These metals generally do not form a protective oxide layer.
(2) Metals that ignite after they melt (aluminum, antimony, bismuth, cadmium, lead, lithium, potassium, sodium, tin, zinc). These metals all have melting points below

650 – 660ºC. All of these metals (except for alkali metals) form a protective oxide layer. Markstein noted that this group of metals tends to show ignition temperature results that are much less dependent on the experimental conditions than the metals of the first group[2].

(3) Metals that do not ignite (silver, platinum, mercury).

The simplest theory to explain ignition of metals was propounded by Monroe et al.[3], based on a heat-balance concept. They proposed two criteria, the melting-point burn ratio and the boiling-point burn ratio. Sustained combustion cannot occur if the amount of heat liberated in combustion is not enough to bring the metal to its melting point. Thus, the melting-point burn ratio is defined as:

$$BR_{mp} = \frac{\Delta h_c}{\Delta h_{mp} + L_{mp}}$$

where Δh_c = heat of combustion, Δh_{mp} sensible heat to raise metal to its melting point temperature, and L_{mp} = latent heat of melting. Similarly, the boiling-point burn ratio is defined as:

$$BR_{bp} = \frac{\Delta h_c}{\Delta h_{mp} + L_{mp} + \Delta h_{bp} + L_{bp}}$$

where Δh_{bp} sensible heat to raise metal from its melting point to its boiling point and L_{bp} = latent heat of vaporization. Then, according to their theory:

(1) if $BR_{mp} < 1$, the metal cannot be burned;
(2) if $BR_{mp} \geq 1$, but $BR_{pb} < 1$, the metal can burn, but only heterogeneously;
(3) if $BR_{pb} \geq 1$, the metal can burn homogeneously.

Some data[4] based on their theory are shown in Table 2.

It will be noted that Monroe considered that the metal is initially at room temperature and that no external energy is supplied to the system. Thus, it would seem that his ratios could only be applicable to pyrophoric metals, which ignite starting from room temperature. As shown later, however, to describe ignition of pyrophoric metals requires consideration of the oxide film which develops on the surface of most metals, and Monroe does not treat this film at all. Thus, his concept is inapplicable to pyrophoric metals but can have some value in other cases. As discussed in Chapter 13, accidents in pure-oxygen systems often involve a surface ignition of an otherwise not-preheated metal. Monroe's BR_{mp} should be able to suggest which metals can burn up under these circumstances, versus those not igniting or exhibiting only a surface flash. Nickel-rich alloys tend to be hard to ignite in oxygen systems, as shown in Chapter 13, and this is consistent with nickel having a low BR_{mp} value, even though it does exceed Monroe's suggested 1.0 value.

Table 2 Burn ratios for some metals, computed according to the theory of Monroe et al.

Metal	BR_{mp}	BR_{bp}
Ag	0.4	0.05
Cu	2.0	0.2
Ni	3.7	0.5
Fe	3.8	0.56
Sn	44.8	0.8
Pb	18.6	0.9
Cr	6.4	1.2
Ti	10.9	1.4
Be	12.6	1.6
Li	41.7	1.6
Al	29.0	2.2
Zn	19.3	2.4
Ca	17.4	3.1
Mg	22.9	3.6

A more comprehensive theory was put forth by Glassman, who postulated that the flame temperature of many metals is limited to the boiling point of its oxide[5]. This is due to the very high heat of vaporization* of metal oxides, which is greater than the heat available from the combustion process. The heat available from the combustion is simply minus the heat of formation of the metal oxide (since the heats of formation of metals and O_2 are both ≡ 0). The heat required to raise the metal oxide from a solid at 298 K to a vapor at T_b is the sum of the sensible enthalpy of raising its temperature from 298 K to T_b, plus the heat of vaporization at 298 K. Data for some metals are given Table 5. It is seen that—except for boron†, tungsten, and a few others—enough heat is not available to fully vaporize the oxide at its T_b. Thus, the metal's flame will have liquid particles in it and is not fully gasified.

Upon ignition, Glassman[6] considers that the conditions which determine whether heterogeneous or homogeneous burning will happen are based on the boiling points of the metal and its oxide, as given in Table 3. Glassman's theory has not been fully validated, and has been criticized by Steinberg et al.[7]. Their criticism centers around the fact that 'boiling' is not what metal oxides tend to do; rather, many tend to dissociate. This is not a serious limitation to the theory, since a temperature of rapid dissociation can equally well be used.

Table 3 Glassman's concept of metals combustion

Boiling point relation	Type of combustion	Nature of condition
T_b (metal) > T_b (oxide)	heterogeneous	sufficient, but not necessary
T_b (metal) < T_b (oxide)	homogeneous	necessary but not sufficient

There are a number of additional thermochemical subtleties involved, including the fact that the composition of the atmosphere—air or oxygen—can sometimes govern whether the combustion will be heterogeneous or homogeneous.

* Some metal oxides decompose before vaporizing so, for them, it is more correct to refer to the heat of decomposition.

† Chemically, boron is classed as a non-metal, however, its combustion characteristics are similar to those of metals, thus it is often included in theories for the combustion of metals.

Table 4 Controlling phenomena of metals ignition, as classified by Breiter et al.

Group	General features	Controlling variable	T_{ig}	Examples
1	Non-protective oxide	direct oxidation of metal	variable	Ba, Ca, Mg
2	Protective oxide; oxide soluble in metal	melting of oxide and its dissolving in metal	variable	Ti, Zr
3	Protective oxide; oxide not soluble in metal; metal is volatile, oxide is not	melting and oxidation of metal	$\approx T_{mp(metal)}$	Zn
4	Protective oxide; oxide not soluble in metal; non-volatile metal and oxide; $T_{bp(metal)} > T_{mp(oxide)}$	melting of oxide	$T_{mp(oxide)}$	Al, Fe, Ni, Si
5	Protective oxide; oxide not soluble in metal; non-volatile metal and oxide; $T_{mp(metal)} < T_{mp(oxide)}$	boiling of metal	$T_{mp(metal)}$	Be
6	Protective oxide; oxide is volatile	oxidation of metal; boiling of oxide	$\approx T_{bp(oxide)}$	B

Numerous other material properties of the metal and its oxide come into play in determining the nature of combustion. Price[8] considers that the following factors can affect the ignitability of a metal:

(1) Ratio of the molar volume for the solid oxide to that of the metal. Values less than 1 cause the surface oxide layer to be non-protective.
(2) Ratio of the coefficients of thermal expansion of the solid metal to that of its oxide. Values greater than 1 tend to cause the oxide film to crack during heating.
(3) Melting point of the metal. Flow of metal facilitates ignition.
(4) Melting point of the oxide. If the melting point of the oxide is higher than that of the solid metal, the oxide may dissolve in the molten metal or may retract from the surface.
(5) Solubility of the molten oxide in the molten metal. If the solubility is high, the molten metal may diffuse to the surface through the oxide layer. If the solubility is low and the interface surface tension is high, the oxide layer inhibits further oxidation. If the solubility is low but the oxide surface tension is high and the interface surface tension is low, then the oxide tends to accumulate on the surface, retract, and expose the metal.
(6) Boiling point of the metal. If the boiling point is low (e.g., magnesium), then the oxide skin is easily destroyed and ignition occurs at or near the surface. If the boiling point is high (e.g., titanium, tungsten, zirconium boron), then it may not be reached and burning will be primarily by a surface reaction
(7) Boiling point or dissociation temperature of the oxide. If this temperature can be attained, then the oxide layer can be removed and direct surface oxidation results.

Point #1 was first proposed in 1923 by Pilling and Bedworth[9] and the ratio is sometimes referred to as the P&B ratio; unfortunately, later research[10] showed that knowing the P&B ratio does not suffice to determine whether the oxide coat will be protective or not. Mellor[11] concluded that the oxides of most metals are protective at low temperatures and non-protective at high temperatures, with each metal having a unique 'transition temperature' separating the two regimes. The largest group of metals (e.g., Ca, Mg, Mo, Ta) had transition temperatures at 400 – 600ºC. Additionally, for some metals, thin oxide layers are protective, but after the layer grows to larger thickness, it proceeds to crack and break up.

On considerations similar to Price's, Breiter et al.[12] proposed placing metals into 6 different groups of behavior (Table 4). This scheme can be especially helpful in understanding the ignition of metal alloys, where changes in T_{ig} often are seen to correspond to different regimes in a metallurgical phase diagram for the system. Breiter et al. illustrated their theory with data on Mg-Zn, Mg-Al, Zn-Al, Al-Ni, Ti-Zr, and Ti-Ni alloys. As always with metals, actual details of the combustion are highly dependent on the specifics of the combustion situation, and quite different regimes are commonly observed when some test conditions are changed.

Hardt[13] proposed that pyrophoric metals are generally distinguished chemically by largely-unfilled *d* electron orbitals (d_0 to d_2), but it is evident that a number of other factors, some chemical rather than physical, also are involved.

Unlike for hydrocarbon fuels, a metal's flame temperature is essentially independent of the fuel/air ratio over a wide range. Certain metals burned in oxygen can attain very high flame temperatures. The metals showing the highest flame temperatures form a diagonal band on the left side of the periodic table[14] and include beryllium, magnesium, aluminum, and zirconium.

Many metals which require high temperatures for ignition will ignite at ambient temperature if they lack the normal oxide coating on the surface. This can occur in processes where finely divided metals are produced.

Table 5 Thermophysical properties of some metals and their oxides

Metal	**Metal oxide**	T_m (K)		T_b (K)		Δh_v (kJ mol^{-1})	$\Delta h_v + (h_{Tb}-h_{298})$ (kJ mol^{-1})	Δh_f (kJ mol^{-1})	Δh_c (MJ kg^{-1})

bold symbols indicate heterogeneous combustion expected, according to Glassman's rule
* forms a mixture of oxides, not a single oxide.
† sublimes.
Δh_v = heat of vaporization of metal oxide at 298 K
$h_{Tb} - h_{298}$ = sensible enthalpy to raise the gaseous oxide from 298 K to its boiling temp.
Δh_f = heat of reaction (= heat of formation of solid metal oxide)

An additional complication of metals is that some can burn in atmospheres of pure N_2 or CO_2. In the former case, metal nitrides are formed instead of metal oxides. In the latter, the CO_2 is reduced to CO or C, and the metal is oxidized to its metal oxide.

Some metal particles explode or fragment shortly after ignition. Those with a propensity for showing this behavior—at least under some heating conditions—include aluminum, plutonium, samarium, tantalum, titanium, zirconium[15].

THEORIES

As some of the discussion above indicated, the ignition of metals is a very complicated phenomenon. Partly, this is because of the uniquely tightly coupled physics and chemistry. Phase changes, surface oxide formation, breakage of oxide films, etc., play little or no role with other fuel types, yet are dominant in the ignition and combustion of metals. Because there is not a great deal of commonality in the combustion of the various metals, most Western researchers have endeavored to develop a theory for a single element. A number of them are briefly cited in Chapter 14. Russian researchers took a more global view where a single theory to fit all metals is strived for. Merzhanov[16] has briefly outlined the numerous Russian studies on this topic. Generally, the Russian theories focused on a thermal self-heating formulation, with only a subsidiary role being allocated to the physical phenomena. The studies are wholly computational in nature, and Merzhanov did not capture any of their trends in closed-form equations or approximations.

Apart from differences among elements in their chemical traits, the physical arrangement is also important. Same as for pyrolyzing solids, there are three basic physical arrangements, each one of which needs to be treated by a separate theory:

(1) a single, isolated mass, which may range from a microscopic particle to a huge object
(2) a pile or layer of small particles
(3) a dust cloud.

Theories for #1 and #2 will be considered below. Theories for dust clouds—including metal dusts—have already been considered in Chapter 5; some additional ones are considered later in this Chapter under *Ignition of carbon*.

THEORIES FOR A SINGLE, ISOLATED MASS

Reynolds[17] developed an ignition theory which is based on a variation of the Taffanel and le Floch postulate (see Chapter 4) that, at the ignition temperature:

$$\frac{d\dot{q}''_G}{dT} = \frac{d\dot{q}''_L}{dT}$$

where $\dot{q}''_G$ = heat generation rate (kW m^{-2}) and $\dot{q}''_L$ = heat loss rate (kW m^{-2}). Assuming heat loss is solely by radiation,

$$\frac{d\dot{q}''_L}{dT} = 4\varepsilon\sigma T_{ig}^3$$

while the heat generation term will depend on the actual chemistry at the surface. Reynolds assumed that metals fall into two categories—those that show a linear oxidation law and those with a parabolic law. The linear law is:

$$\dot{q}''_{G1} = QA\exp\left(-E/RT\right)$$

while the parabolic law (as corrected by Markstein[2]) is:

$$\dot{q}''_{G2} = \frac{\gamma QA}{2\delta\rho_{ox}}\exp\left(-E/RT\right)$$

where Q = heat of reaction (kJ per kg of oxygen), A = pre-exponential factor (kg m^{-2} s^{-1} for linear law, kg^2 m^{-4} s^{-1} for parabolic), E = activation energy (J mol^{-1}), R = universal gas constant (8.314 J mol^{-1} K^{-1}), δ = oxide layer thickness (m), and γ = stoichiometric ratio of mass of oxide/mass of oxygen. The dimensionless solution to the equation is:

$$\exp\left(-1/\theta\right) = \frac{\theta^5}{\eta}$$

where $\theta = RT_{ig}/E$ and $\eta = \frac{QA}{4\varepsilon\sigma}\left(\frac{R}{E}\right)^4$ for the linear law and $\eta = \frac{\gamma QA}{8\varepsilon\sigma\delta\rho_{ox}}\left(\frac{R}{E}\right)^4$ for the parabolic law. The solution would seem to be of limited utility, since obtaining the needed constants, especially A, E, and δ, would be much more of a challenge than measuring ignition temperatures. Reynolds presented some data showing fairly good agreement of experiment with theory for a number of metals but did not describe a procedure for obtaining the constants, nor for deciding whether to apply the linear law or the parabolic. Even worse, Reynolds' data showed that, in most cases, A and E are in fact not constants but depend strongly on the temperature.

Mellor[11] noted that, due to certain simplifications, Reynolds' theory predicts that neither specimen size nor ambient pressure affects the ignition temperature, both of which are at variance with a number of experimental studies. He then formulated an improved theory that generalized Reynolds' theory by assuming that each metal oxidizes according to a parabolic law below its 'transition' temperature and according to a linear law above it*.

Mellor based his generalized theory on Frank-Kamenetskii's scheme[18] where the reaction rate at a surface is limited by a combination of diffusion and chemical kinetics. In addition, he included radiative losses from the heated surface. This led to a complicated formulation, however, and Mellor did not even attempt to solve the model he had set up. Mellor did point out that his theory had the possibility of correctly predicting that for small particles T_{ig} varies inversely with diameter. He noted that, for simplicity, many of the more-tractable theories assume a constant Nusselt number and thereby assume that heat losses vary inversely with diameter. Consequently, such theories are unable to predict the experimental results for small particles. Surprisingly, there is not a great deal of literature on the size effect (see Chapter 14), so Mellor conducted experiments which showed that 0.127 mm thick magnesium foils ignited in oxygen at about 100ºC lower than did ones of 0.254 mm thickness; similar results were also shown for calcium foils of two thicknesses.

Yuen[19] proposed an ignition theory which had many required constants but lacked a systematic means for obtaining them. As a result, even though he also presented some experimental data, he was not able to validate the theory. In addition, a number of the Russian theories (e.g., those by Arutyunyan[20] and Gremyachkin[21]) are available in English, but these require wholly-numerical solutions and have generally not been validated against experimental data. Khaikin's[22] is interesting in that it effectively represents a generalization of Reynolds' theory but, again, obtaining suitable data is also a major limitation with its use.

Most simple theories of the ignition of metals treat heat losses in such a way that their predictions are the opposite of Mellor's experimental findings: small particles are predicted to be harder, not easier to ignite. The theory of Friedman and Maček[23] is perhaps the best known of these. Dealing solely with aluminum combustion, they found that experimental data support the concept that, at ignition, the temperature of the particle is always that of the melting point of aluminum oxide, T_{mo}, which is 2327 K. But, because of the exothermic reactions, the environment temperature T_o needed for ignition is lower than T_{mo} and decreases with decreasing particle size. They assumed that the reaction is first-order with respect to oxygen (which is not true in the general case of metals combustion). Then, they postulated that, at the critical temperature T_c, the heat generated $\dot{q}''_G$ must be identical to the heat loss $\dot{q}''_L$. But, in turn, they assumed that the reaction rate is equal to the amount of oxygen that can be delivered to the surface by diffusion, $\dot{q}''_D$. Thus,

$$\dot{q}''_G = \dot{q}''_L = \dot{q}''_D$$

Now $\dot{q}''_G = QAC\exp\left(-E/RT_{mo}\right)$, where Q = heat of reaction, A = pre-exponential factor, and C = concentration of oxygen in the gas phase at the fuel surface. The heat losses were assumed to be solely due to gas-phase conduction loss, $\dot{q}''_L = \frac{2\lambda}{d}\left(T_{mo} - T_c\right)$, where λ = gas-phase conductivity

* But beryllium was found to be an exception to the rule, in that it oxidizes according to a linear law at low temperatures, and parabolic at high.

and d = particle diameter. The diffusion limit to the reaction rate is taken as $\dot{q}''_D = \frac{2QD}{d}(C_o - C)$, where D = diffusion coefficient and C_o = ambient oxygen concentration. The solution for T_c is obtained as:

$$T_c = T_{mo} - \frac{QC_o}{\lambda[(1/D) + (2/dA\exp(-E/RT_c))]}$$

The authors then note that the $1/D$ term is very small and thus the solution simplifies to:

$$T_c = T_{mo} - \frac{QAC_o \exp(-E/RT_c)}{2\lambda} d$$

Thus, in their theory, the particle surface temperature needed for ignition (T_{mo}) is independent of size, but the furnace temperature needed for ignition (T_c) decreases linearly with increasing particle diameter. Numerically, however, the effect is small. For a 35 μm particle, their theory predicts that $T_c - T_{mo} = 7°\text{C}$. This, of course, is below the experimental uncertainty level. They also obtained a simplified expression for ignition time using their theory:

$$t_{ig} = \frac{\rho d^2}{12\lambda}\left[C_p \ln\left(\frac{T_g - T_\infty}{T_g - T_{mo}}\right) + \frac{L}{T_g - T_m}\right]$$

where ρ = density of metal, C_p = heat capacity of metal, λ = thermal conductivity of air, T_g = the furnace temperature ($\geq T_c$), T_∞ = initial particle temperature, and T_m = melting point of metal. The prediction that ignition time should be proportional to d^2 was validated by experimental data. A number of other theories have been reviewed by Glassman et al.[24], but the less well-known ones were also seen to either not predict experimental trends successfully or else to be based on dubious assumptions.

More recently, Glassman et al.[25] proposed a heat balance model for assessing the propensity of various metal particles to undergo pyrophoric ignition. The basic principle is that, for pyrophoric ignition to take place, a particle, when initially in an unoxidized state, must be small enough so that the initial oxide layer that develops due to heterogeneous reaction with air generates sufficient heat to vaporize the metal and to raise the oxide layer temperature to T_m. Assuming that the metal particles are spheres of diameter r (including the oxide coat) and that δ is the thickness of the oxide layer, Glassman et al. consider the following heat balance.

heat available:

$$\frac{4}{3}\pi\left[r^3 - (r-\delta)^3\right]\rho_{ox}\left(-\Delta H^o_{298}\right)_{ox}$$

heat needed to vaporize the metal:

$$\frac{4}{3}\pi(r-\delta)^3\,\rho_m\left[\left(H^o_{bpt} - H^o_{298}\right) + L_v\right]_m$$

heat needed to bring the oxide layer to T_m:

$$\frac{4}{3}\pi\left[r^3 - (r-\delta)^3\right]\rho_{ox}\left(H^o_{bpt} - H^o_{298}\right)_{ox}$$

where H^o_T = standard-state enthalpy at T; $\left(\Delta H^o_{298}\right)_{ox}$ = standard-state heat of formation of the oxide at 298 K; *bpt* denotes the metal vaporization temperature; *m* denotes metal; and *ox* denotes oxide. Solving the heat balance equation gives the thermal runaway condition as:

$$\frac{\rho_{ox}}{\rho_m} \times \frac{\left(-\Delta H^o_{298}\right)_{ox} - \left(H^o_{bpt} - H^o_{298}\right)_{ox}}{\left[\left(H^o_{bpt} - H^o_{298}\right) + L_v\right]_m} \geq \frac{\left(1 - \delta/r\right)^3}{1 - \left(1 - \delta/r\right)^3}$$

The left hand side of the above equation is a group of constants with known values for any particular metal, thus, the maximum radius r for pyrophoric ignition will occur can be obtained if a value for δ is known. Metals with a greater pyrophoric tendency have a larger critical r, or a smaller value of δ/r. Empirically, the data in Chapter 14 show that pyrophoric properties, if exhibited at all, require a diameter roughly 0.03 μm or smaller. Since the physical thickness of oxide layers is normally in the range of 0.0025 – 0.0050 μm, this led Glassman to the criterion that pyrophoric metals are those corresponding to $\delta/r < 0.2$; in other words, if $\delta \leq 0.03$ μm and

$$\frac{\rho_{ox}}{\rho_m} \times \frac{\left(-\Delta H^o_{298}\right)_{ox} - \left(H^o_{bpt} - H^o_{298}\right)_{ox}}{\left[\left(H^o_{bpt} - H^o_{298}\right) + L_v\right]_m} \geq 1.05$$

Metals that satisfy this requirement include aluminum, calcium, cesium, lithium, magnesium, potassium, rubidium, and sodium. But it turns out that uranium and zirconium, which are exceptionally problematic in terms of pyrophoric behavior, do not qualify as pyrophoric metals under Glassman's definition. The reason they exhibit rapid combustion is because the oxide coat which is formed is non-protective—crevices form and oxidation continues to attack the metal through the crevices, thereby maintaining combustion, even though the heat balance is not sufficient to account for total vaporization.

THEORIES FOR METAL DUST LAYERS

If the metal is in the form of a powder or a dust then, under storage conditions it will be held in a container or settled into a layer. This introduces additional complexity, since there are now two separate sizes involved in the problem—the diameter of each particle and the dimension of the pile. Tetenbaum et al.[26] suggested that Frank-Kamenetskii theory (see Chapters 4 and 9) can be applied, with some modification. The basic theory envisions a reaction which is volumetrically uniform throughout the system. But for oxidizing metal particles, reaction can only occur at the surface of each particle. Thus, they concluded that the concentration of substance should be replaced by the total surface area of the all of the particles, divided by the gross system volume. In other words, the mass loss rate due to chemical reaction is taken to be:

$$\dot{m}''' = sA' e^{-E/RT}$$

where s = total surface area/gross volume (m^{-1}), and A' is now a pre-exponential factor which has the units kg m^{-2} s^{-1}. Then the Frank-Kamenetskii parameter δ becomes:

$$\delta = \frac{QA's}{\lambda}\left(\frac{E}{RT_o^2}\right) r^2 \exp\left(\frac{-E}{RT_o}\right)$$

and r (the half-thickness of the layer, sphere, etc.) can be solved for once the other variables are known; the meaning of the variables is the same as given in Chapters 4 and 9. Tetembaum et al. validated their theory against data for uranium powder. Values of E and A' were obtained from unpublished chemical kinetics studies, while the effective thermal conductivity λ was estimated on the basis of data for other metal powders. This effective conductivity is not constant, but decreases with decreasing particle size. The experimental ignition temperature data were obtained by using a fixed-diameter crucible and varying the particle size. The results showed a straight-line plot when the specific area (m^2 kg^{-1}) is plotted against $1/T_o$. Specific area can be measured by any number of experimental techniques and allows particles to be treated which are not necessarily spheres. Results for several metals are shown in Chapter 14 in this format. Note, however, that no data exist where both the particle size and the size of the pile would have been varied, thus, this crucial aspect of the theory is not validated.

EFFECT OF OXYGEN CONCENTRATION

The effect of oxygen concentration on the ignition of metals is generally small, at least in comparing results at 21% and at 100% oxygen. In a study on pressed metal powder tablets, Rozenband et al.[27] found a small effect, as shown in Table 6. The particular metals tested were not able to ignite in pure nitrogen atmospheres. The specimens incandesced at higher temperatures, but did not show overt ignition, due to the stable nature of the nitride film on the surface.

Table 6 Effect of oxygen concentration on ignition of pressed metal powder tablets

Metal	Ignition temperature (°C) at given oxygen concentration			
	25%	50%	75%	100%
hafnium	410	360	370	370
titanium	572	560	535	520
zirconium	350	322	310	300

Maček studied the ignition of single particles of aluminum as a function of the partial pressure of oxygen, and found the T_{ig} to decrease slowly with increasing oxygen pressure[28]. The amount of data collected was not large, but a relation of the form $T_{ig} \propto P_{O_2}^{1/2}$ was found to be reasonable.

EFFECT OF PRESSURE

The effect of pressure on ignition of metals is generally minimal.

EFFECT OF FLOW VELOCITY

The effect of flow velocity on ignition of metals is generally minimal, even for high-speed convective flows.

EFFECT OF MOISTURE

The effect of moisture on the ignition of metals is complex. Some require a dry atmosphere for this to occur (e.g., cerium amalgams, Raney nickel, thorium-silver alloys). However, while zirconium is easier to ignite in a dry atmosphere, moist powder, if ignited, burns more violently[29]. In some cases, introducing water into a pile of finely-divided metal powder will lead to explosion because of the rapid oxidation that is thereby caused[13]. This can have the additional complication in that hydrogen is liberated from the water and so the potential for a hydrogen explosion is created. Aluminum, magnesium, titanium, zinc, and zirconium powders are especially susceptible to this effect.

Ignition of carbon

Pure carbon in the form of graphite can ignite but cannot pyrolyze. Graphite can vaporize, but in common with metals, the vapor pressure is exceedingly low. Thus, surface phenomena play a strong role in its combustion. Coal, coke, char and other materials composed mostly, but not wholly, of carbon have a wide spectrum of ignition responses since some non-carbon material is present and consequently there is an ability to pyrolyze and to release combustible gases at moderate temperatures.

GRAPHITE AND OTHER RELATIVELY PURE FORMS OF CARBON

Goard and Mulcahy[30] studied the ignition of pure graphite rods in an oxygen stream and found T_{ig} values of 815, 803, and 769ºC for three commercial varieties tested. The first variety was re-tested in air and showed an ignition temperature there of 931ºC. These results pertain to the minimum gas flow rate they used, 0.3 m s^{-1}. At higher flow rates, T_{ig} values progressively rose. The authors also presented a theoretical model, but this was complicated by the fact that diffusion of oxygen into pores of the specimen needs to be considered. Actual ignition was found to invariably originate inside the pores for the specimens tested which ranged in porosity from 20 to 30%.

Makino et al.[31,32] studied the ignition of 10 mm graphite rods in a stagnation flow geometry and found that below ca. 800ºC reaction rates are minimal. Over the range 800 – 1200ºC, non-flaming surface combustion is found to occur. At about 1200ºC, flaming ignition occurs, with a CO flame being observed. When O_2 was used instead of air as the oxidizer, the appearance of a CO flame was found at ca. 900ºC. If the velocity of oxidizer gas was increased to higher values, the ignition temperatures rose. In additional studies in room air, Makino and Law[33] found that the lowest T_{ig} values were around 1100ºC, while at 100% O_2 the lowest value was 1000ºC, but the flow velocities were not identical

for the two cases. Under comparable conditions, the specimens in pure O_2 ignited at about 250ºC lower than ones in ambient air. The authors also offered a rather complicated theory which appeared to predict trends reasonably well, but did not include closed-form explicit solutions.

Visser and Adomeit[34] measured the ignition temperatures (homogeneous ignition only) of highly pure graphite in a stagnation-point geometry by subjecting specimens to a high-temperature convective flow field. They found effects of flow velocity, oxygen concentration, and moisture. The latter effect was quite pronounced, with very dry atmospheres leading to ignition temperatures about 250ºC higher than moist ones (> 0.1% H_2O by mass). The moisture effect arises since graphite contains no hydrogen and, consequently, a 'dry' CO flame occurs unless moisture can be picked up from the atmosphere. For ambient oxygen concentration, slow velocities, and moist conditions, an ignition temperature ca. 1100ºC was found. Makino et al.[35] conducted similar experiments and found a specimen temperature of ca. 1000ºC at ignition for moist conditions; for very dry atmospheres, the value rose by about 80ºC.

The effect of the partial pressure of oxygen was studied in the ignition of carbon powder having a particle diameter of 0.025 μm[36]. Ignition took place at 600ºC for an oxygen pressure of 0.5 atm and at 560ºC for 1.0 atm. It was reported that half the mass was already depleted by the time that ignition took place. At lower oxygen pressures, ignition did not occur.

Graphite can pyrophorically ignite in air, if it is first cooled down in liquid argon[37]. This is because available surface sites are first occupied by argon, when the argon evaporates, oxygen can rapidly get to the surface layer, and a heterogeneous ignition occurs.

The ignition temperature of diamond has been quoted as 700 – 800ºC in pure oxygen[38], although in view of the generally higher values found for graphite it is not clear if this is correct.

COAL, COKE, AND OTHER RELATIVELY IMPURE FORMS OF CARBON

Coal is a complex substance which is mostly carbon (for higher-rank coal), but may contain large amounts of volatile matter (for lower-rank coal). Thus, for a number of years, there has been a controversy in the scientific community as to whether coal particles ignite heterogeneously (at the surface) or homogeneously (that is, pyrolyzing first, with the pyrolysis gases igniting and burning at some distance away from the surface). A good introduction to some of the basic principles—and complexities—of coal combustion is provided by Chomiak[39].

The ignition temperature of coal particles has also been an exceptionally controversial issue. Essenhigh et al.[40] observed that: "Typically, the range of values cited for ignition temperatures of coals is 500º to 1000ºC. This is totally at variance with standard practice in the boiler industry, where decades of experience have established that there is a risk of explosion unless the temperatures leaving air-swept mills grinding bituminous coals are limited to about 70ºC; lignites and brown coals generally require grinding to be in inert gases. The discrepancy between recognized industrial safe practice and the reported laboratory measurements is too great for the latter to be credible to design engineers." Presumably this is because industrial hazards generally involve stockpiles where self-heating governs and not a single-particle ignition mode. Self-heating of carbonaceous materials is examined in Chapter 9 (theory) and Chapter 14 (empirical studies). In this Chapter ignition of single particles and dust clouds is considered, although for dust clouds Chapter 5 should also be consulted.

SINGLE PARTICLES

A simplified theory for the heterogeneous ignition of individual carbonaceous particles can be formulated along similar principles as the Semenov theory of the ignition of gases, discussed in Chapter 4, except that the reaction occurs at the surface and not in the volume. Thus, the heat generation is:

$$Q_G = AQc_O^n S \exp(-E/RT)$$

and the heat loss is:

$$Q_L = \frac{2\lambda}{d}(T_s - T_o)S$$

where A = pre-exponential factor, Q = heat of reaction, c_O = oxygen concentration, n = order of reaction, S = particle surface area, λ = conductivity of air, d = particle diameter. To obtain a closed-form solution requires a number of approximations, but the final result for the *gas* temperature needed to cause ignition is obtained as[40,41]:

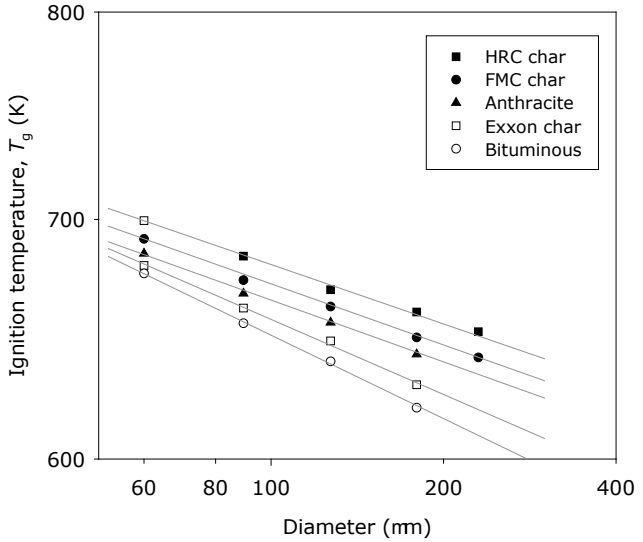

Figure 1 Plots of ignition data of five different coal types according to heterogeneous ignition theory

$$T_g^{\alpha-2} c_O^n d = b$$

The particle *surface* temperature, T_s, at ignition will be higher and can be computed from:

$$T_s = \frac{\alpha}{\alpha - 1} T_g$$

where α is obtained from:

$$E = \frac{\alpha^2}{\alpha - 1} RT_g$$

or

$$\alpha \approx \frac{E}{RT_g} \approx \frac{E}{RT_s}$$

In the above relations, α, b, and n are empirical constants, to be obtained from a fit of the data by log-log plots of T_g as a function of d, and T_g as a function of c_O. Figure 1 shows some results obtained by Chen et al.[42], as plotted according to the heterogeneous ignition theory. From the slopes of the line, values of α are found ranging from 15 (for bituminous coal) to 21 (for HRC char). This means that activation energies of 88 to 125 kJ mol^{-1} are found.

In their study, Chen et al. used specimen with volatile matter ranging from 3 to 45% and tested them by injecting single particles into a tube furnace. The authors estimated that the particle surface temperatures were 20 – 40ºC higher than the furnace temperature. No effect of volatile matter was found on the results.

Results giving the opposite trend are also to be found in the literature. Sinnatt and Moore[43] conducted ignition tests on a variety of coal types. In their experiments, 5 mg samples of powdered material were ignited using a modified Moore tester (see Chapter 6). Using only two particle sizes, they found that lower AIT values were obtained for the smaller particle size for the case of all the 5 coal types studied. Their results, consequently, fall along similar lines as do experimental data for the size effect on very fine metal particles. The coal particles, however, were relatively large, being those that pass through 75 and 150 μm sieve openings. Wall et al.[44] reviewed the literature through 1991 on this topic in some detail. For single-particle experiments, they found:

- T_{ig} decreases with increasing particle size: 9 studies
- T_{ig} increases with increasing particle size: 4 studies

In all of these studies, T_{ig} refers to the furnace temperature and not the particle temperature. Unlike in Chen's study, Wall et al. found that there is a roughly-linear decrease in T_{ig} with increasing volatile content. Generalizing from 6 studies, T_{ig} drops, on the average, from 800ºC for particles of zero volatile content, to 500ºC for particles with 50% volatile content.

Tomeczek[45] proposed a variant on the Semenov solution, whereby the loss term includes a radiant loss term $\varepsilon\sigma\left(T_s^4 - T_g^4\right)$ and conservation of energy gives:

$$AQY_o^n \exp(-E/RT_s)\, S = \left[\frac{2\lambda}{d}\left(T_s - T_g\right) + \varepsilon\sigma\left(T_s^4 - T_g^4\right)\right] S$$

Differentiating with respect to surface temperature gives:

$$\frac{AQEc_o^n}{RT_s^2} \exp(-E/RT_s) = \frac{2\lambda}{d} + 4\varepsilon\sigma T_s^3$$

Tomeczek suggested that in the intermediate temperature regime, n = ½ should be taken and that $E \approx 60 - 120$ kJ mol^{-1}, but he did not provide a full validation.

Brooks and Essenhigh[46] found that the effect of oxygen concentration progressively diminishes with increasing oxygen concentration. For 15 – 25 vol% O_2, raising the concentration significantly reduces T_{ig}, but as 100% is approached, further changes become small. Essentially identical results were obtained by Tognotti et al.[47] This is due to reaction rates being governed by Langmuir-Hinshelwood kinetics at low c_O values (wherein the reaction rate is proportional to c_O^n, with $n \approx$ ½ – 1.0), while at high c_O values T_{ig} becomes independent of c_O since desorption of the adsorbed O_2 film becomes the governing step. Bews et al.[48], analyzing data from a series of experiments on carbon particles where hydrogen impurities were very low, concluded that n = ½ on the basis that the governing step is one of chemisorption of oxygen atoms:

$$C_{(s)} + ½O_2 \rightarrow (C–O)_{(s)}$$

followed by a slow production of gaseous CO according to:

$$(C–O)_{(s)} \rightarrow CO$$

where the subscript (s) denotes solid state. Since intra-particle diffusion can play a role, however, such single-exponent treatments are rather approximate.

The above treatment is very simplified, since radiation, which will dominate at higher temperatures, is ignored. Bar-Ziv et al.[64] considered a theory which includes a radiative loss term, but they did not derive general correlations with it.

Another theory, with a different set of approximations, has been put forth by Annamalai and Durbetaki[49]. It predicts that ignition temperature should vary inversely with the $Y_O d$ product, where Y_O = oxygen mole fraction. Phuoc and Annamalai[50] included radiation losses from the particle and showed that the monotonic decrease of T_{ig} with increasing diameter does not continue for large diameters, if radiation is taken into account. Instead, they predicted that for $d >$ 200 μm, ignition temperatures would start to increase. Unlike most other theories, their theory was able to correctly anticipate a minimum oxygen concentration which is needed for ignition; using typical values for chemical constants, they estimated this at about 11 vol%. Du and Annamalai[51] developed a fairly comprehensive theory which encompassed both surface reactions and gas-phase reactions, thus being able to simulate the entire range of conditions involved in heterogeneous or homogeneous ignition. Homogeneous ignition was shown to occur at low oxygen con-

centrations or for large particle sizes (> 500 μm), with ignition being heterogeneous otherwise. Their calculations, while plausible, were not compared against any experimental data. Jüntgen and van Heek[52] did evaluate experimental data and concluded that the issue of heterogeneous/homogeneous ignition is influenced also by the heating rate to which the specimen is subjected: a medium heating rate (ca. 300 K s^{-1}) facilitates heterogeneous ignition, while particles subjected to much higher or much lower heating rates are more likely to show homogeneous ignition. In their study, all particles larger than about 120 μm also showed homogeneous ignition. The volatile content also affects the outcome, but was not examined by them as a variable.

In general, reported experimental ignition temperatures of coal, coke, char and other forms of impure carbon vary over a tremendous range, and known physical/chemical factors do not account for the spread. Volatile content and size are probably the two most important variables, but the study of Wall et al. found that these cannot adequately explain the data spread. As examples of extreme values, the ignition temperature of carbon soot, in the form of dust of unspecified particle diameter[53], was reported by NIST in 1947 as being 186ºC but details of their procedure are not available. Conversely, Khitrin[54] reported some extraordinarily high ignition temperatures, with the gas temperature needed for ignition of anthracite coal particles in the 75 – 100 μm size being 1027ºC in an environment of 21% oxygen, dropping to 805ºC in 100% oxygen. The surface temperature of the particle was stated to be about 100ºC higher, due to self-heating. Smaller particles required a yet-higher temperature for ignition, with a 20 μm particle igniting at about 1287ºC in 21% oxygen. Tomeczek and Wójcik[55] measured the ignition temperatures of single particles of coal. For 400 μm particles of anthracite coal (volatile matter 5.2%), they found T_{ig} = 970ºC at 21% oxygen. Sub-bituminous coal (volatile matter 32.3%) showed T_{ig} = 640ºC, while coal char gave T_{ig} = 660ºC. Larger particle sizes gave lower ignition temperatures. For example, sub-bituminous coal dropped to 600ºC for a particle size of 1000 μm. Raising oxygen concentrations lowered the ignition temperatures over the whole range of values explored, 10 – 100%. For very large particles, Fu et al.[56] found that varying the particle diameter did not change T_{ig} values. Using 3 – 6 mm coal chars, they found ignition temperatures of 500 – 700ºC, depending on the rank of the coal.

Boukara et al.[57] dropped single particles into a furnace supplied with pure O_2. Two, opposite trends for T_{ig} vs. particle size were found. Char particles showed decreasing T_{ig} values with particle diameter, dropping from 865 – 880ºC for 110 μm diameter, to 740 – 790ºC for 285 μm. Conversely, a high-volatile bituminous coal rose from 800ºC to 875ºC. In all cases, the temperatures refer to the temperature of the furnace.

Essenhigh et al.[40] surveyed a number of other studies and found that reported ignition temperatures spanned the range 300 – 1350ºC, without sufficient reasons being evident for the wide spread. Another recent survey is by Annamalai and Ryan[58]. Most of the studies have focused on a relatively few material types, making it hard to discern systematic trends. A systematic, although old, study by Blayden et al.[59] is thus of high value for illustrating trends. They exposed a small cup containing 0.25 g of powdered sample in a vertical tube furnace, with the samples being various coals that had been carbonized at a variety of temperatures. Their results (Figure 2) show a roughly-linear increase in ignition temperature with carbonization temperature. For a number of the specimens, they also obtained elemental analysis results, and this correlation is shown in Figure 3. For carbon content > 92%, the ignition temperature rises directly with carbon content. Furthermore, other aspects of the coal chemistry appear to be unimportant, in that data for three different coals fall on the same line. Thus, it can be concluded that, while the temperature of carbonization partly controls the carbon content of the char, it is the carbon content which is the controlling physical variable.

Apart from their work with the heterogeneous ignition theory, Essenhigh et al.[40] considered at length the arguments in favor of homogeneous ignition of coal particles, at least for some combinations of particle size and thermal environment conditions. The most persuasive argument was found to be the one concerning the effect of oxygen concentration. If coal particles ignited homogeneously, then the ignition temperature, according to homogeneous ignition theory, would *rise* with increasing oxygen concentration. However, the opposite has been found to be true in experiments. This is consistent with heterogeneous ignition theory which, as outlined above, predicts a fall in ignition temperature. It should be noted that actual coal particle combustion sometimes involves three stages: (1) ignition at the surface; (2) a transition to homogeneous (a flame away from the surface) combustion a while later; (3) followed by exhaustion of volatiles and re-ignition of char (surface burning).

Austin[60] conducted ignition experiments on individual carbonaceous particles in a high-temperature furnace and found that ignition times could be correlated by:

$$t_{ig} = a\frac{\rho d^{3/2}}{T_\infty^7} + b$$

where a and b are constants, ρ = particle density (kg m^{-3}), T_∞ = furnace temperature (K), and d = particle diameter (m). The very strong dependence on furnace temperature implies that radiant heat transfer predominates.

Laser ignition has been studied by several researchers. Phuoc et al.[61] used laser radiation at a wavelength of 1.06 μm to ignite single 3 mm coal particles. Using a pulse duration of 5 ms, they found that a minimum heat flux of 8000 kW m^{-2} was needed for ignition, but that up to 80% of the

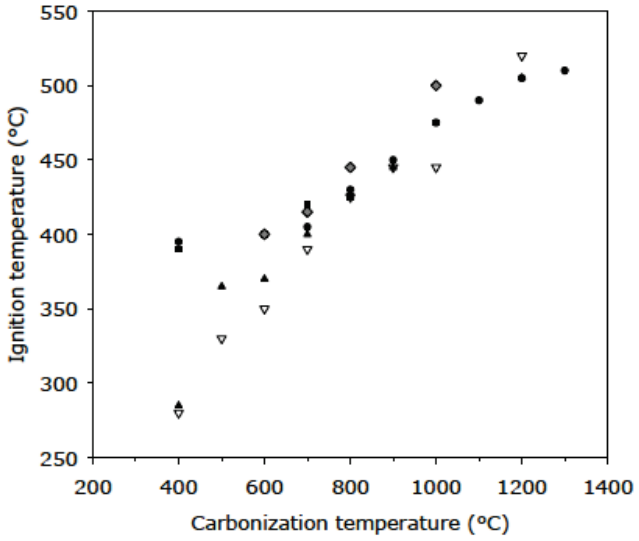

Figure 2 Effect of carbonization temperature on the ignition temperature of 5 different coal chars

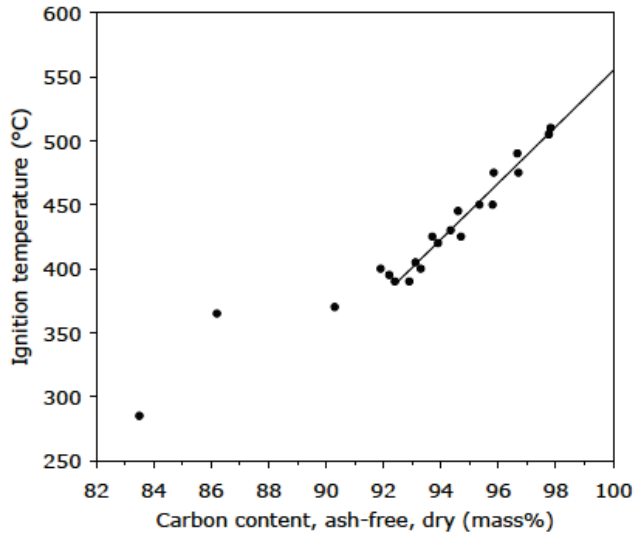

Figure 3 Ignition temperature of coal, expressed as a function of carbon content (data for 3 different coal types)

beam energy was absorbed by the pyrolysis gases emitted from the fuel. In their experiments, bituminous coal samples ignited solely in the gas phase, but subbituminous coal ignited in two stages, first at the surface, followed by a gas phase ignition. Temperature non-uniformities in particles undergoing laser ignition have been studied by Chen et al.[62] Zhang[63] ignited particles of various coals and chars with a laser; the particles were of 50 – 100 μm diameter. He observed that the percent of volatile matter was a crucial factor in determining the mode of ignition. Chars and cokes ignited only heterogeneously, coals of 17 – 30% VM ignited in a two-stage manner, while coal of 30 – 40% VM ignited homogeneously. He pointed out, however, that these conclusions should not be interpreted as general findings, since the thermal exposure conditions are also expected to play a role.

Small particles are difficult to study, since they must somehow be supported, or else studied in free-fall. More recently, it has been found possible to levitate small particles in an electric field by imparting to them an electric charge. Bar-Ziv et al.[64] and Wong et al.[65] ignited coal char particles with laser energy, while suspended in air with this arrangement. They found an ignition temperature of 1227ºC for 150 μm Spherocarb (nearly pure carbon) particles in O_2. In air, apparently a higher temperature would have been required, but the apparatus was not suitable for higher temperatures.

DUST CLOUDS

When a number of particles are suspended in the air in the form of a dust cloud, ignition may be achievable more easily than for single particles, but the phenomenon proved difficult to quantify, and little progress was made until rather recently. As shown above, for single particles, results are inconsistent, but more studies have found that the ignition temperature decreases with increasing particle size than the opposite. But in dust clouds, studies are generally consistent (see Chapter 5) in showing that the ignition temperature increases with particle size, although a lower asymptote is found, so that for smaller particles, there is a negligible effect of diameter. Krishna and Berlad[66] developed a theory based on heterogeneous ignition of the particles themselves and convective (but not radiative) heat transfer in the cloud. For dense clouds, they provided the solution:

$$\frac{1}{T_s}\exp\left(-E/RT_s\right) = d\,\frac{h_c\rho_p}{R_e c}\,\frac{R}{EQA\rho_g Y_o}$$

where d = particle diameter, h_c = convective heat transfer coefficient towards external environment, ρ_p = density of particle, R_e = radius of cloud, c = concentration of particles in dust cloud (g m^{-3}), E = activation energy, Q = heat of reaction, A = pre-exponential factor, ρ_g = density of air, and Y_o = oxygen mole fraction. Essenhigh et al.[40] pointed out that this relation can be approximated as:

$$T_s^{\alpha-1} = const. \times d$$

Since α is around 5 – 20, the relation is consistent with the experimental observation that the dust cloud ignition temperature decreases as particles become smaller. For dilute clouds, theory would predict the opposite effect, that is:

$$d \times T_s^{\alpha-1} = const.$$

however, available data do not suggest that there are ignition regimes for clouds of carbonaceous particles where decreasing the particle diameter would cause an increase in the ignition temperature. Higuera et al.[67] formulated a theory which does include radiation, but with no attempts at validation against experimental data.

Experimentally, Howard and Essenhigh[68] studied the ignition of bituminous coal dust clouds containing 36% volatile matter and found an ignition temperature of 1100ºC. For the samples studied (polydisperse, with particle size mode = 15 μm), they concluded that ignition is heterogeneous, and that volatiles do not play a significant role until after ignition. A much lower value, 550ºC was found by Hertzberg et al.[69], who studied dust clouds of bituminous coal particles; over the smallest particle size range of 17 – 55 μm, no significant size effect was found. For larger particles, increasing ignition temperatures were found, with 400 μm particles requiring 875ºC.

Lucas and Wall[70] conducted experiments where clouds of coal particles were introduced into a vertical furnace, but 'cloud ignition' and 'particle ignition' were separately identified. The latter occurred at low enough temperatures that only a very few particles ignited and there was no 'cooperative mechanism.' Cloud ignition, by contrast, comprised an explosion involving the entire combustible mass. For coals having very high volatile matter (32 – 51%), they found that 70 μm particles showed particle ignition at 420 – 540ºC, decreasing to 380 – 530ºC for 150 μm size. Cloud ignition temperatures were 540 – 670ºC for 70 μm particles and 550 – 670ºC for 150 μm particles. In all cases, the temperature reported were those of the furnace. It is not clear why the cooperative mechanism should result here in higher ignition temperatures being needed.

When dust clouds are dilute enough, experimental trends simply follow those for single-particle. Rybak et al.[71] released 'small clouds' of ca. 10 mg into a furnace. For 90 μm particles of nearly pure carbon (97%), they found T_{ig} = 740ºC at ambient oxygen concentration. Char particles derived from sub-bituminous coal (17% volatile matter) gave T_{ig} = 460ºC. Both materials showed a smooth decrease of ignition temperatures vs. oxygen concentration over the range 8 – 50%. The same group[72] later reported on results where smaller quantities (0.2 – 0.5 mg) of particles were introduced into the furnace. Using 97%-pure carbon, they obtained lower ignition temperatures, indicating the expected lowering of ignition temperature due to the cooperative mechanism. Particles of 60 μm size gave T_{ig} = 560ºC, decreasing to 500ºC for 150 μm. They considered that their results indicated homogeneous, rather than heterogeneous ignition. Flashing was reported to occur at lower temperatures than sustained ignition. In both sets of experiments, the temperatures reported were the furnace temperature needed for ignition.

The state of research must be assessed as being incomplete and contradictory at this point. Not only are widely disparate values reported, but even qualitative trends seem to depend greatly on the details of the experimental procedure adopted. In addition, it is not clear that research findings and actual fire experience have converged sufficiently since Essenhigh's warning in 1989.

Test methods

Unlike for other substances, there are no standard test methods for ignition of metals. Almost every research study on the ignition of metals has been based on a different experimental technique. References are given in Chapter 14 under *Metals*. Schmitt[73] considers that experimental arrangements generally fall into the following categories:

- rising temperature method (similar concept to thermal analysis studies)
- shielded ignition method (specimen is preheated in an inert atmosphere, then oxidizer is introduced)
- flame or torch heating
- crucible tests and pot furnaces
- tube furnaces
- high-pressure reactor
- centrifugal reactor
- electrically heated wire in an air stream
- bell jar combustion
- liquid metal spray
- plus various general techniques for small particles—single particle dropped in furnace, particles introduced into flat-flame burners, and dust cloud/dust layer methods.

ASTM considers[74] that testing of metals for autoignition is not an appropriate endeavor, because ignitions of metals generally occur by means other than a homogenous, bulk raising of the temperature. For use of metals in high-pressure oxygen systems, a number of specialized tests have been developed, and these are covered in Chapter 13.

Highlights and summary of practical guidance

Spontaneous combustion is the general topic of this Chapter. Specific theories and examples in this Chapter deal with porous or granular solids, although many concepts are also applicable to non-porous solids or to liquids, which are considered in Chapter 10. For open flaming to occur due to self-heating of a porous solid material, it is necessary that:

(1) the material be capable of self-heating;
(2) self-heating of the material must be sufficient to lead to thermal runaway;
(3) thermal runaway must initiate self-sustained smoldering;
(4) the smolder front must reach the outside of the material (or the process must create large enough cavities) where flames can be established.

The basic process of smoldering was already considered in Chapter 7. The new concepts introduced in this Chapter are defined as follows:

Self-heating: an increase in temperature due to exothermicity of internal reactions.

Thermal runaway: self-heating which rapidly accelerates to high temperatures.

Spontaneous combustion: visible smoldering or flaming caused by thermal runaway.

Thus, the *process* is called 'self-heating,' a critical *intermediate outcome* of 'thermal runaway' may or may not occur, while the *final outcome* (if thermal runaway does occur) may be 'spontaneous combustion.' There is no single, universally accepted definition of 'spontaneous combustion,' but the definition above can be considered to be the most reasonable one. Sometimes spontaneous combustion is understood in a more restricted sense, whereby it is said to occur only if open flaming occurs. Much of this Chapter is concerned with theories of self-heating and their application to testing. There exists essentially no systematic knowledge on the question of whether thermal runaway will lead to self-sustained smoldering, but it is often conservatively assumed that if thermal runaway occurs, then the process will continue until spontaneous combustion is seen. The question of whether smoldering will or will not lead to flaming has been discussed in Chapter 7, where it was shown that there is little useful guidance available. Again, it is often conservatively assumed that flaming will automatically occur if thermal runaway occurs.

Since almost all organic substances (and many inorganic ones) can undergo exothermic reactions, it is necessary to understand why everything is not going into thermal runaway and manifesting spontaneous combustion. Self-heating involves an exothermic chemical reaction which serves to raise the temperature of a substance. The most common type of chemical reaction which is encountered in substances showing this problem is oxidation, whereby molecules of the substance react with molecules of oxygen from the air. Almost all organic substances can exhibit exothermic oxidation. For self-heating to be a problem, however, rather than merely a scientific curiosity, normally requires that the substance being oxidized be porous, since oxygen reacts with the solid only at the surface and non-porous materials have a small surface-area/volume ratio. Thus, most solids and liquids do not show the problem, since they are not porous. The problem commonly arises in agricultural products, such as grains or hay, in porous wood products, and in rags oiled with certain vegetable oils. In all of these situations, there is a large surface area over which oxygen may contact the organic substance. In addition, it is necessary that natural cooling, which occurs by convection on any surfaces exposed to air, be insufficient to remove the heat being generated.

If only a small pile of material is present, or if access of oxygen is poor to the interior (for reactions that need oxygen) then self-heating, but not thermal runaway may occur. The material will rise in temperature slightly above ambient, but the rise will not be sustained and eventually the temperature will start going down since reactants will become depleted.

The mechanism involved in spontaneous combustion is fundamentally different from ignition of solids from external heating. When a solid is externally heated, ignition typically occurs due to a gas-phase oxidation reaction. But when a substance goes into spontaneous combustion, the chemical reactions involved are those of the solid phase, which are exothermic pyrolysis or surface oxidation reactions. As a result, there is no correlation between ease of ignition from external heating and propensity to spontaneous combustion.

Industrial accidents involving self-heating often involve non-oxidative reactions, such as polymerization or decomposition. These reactions are a problem with certain liquids, and self-heating reactions in those cases can be exceptionally violent (explosions, not just fires). For oxidizing porous bodies, molecular diffusion is necessary to supply oxygen to the reaction, and it is a relatively slow process. In the case of a liquid which is polymerizing or decomposing, no such slow step exists to limit the reaction rate. The problems of reactive liquids are treated in Chapter 10.

The self-heating reactions in porous solids (or oiled, porous materials) occur at the surfaces of the solid or liquid, not in the gas phase. Thus, if self-heating 'runs away,' it manifests itself initially as a propagating smolder front. The process most commonly starts at the center of the material. Thus, piles may sometimes be cut open to reveal a charred center, but virgin outer areas. Eventually, flaming can occur if the reaction front reaches an open-air surface. Self-heating may be localized to an area that is not at the center if the material is heated from one side, or if it is sufficiently non-homogeneous that hot spots occur. Flaming normally can-

not occur inside porous bodies (unless the process creates large cavities) because (a) pore sizes are typically less than the quenching distance for flames; (b) the oxygen concentration may be too low for flaming; and (c) the internal flow rate of flammable pyrolysis gases within the pores of the material may be too small to sustain a flame.

For some materials, bagging a self-heating commodity into modest size bags is an effective strategy, even if the bags are then stacked in large stacks. This is attributed to the cooling that becomes available through the gaps between the bags. It is helpful if the material from which the bags are made is relatively air-tight, but even materials having a measurable permeability can reduce oxygen availability.

When laboratory data are put into theoretical relationships, predictions can be made of the maximum size of pile that can be stored at a given temperature without undergoing spontaneous combustion. Example results are shown in Figure 1. These were obtained from laboratory data (E and P values) provided for various substances in Chapter 14. It was assumed that the pile is a cube and that cooling is inefficient (Bi = 1.7). The two extreme substances shown are fire-retarded cellulosic attic insulation, which is highly resistant to self-heating, and linseed oil spread on cotton cloth, which is highly prone. The same graph also illustrates that blind faith cannot be placed in theoretical computations. Actual experiments (see Chapter 14) show that as little as 50 g worth of rag, well-covered in linseed oil, can lead to spontaneous combustion. Yet, the theoretical results of Figure 1 suggest that, at a room temperature of 25ºC, a cube of 0.3 m (1 ft) on a side is the minimum. Part of the problem may be that the input data used for the theoretical calculation are of uncertain accuracy. It may be noted that the lines in Figure 1 are all curved. This means that it would not be reasonable to plot a few points and then extrapolate graphically. Instead, methods are developed in this Chapter which transform the size/temperature relationship so that linear plots can be made and extrapolations—if there is confidence in the underlying theory—can be undertaken. It must be emphasized that the temperature of interest is the critical ambient temperature, which is the temperature of the *environment* which must not be exceeded to avoid thermal runaway. The material itself will be at a higher temperature (critical stacking temperature), as shown in Figure 3, where T_o denotes the critical ambient temperature and T_c denotes the critical stacking temperature. T_c may be 20 – 30º higher than T_o.

As with any other type of fire safety problem, the most reliable results are obtained if full-scale tests are done. The present Chapter contains details on conducting a variety of small-scale tests, but it must be appreciated that uncertainty is much higher when only small-scale tests are run. The

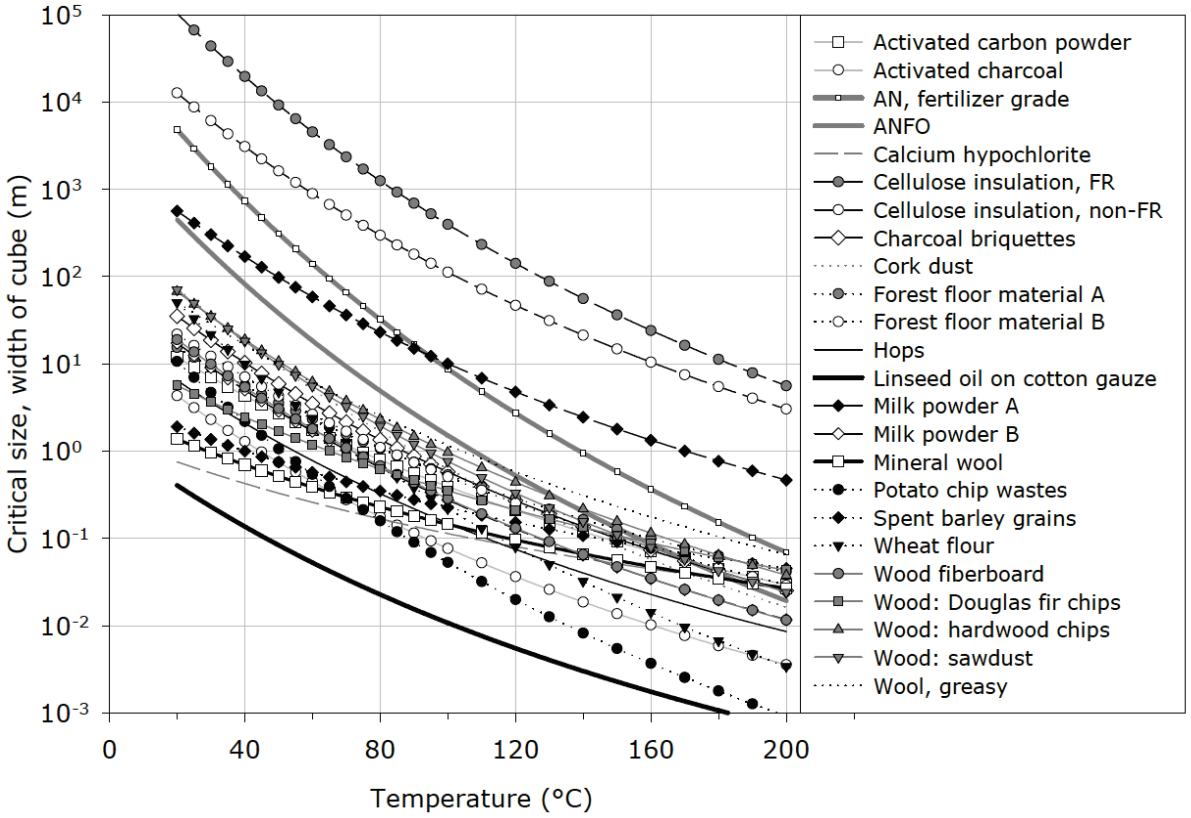

Figure 1 Relationship between size and critical ambient temperature estimated for various substances by applying a theoretical relationship to small-scale test results

basic principle of the small-scale testing is that putting a smaller sample into a higher-temperature environment is equivalent to putting a larger sample into a lower-temperature environment. But unquestioningly using scaling rules can lead to wrong predictions. For example, test results for calcium hypochlorite (see Chapter 14), indicate that two different temperature regimes exist. If extrapolations were made from the high-temperature (small size) data only, an unconservative estimate of the full-scale critical conditions would be produced.

The standard theory presented in this chapter has been shown not to be applicable to (at least some types of):

- bagasse (due to pivotal role of moisture flow)
- benzoyl peroxide (due to multiple reactions and effects of phase change)
- calcium hypochlorite (due to two different reaction regimes)
- coal (due to strong role of oxygen and moisture flow; also since the problem time constants are typically so long that a full time-dependent solution must be sought, rather than being able to rely on steady-state results)
- fertilizers (due to multiple reactions, high variations in thermal conductivity, moisture flow, and melting)
- haystacks (due to biological heating by micro-organisms)
- liquid-soaked pipe insulation (in cases where the fluid is of high volatility and low exothermicity)
- sodium dithionite (due to two exotherms)
- synthetic dyestuffs, certain types (due to complex reactions)
- synthetic rubber, SBR type (due to presence of both endothermic and exothermic reactions).

For such products, either full-scale testing or a comprehensive computer model is required. Each of these products is discussed in Chapter 14.

Theoretical and empirical (e.g., data extrapolations) methods exist for predicting the *time* to runaway, but all of these methods are highly uncertain, due to chemistry complications in the reactions of real materials.

Introduction

Self-heating can occur in any of the states of matter—gas, liquid, or solid. The use of self-heating theory to explain the autoignition of gases was already presented in Chapter 4. Self-heating of liquids is a specialized problem which will be taken up in Chapter 10. In this Chapter, the development will center around self-heating of solids, specifically porous solids. This state of aggregation covers a very wide range of practical problems of spontaneous combustion, ranging from coal mines, to hay stacks, to linseed-oil soaked rags.

Self-heating problems have been known in connection with hay and other agricultural products since time immemorial. However, the science of self-heating is relatively young, largely because it is such a complicated phenomenon. In 1760 the Frenchman Montet wrote a paper about the problem. Active research was triggered when the Russian frigate MARIE caught fire in Cronstadt harbor on 20 April 1781. Count Ivan Tschernichev, the Vice-President of the St. Petersburg Admiralty College, suspected that this may have been due to storage of a hammock which had soaked up a staining preparation—boiled hempseed oil and pine soot. Thus, during the spring of 1781, he conducted a series of experiments to determine the self-heating properties of oil-soaked materials[1]; this is perhaps the first scientific series of experiments on ignitability recorded in the world's literature. Tschernichev's work immediately aroused great interest, and similar experiments were conducted almost imme-

Table 1 US structure fires (average annual data for 1994-1998) involving spontaneous heating or chemical reaction, by type of material first ignited

Type of Material	Fires	Civilian deaths	Civilian injuries	Direct property damage (in millions)
Cotton or rayon fabric or finished goods	905 (16.6%)	1 (9.6%)	27 (19.5%)	$14.1 (12.1%)
Oily rags	710 (13.0%)	0 (0.0%)	11 (8.2%)	$18.8 (16.2%)
Grass, leaves, or brush	568 (10.4%)	0 (0.0%)	6 (4.4%)	$12.7 (10.9%)
Manmade fabric or finished goods	244 (4.5%)	0 (0.0%)	6 (4.0%)	$2.8 (2.4%)
Sawn wood	239 (4.4%)	1 (11.8%)	3 (2.0%)	$5.1 (4.4%)
Grain or natural fiber	190 (3.5%)	0 (0.0%)	1 (0.8%)	$3.3 (2.8%)
Food fat or grease	173 (3.2%)	1 (6.8%)	7 (5.3%)	$1.2 (1.0%)
Unclassified type of material	163 (3.0%)	0 (0.0%)	4 (2.9%)	$3.0 (2.6%)
Adhesive, resin or tar	135 (2.5%)	0 (0.0%)	2 (1.3%)	$1.1 (1.0%)
Untreated, uncoated paper	135 (2.5%)	0 (0.0%)	1 (0.7%)	$3.2 (2.8%)

Structural member or framing	170 (3.1%)	0 (0.0%)	0 (0.0%)	$4.4 (3.8%)
Cooking materials	157 (2.9%)	0 (0.0%)	9 (6.7%)	$0.8 (0.7%)
Dust, fiber or lint	150 (2.8%)	0 (0.0%)	4 (3.0%)	$2.2 (1.9%)
Multiple items first ignited	146 (2.7%)	6 (67.8%)	5 (3.8%)	$4.9 (4.2%)
Other known item	1,715 (31.5%)	2 (21.7%)	46 (33.0%)	$42.3 (36.5%)
Unknown-type item	212 (3.9%)	0 (0.0%)	7 (5.4%)	$4.1 (3.6%)
Total	5,444	9	139	$116.0

diately afterwards by the German pharmacist Johann Georgi and the British scientist Joseph Banks[2]. Despite practical experiments demonstrating the phenomenon, there was not yet any understanding of the basic principles. Indeed, scientific writers of the era were viewing self-heating and 'spontaneous human combustion' (see Chapter 14) as one and the same phenomenon[2].

A century later, while still there was no basic understanding, a proliferation of books dealt with the topic. One of the earlier to focus on spontaneous combustion as a whole was Francis Moore's 1877 work[3], intended as a primer to insurance agents on fire hazards. A British book devoted solely to the topic of self-heating of coal in ships' holds was written by Thomas Rowan in 1882[4]. Shortly thereafter, in New York, John Hexamer was the author of an 1888 book[5] covering diverse aspects of spontaneous combustion. It pulled together in book form a number of articles the author had previously contributed to THE SPECTATOR. In Germany, Hapke[6] wrote a textbook in 1893 devoted wholly to self-heating problems. This was followed by another German textbook on the subject by Medem in 1895[7]. Another German textbook with significant discussions of self-heating was written by Schwartz in 1901, which became popular in its English translation[8]. By 1907 Miehe[9] understood, albeit in qualitative terms, some of the fundamental aspects of self-heating theory, such as the role of heat transfer and of the size of the pile. It is perhaps interesting that publishing of books on this topic tapered off in the 20th century. The first, and only, book on the general subject of self-heating to approach it from a unified, systematic point of view was published in 1984 by the late Philip Bowes[10], a researcher for many years at the Fire Research Station in the UK.

Table 3 Self-heating accidents in American railroads, 1910-1927

Material	Percent
charcoal	62.0
alfalfa and molasses feeds	12.7
rags, oily or wet	3.9
tankage, fertilizer	3.3
coal, pulverized	3.1
oiled or varnished textiles and paper	2.9
fish scrap	2.5
distiller grains, dried	2.5
sponge iron	2.1
rubber scrap, reclaimed rubber	1.6
bran	1.2
wool waste	1.0
baled hay	0.7
cotton waste, oily	0.5

Subsequent to the publication of Bowes' book, there has been quite a large number of research papers published on some of the more theoretical aspects of self-heating. Many of these have originated from a research group at the University of Leeds. Researchers in Australia and New Zealand have also had significant interest in the topic over the last couple of decades. The topic has also been of interest to researchers in Germany and in Russia, and the basic theoretical treatments all start with an adaptation of theories by the Russian researchers Semenov and Frank-Kamenetskii (as originally developed for gases, see Chapter 4). Curiously, scientific interest in the US in self-heating problems has been limited, and there is no American research group that has had long-standing or extensive research programs in this area.

Moore's 1877 book[3] provides some detailed loss experiences with various substances liable to spontaneous combustion. He included the following substances as being considered to be causes of spontaneous combustion fires in that era:

- charcoal, especially if powdered
- coal
- coffee (roasted)
- cotton (wet; or saturated with cotton-seed oil)
- fabrics and yarns dyed black (the author felt that the radiant absorptivity of black surfaces was to blame)
- felt (tarred)
- guano (wet)
- hay
- hemp (moist)
- iron or steel powder
- lampblack, especially when mixed with linseed oil
- rags soaked in linseed, cotton-seed, or rape-seed oil
- oatmeal, bran, and other grains (damp)
- saw dust
- silk, when treated with certain nut oils (this was used in 19th century tassel-making)
- tan bark
- tracing paper, made transparent with linseed oil and not cooled prior to storage
- varnish made from softwood soot and rape oil.

He also listed some pyrophoric substances, which in this Handbook are covered in Chapter 10. Moore already presented as a well-known fact that only vegetable-origin oils are prone to self-heating, and not petroleum-based oils. For an explanation of self-heating fires, he invoked heating due to oxidation, heat of wetting, and presence of pyrites.

Current US statistics, as compiled by NFPA[11], are given in Table 1 and Table 2. It is reasonable to consider that the top two categories both comprise oily rags, even though the coding "cotton or rayon fabric or finished goods" does not make this explicit. Since NFPA obtains its statistics only from municipal fire departments, the statistics will not reflect wildland fires, agricultural operations, or industrial incidents that are dealt with by plant staff without obtaining fire department assistance.

The above current statistics can be compared to a very old study where self-heating accidents in American railroads were tabulated (Table 3)[12]—charcoal is a rare enough cause today so that it is not even on the current list of top materials.

Basic phenomena

"Any material, regardless of its chemical nature, if it can either decompose or be oxidized by air exothermically (giving out heat), is capable of spontaneous combustion." This succinct explanation of the problem is by Prof. Brian Gray[13], who has made a number of mathematical studies of the self-heating problem. Since *runaway self-heating* is one of the ways in which unwanted ignitions occur, it is important to first understand the concept of self-heating, then to be able to quantify runaway conditions. A temperature rise occurs in any body where internal heat is being generated—this is the self-heating process. Whether the temperature rise is immeasurably small, small but measurable, or so large as to lead to thermal runaway depends on the relative rates of heat generation and heat removal.

Heat generation occurs primarily through one (or a combination of several) of the following processes:
(1) exothermic chemical reactions
(2) biological metabolic reactions
(3) heat-producing physical processes.

Heat losses from a body that is self-heating normally occur at the surface. For bodies at a relatively low temperature, convection will tend to be dominant. In places where the body is touching other solid substances, instead of being exposed to air, heat conduction needs to be considered. In principle, thermal radiation also has to be quantified. Radiative effects, however, only become important at high temperatures, and if a body subject to self-heating is at a high temperature, it may already be presumed to have ignited. Thus, thermal radiation heat transfer is typically treated as a correction to the convective heat loss term.

The most common sources of heat generation are exothermic chemical reactions. A wide variety of chemical reactions can occur that are exothermic in nature. In terms of self-heating caused ignitions, the dominant ones are:
(a) oxidation
(b) polymerization
(c) isomerization
(d) decomposition.

Oxidation is the most common of the chemical reactions. The oxidant that is usually involved is oxygen from ambient air, although in pyrotechnic and other less common substances, the oxidant may be a component within a solid body. Some porous and granular materials often suffer from self-heating problems, because air from the atmosphere can flow into the interior of a pile of such material. If oxidation from atmospheric oxygen is the cause of self-heating problems, a sufficient remedy may be to encapsulate the substance in an impermeable barrier material.

Polymerization occurs when molecules combine in order to form a chain. Such a chain can become thousands of units long. Polymerization is a desired process in making plastics, which are man-made polymers. It is undesired when it occurs in other circumstances unexpectedly. Polymerization cannot be stopped by excluding air since no 'external' molecule is required for this type of reaction—the substance is simply agglomerating on a molecular scale.

Isomerization is a somewhat similar process to polymerization. In this process, the atoms in a molecule rearrange themselves in a different way. Oxygen is not a general requirement for isomerization but, in some specific cases, may be involved.

The final type of chemical reaction that is common in self-heating is decomposition. Here, again, no second reactant is needed—the molecule simply flies apart into two or more pieces.

Until the World War II era, it was often believed that self-heating of many substances is caused by chemical impurities (e.g., sulfur in coal), and that pure materials would not self-heat. This has generally been found not to be true, with impurities generally playing a limited, minor role at best.

Biological activity occurs with living matter of all kinds, including plants and microbes. Cell respiration is an exothermic process which is not just confined to living plant matter—it continues for some time after a plant has been harvested. This process stops, however, if the material is dried to below about 30% moisture content. Thus, adequately drying agricultural products can remove one source of self-heating. Even if re-wetted later, metabolic activity is not reestablished. To metabolize their food, plants, fungi, and most bacteria also need oxygen. Thus, metabolic activity also stops at extremely high moisture contents, when water starts to exclude oxygen from the cells. Self-heating also occurs due to microbial action, especially when plant matter is rotting. The self-heating of compost heaps occurs mainly due to microbial action. Biological self-heating activity in plant matter has been reviewed by Kubler[14].

Finally, there are some cases where physical heat-producing processes need to be considered. The only one common in self-heating is the adsorption of water. Many substances prone to self-heating tend to adsorb ("stick onto the surface") large amounts of water. This physical process releases a significant amount of energy and is important with many practical products, e.g., charcoal. Adsorption of water rarely is the sole cause of self-heating; usually it is a contributing factor. When adsorption of water is occurring, other thermophysical effects also need to be considered, apart from the generation of heat. One important one is the effect on the thermal conductivity of the substance. The thermal conductivity of wet, porous substances at temperatures in the range 60 – 100ºC is significantly affected by the moisture content. Friction is another physical phenomenon that has been known in rare instances to contribute to self-heating[15].

In studying problems with electronic equipment, one may find the term 'self-heating' used in a slightly different context. Certain semiconductor devices can have operating regimes where increased temperatures cause increased current flow, which in turn causes higher temperatures and can lead to thermal runaway, if the circuit lacks proper design precautions. For the purpose of understanding fires, however, any ignitions that occur from such devices are simply treated as occurring due to an overheated component; only the manufacturer will generally be interested in detailed theory of why the component overheated.

As the points discussed above indicate, materials subject to self-heating exhibit a wide variety of chemical mechanisms by which heat generation occurs. In the theory portion of this Chapter, a rather simple view of chemistry will be taken, but one which many researchers have verified to yield good results. We leave details of the chemistry of specific materials to Chapter 14.

Theory of self-heating

The theory of self-heating is considered to have been established by three researchers. In 1928, the Russian Nikolai Semenov first described a theory for a substance which rises in temperature, but where the entire substance is at a uniform temperature. Semenov's theory has applications to gases and liquids, but for porous solids the assumption that the substance is at uniform temperature is generally a poor one. In 1939 another Russian, David Frank-Kamenetskii, offered a theory wherein the substance can heat in a realistic manner inside, but it is subjected to a fixed, invariant temperature along all of its edges. This was more realistic, but many porous solids subject to self-heating are simply exposed to air on most of their sides. In that case, convective cooling occurs at the edges (once the substance starts showing a temperature rise) and a more articulated theory is needed. Such a theory was provided by the British researcher Philip Thomas in 1958, who described a substance that is convectively cooled externally and which can assume a natural temperature distribution inside, one set by the interplay between heat generation, thermal conductivity, and convective edge cooling. We will mostly delve into Thomas' theory in this Chapter, along with various later extensions and alternatives. Despite the important role of Thomas in today's understanding of the problem, in the technical literature any theoretical analysis which takes into account internal temperature differences is commonly referred to as an 'F-K theory,' on the basis that Frank-Kamenetskii was the first to develop a way of treating non-uniform temperatures within the material.

The basic ideas on which self-heating theory is founded are simple. The generation of heat occurs throughout the interior of a substance. The total amount of heat generated is proportional to the mass (or volume) of the substance. The amount of heat being generated is also dependent on the temperature, and increases very rapidly with increasing temperature. The mathematical details of this dependence will be considered in the next section. If heat were being generated but not lost, very soon the system would reach an 'infinite' temperature. This, of course, does not occur, since substances normally receive cooling at their edges. This occurs due to convection, as soon as the substance's temperature rises above the ambient temperature.

With increasing temperature, the heat loss due to cooling at the edges increases. This increase is commonly found to be roughly linearly-dependent on the temperature. But the heat generation rises sharply with temperature. We note that

under steady conditions, when a body's temperature is not changing, the heat gained and lost by it must be identical, according to the law of Conservation of Energy. The situation can be illustrated with the aid of Figure 2. This figure is drawn in the context of Semenov theory, since, according to it, the substance is at a single temperature. The heat balance concept equally applies to F-K theory, but a more complicated presentation would be needed since the body is allowed to have internal temperature gradients.

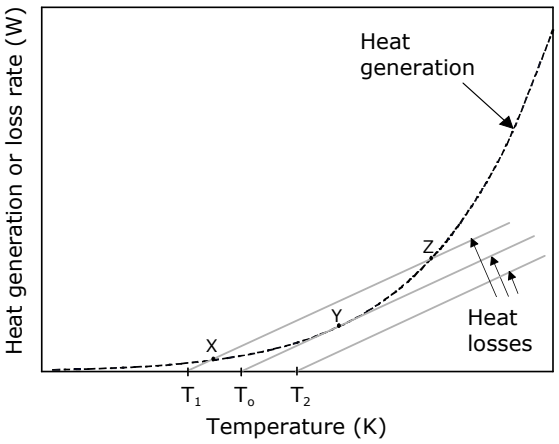

Figure 2 Heat losses and gains, as represented in the Semenov theory

Let us suppose that the substance is initially at temperature T_1. At that temperature, the heat losses and heat gains are not in balance, therefore the substance will heat up until point X is reached. At that point, the heat losses and gains are equal and the substance will be in thermal equilibrium at the temperature of point X. The heat losses and gains would also be at equilibrium at a much higher temperature, marked Z on the graph. Some consideration of the shapes of the curves will indicate that point X is a stable equilibrium, while point Z is not. Suppose, while the system is at point X, that a tiny increase in temperature takes place, meaning the system will move to the right. But as the system moves to the right off point X, the slope of the heat generation line is less than the slope of the heat loss line. Thus, more heat will be lost than generated. The consequence is that the system will return back to point X. In the same manner, if a small excursion to the left of point X would take place, then the heat gains would exceed the losses, the system would heat up and would also return to point X. At point Z, however, the situation is different—a small temperature rise would cause heat generation to exceed heat losses and the system would run away (ignite). A small temperature drop while at point Z would result in the system dropping back down to point X. Thus, we conclude that the equilibrium at point Z is unstable, and a real system would be able to spend more than a moment only at point X.

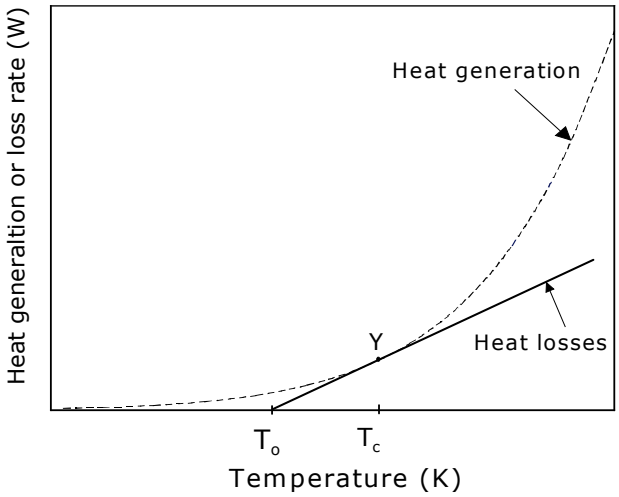

Figure 3 The critical condition

Now, if we consider the system starting at a higher room temperature T_2, it can be seen that there will be no place that the heat gains and the heat losses will be in equilibrium. Thus, the system will just keep rising in temperature until ignition occurs. A system such as this is called *supercritical*; a system which starts at T_1 is *subcritical*.

It can also be seen that the starting room temperature T_o is the highest value at which heat losses and gains could be in equilibrium. Point Y represents an equilibrium condition, but it is an unstable equilibrium. However, any room temperature lower than T_o will lead to a stable solution. Thus, for all room temperatures less than T_o, stable, non-igniting behavior will be found. The substance itself will become warmer than the room temperature and, in principle, will stay indefinitely at some temperature below T_c (Figure 3). In practice, we shall see later, other effects preclude a system from staying at a fixed elevated temperature forever.

It can be confusing to learn that the term 'critical temperature' is often used ambiguously and can refer either to the maximum permissible value of the environment T_o, or else the maximum permissible temperature of the material T_c. In most cases, however, it refers to T_o, since the latter can be externally controlled, while the material's own temperature can only be determined by theory or experimental instrumentation. To make this point more clear, T_o, is sometimes referred to as CAT, critical ambient temperature, while the material's own temperature, T_c, is referred to as CST, critical stacking temperature.

It is interesting to consider what happens when the critical conditions are reached. The above graphs are simplified by only presenting one temperature of the substance. In fact, the temperature of the substance is not uniform: it is the highest at the center and the lowest at the edges. Thus, for a body that is uniformly cooled along all its exterior, the runaway heating must start at the center and progress from there. However, flaming is generally only possible at the

edges. This is because the porous channels of the substance will normally be smaller than the quenching diameter (see Chapter 4). Thus, the typical history of such an incident is that *smoldering* starts at the center, then propagates towards the edges. Commonly, but not always, flaming may break out when the smolder front first reaches an edge exposed to air. In a simplified view, the smolder spread would be uniform, and there could be nothing (or little) left to flame once the smolder front reached the edge. In practice, the material will rarely be uniform, and the smolder spread will rarely also be uniform. Thus, in a typical incident the smolder front can break out to the surface at a single spot, flaming starts there, then the remaining substance starts flaming combustion outside-in, in addition to continuing smoldering inside-out.

In addition to changing the initial temperature of the environment, it may be that the heat transfer coefficient can be changed, for instance by directing air flow from fans onto the substance. The possibilities are shown in Figure 4. Note that there are also two extreme conditions. If infinite heat transfer could be provided, then the *isothermal* line would be followed. Runaway conditions could never be reached, regardless of the temperature at which the isothermal conditions are established. Conversely, if the heat losses are made zero, then the *adiabatic* line would be followed. From any starting point, an adiabatic system will, in time, run away. Adiabatic situations do not occur in normal practice, but a number of test apparatuses have been developed where this condition is approximated.

To be treatable under the F-K theory, the self-heating substance must show rather simple exothermic chemistry. If there is only one pertinent reaction and it can be represented by an Arrhenius-form kinetic expression, then the substance can be analyzed. In general, self-heating solids may show two types of reactions:

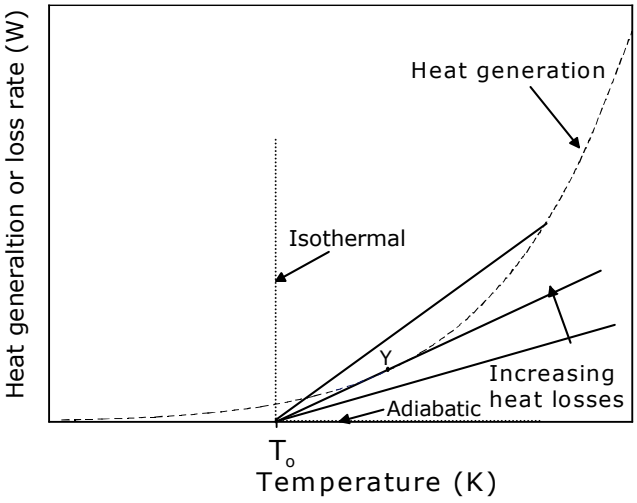

Figure 4 The effect of changing the heat transfer coefficient

- Unimolecular—these include decomposition and isomerization. Such problems would appear to be very simple, since there is not a second reactant to consider. In practice, however, many such reactions have multiple steps, often involving autocatalytic reactions, so real-world complications can arise. Polymerization reactions are not strictly unimolecular, since at least two molecules must be present, but behave the same way as unimolecular reactions, since only one kind of molecule is needed.
- Polymolecular—this is most commonly an oxidation reaction. F-K theory assumes that the necessary oxidant is available in abundance. This is often a good assumption for porous materials since oxygen can simply flow in as needed from the ambient environment. Standard F-K theory cannot treat situations where a reaction may be limited by paucity of oxygen, but some extensions to the theory are considered later in the Chapter.

F-K theory cannot treat situations where more than one reaction takes place, or autocatalytic reactions are involved, or there are non-chemical sources or sinks of energy (e.g., enthalpy of phase change). These complications are briefly considered towards the end of the Chapter.

The above discussion suggests that the most important question in self-heating is *whether* a runaway condition can occur and has ignored the role of *time*. If critical conditions are to be attained, then the time to achieve criticality is an engineering variable of considerable importance. This will be discussed later in this Chapter. If cooling is sufficient that critical conditions are not reached, then the simplest thing that could happen is that the substance just reaches a temperature mildly higher than ambient and stays at that temperature indefinitely. This would be possible if the chemical reaction took place without depletion of reactants[*]. Theoretical treatment is generally much simpler if depletion of reactants is ignored, so this assumption is often made. In the real world, depletion of reactants inevitably occurs, thus, for a subcritical system a modest peak is attained, then temperatures start to drop because of depletion of reactants.

Time is also handled somewhat artificially in defining the problem to begin with. If the chemical reaction is relatively fast, it may be difficult to imagine the 'creation' of the substance at a known temperature. How did it get to be at some one, fixed temperature if the system has a tendency to self-heat (either to runaway, or at least to a stable, higher temperature than the initial one)? It is best to envision that the substance was initially dispersed in very small sizes, so that self-heating would be negligible. At time $t = 0$, it is sudden-

[*] Most authors use the term 'consumption of reactants.' This term seems self-contradictory, since no products could be formed, if no reactants were consumed. The simplification alluded to, on the other hand, does not demand no consumption, merely no depletion of supply.

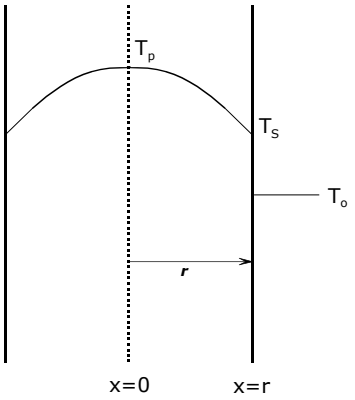

Figure 5 The geometry of a self-heating substance, in the form of a symmetric slab

ly agglomerated into its actual size. This starts the self-heating problem.

STEADY-STATE THEORY FOR SYMMETRICALLY COOLED BODIES

The formulation of the steady-state theory is due to Frank-Kamenetskii[16], with later extensions by Thomas[17]. A number of approximations are made in order to obtain a tractable solution. As we shall see later, some approximations can be relieved with more detailed theoretical solutions, and this can be necessary to get good numerical agreement for various practical problems. Runaway self-heating is sometimes known as a *thermal explosion* and much of Russian literature in this field uses the term. When applied to solid self-heating materials, the term 'explosion' does not denote an audible noise. Instead, it signifies that an extreme change in reaction rate has occurred, from some modest value to near-infinite.

The primary assumptions made are the following:

- The substance is in the form of an infinitely wide/long slab, with thickness 2*r*.
- The surfaces are convectively cooled with a convective coefficient *h*.
- The cooling of both faces is identical (i.e., the problem is symmetrical).
- Natural convection occurring inside the body is ignored.
- The reaction rate proceeds according to zero-order Arrhenius kinetics.
- There is an infinite supply of fuel and oxygen (that is, fuel depletion is ignored, as is any limitation to free diffusion of air into the interior).
- The only temperature gradients are in the thickness direction.

This slab problem is illustrated in Figure 5. T_o is the temperature of the air, T_s is the temperature of the surface of the slab, while T_p is the peak temperature at the center of the slab.

For one-dimensional heat flow with heat generation, the basic energy conservation equation is:

$$\lambda \frac{d^2T}{dx^2} + \dot{q}'''(T) = \rho C \frac{dT}{dt}$$

But in steady state, the right-hand side, by definition, is zero. Thus,

$$-\lambda \frac{d^2T}{dx^2} = \dot{q}'''(T)$$

where λ = thermal conductivity (kW m^{-1} K^{-1})
T = temperature (K)
x = distance (m)
$\dot{q}'''$ = heat generation rate per unit volume (kW m^{-3})

We must now consider the nature of that volume-heating term. It is assumed that the reaction rate has the form of Arrhenius' Law, which was already considered in Chapter 3. For a solid, homogeneous reactant, its concentration is equal to its density. In addition, it is assumed that the heat of reaction is constant, with Q heat being released for each kg of reactant consumed. Thus,

$$\dot{q}'''=\rho Q A e^{-E/RT}$$

where
ρ = density (kg m^{-3}); this is the initial density of the material* and is assumed not to change as the reaction proceeds
Q = heat of reaction (kJ kg^{-1})
A = pre-exponential factor (s^{-1})
E = apparent activation energy (kJ mol^{-1})
R = universal gas constant (= 8.314 J mol^{-1} K^{-1})

To the basic differential equation expressing conservation of energy, we must add boundary conditions to obtain a solution. For moderate temperature increases, it is experimentally found that the heat flow at the boundaries of the slab can be represented by convective cooling:

$$\dot{q}'' = h\,(T_s - T_o)$$

where
$\dot{q}''$ = the heat loss rate per unit area of surface (kW m^{-2})
h = convective heat transfer coefficient (kW m^{-2} K^{-1})
T_s = surface temperature (K)
T_o= ambient air temperature (K)

But performing a heat balance on an infinitesimal layer at the surface, the same amount of heat that is leaving the air side by convection must also be flowing from the substance by conduction:

$$-\lambda \frac{dT}{dx} = h\,(T_s - T_o) \qquad \text{at } x = r$$

Also, the same conditions must hold on the other face of the slab:

* The basic F-K theory presented in this Section assumes a zero-order chemical reaction. Thus, the density of the fuel is a constant and does not change with time. If fuel is significantly depleted before thermal runaway occurs, then a theoretical treatment is needed where the fuel's density (or concentration) is time varying; this is treated in a later Section.

$$\lambda \frac{dT}{dx} = h(T_s - T_o) \qquad \text{at } x = -r$$

Finally, by symmetry it can be seen that:

$$\frac{dT}{dx} = 0 \qquad \text{at } x = 0$$

In the general solution to the energy conservation equation, initial conditions would also be needed, which would describe the 'starting point' of the system. The steady-state theory, by definition, has no time element, so this does not need to be considered here.

To get analytic problem solutions, it is customary to make various approximations. The above system of equations is not solvable in any closed form. Thus, the innovation of Frank-Kamenetskii was to realize that a solution may become possible if the exponential expression is approximated. In many practical cases, the values of E and T_o will be such that

$$\frac{E}{RT_o} >> 1$$

Furthermore, the temperature rise ($T - T_o$) will generally be much less than T, keeping in mind that the temperatures are absolute (K). Starting with the identity:

$$\frac{1}{T} = \frac{1}{T_o}\left[1 - \left(\frac{T - T_o}{T_o}\right) + \left(\frac{T - T_o}{T_o}\right)^2 \frac{T_o}{T}\right]$$

and using the approximations that $E/RT_o >> 1$ and $(T - T_o) << T$, the expression is obtained:

$$\frac{E}{RT} \approx \frac{E}{RT_o}\left[1 - \frac{T - T_o}{T_o}\right]$$

In more recent times, a number of authors have pursued theories where the exponential term is not approximated[18]. It does not appear that any such refined theories have led to improved engineering methodologies, so we will not discuss them here. In some specialized cases, however, the approximation that $E/RT_o >> 1$ is not fulfilled. A practical approach to treating such 'low activation energy' problems is presented later in this Chapter.

Next, a variable θ is defined which is a non-dimensional temperature:

$$\theta = \frac{E}{RT_o^2}(T - T_o)$$

A non-dimensional distance z is defined as:

$$z = \frac{x}{r}$$

Finally, a non-dimensional heat generation rate δ can be defined as:

$$\delta = \frac{E}{RT_o^2}\frac{r^2 \rho Q A}{\lambda} e^{-E/RT_o}$$

Then the energy conservation equation, expressed in the non-dimensional variables becomes:

$$\frac{d^2\theta}{dz^2} = -\delta e^{\theta}$$

The boundary conditions also have to be expressed in the same non-dimensional variables:

$$Bi\,\theta + \frac{d\theta}{dz} = 0 \qquad \text{at } z = 0$$

$$\frac{d\theta}{dz} = 0 \qquad \text{at } z = 1$$

where the convective heat transfer coefficient was expressed as the non-dimensional Biot number* Bi:

$$Bi = \frac{hr}{\lambda}$$

It can then be shown that a suitable solution[17] to the non-dimensionalized conservation equation is:

$$\theta = \ln C_1 - 2\ln\left[\cosh\left(z\sqrt{\delta C_1 / 2} + C_2\right)\right]$$

where C_1 and C_2 are constants of integration. For this solution, $C_2 = 0$, but a numerical evaluation was needed to obtain C_1. However, the primary variable of interest in solving this equation is not the temperature rise itself, but, rather, the critical value of heat generation which corresponds to the runaway condition. This critical value of δ is denoted as δ_c. Physically, any bodies which have a $\delta > \delta_c$ have too little cooling at the boundaries, or they are too large, or their chemical reaction rate is too high for a stable condition. Mathematically, a solution of the conservation equation does not exist for any value $\delta > \delta_c$. Figure 6 shows the results for δ_c as a function of the Biot number. Also shown are the corresponding values for two other common geometries—the cylinder and the sphere. Note that the x-axis represents, in non-dimensional terms, the amount of convective cooling available, while the y-axis is the non-dimensional heat generation rate. Thus, the asymptotes are as expected: for very large cooling, a sizeable heat generation rate can be tolerated without thermal runaway. As the convective cooling is progressively reduced, the system can only tolerate smaller heat generation rates. As the cooling rate goes to zero, the heat generation rate must also go to zero.

An analytical approximation[19] to the results for $\delta_c(Bi)$ shown in Figure 6 is:

$$\delta_c(Bi) = \frac{1}{\dfrac{1}{\delta_c(Bi \to \infty)} + \dfrac{e}{(j+1)Bi}}$$

where $j = 0, 1, 2$ for slab, infinite cylinder, and sphere, respectively, and the values of $\delta_c(Bi \to \infty)$ are given in Table 4.

* There are two similar-seeming nondimensional numbers related to convection which must not be confused: Bi is the ratio (resistance to heat transfer due to conduction inside the solid)/(resistance to heat transfer due to convection in the fluid). The Nusselt number Nu is the ratio (resistance to heat transfer due to conduction in the fluid)/(resistance to heat transfer due to convection in the fluid).

In certain cases, it is useful to consider even simpler approximations valid for very small or very large cooling. For very large cooling ($Bi \rightarrow \infty$), the surface temperature is forced to be identical to that of the surrounding air; this is the original Frank-Kamenetskii problem, before its generalization by Thomas. Conversely, if the edge cooling is very small, then $Bi \rightarrow 0$, and we have what is called the Semenov condition. Thomas' limiting values for those two conditions are given in Table 4. In the Table, e denotes the value 2.718.

Table 4 Thomas' computation of the critical values

Geometry	Surface/ volume ratio	δ_c for Semenov condition (Bi→0)	δ_c for F-K condition ($Bi \rightarrow \infty$)
slab	1/r	Bi/e	0.88
infinite cylinder	2/r	2Bi/e	2.0
sphere	3/r	3Bi/e	3.32

The interpretation of the δ results is as follows. If $\delta < \delta_c$, then after infinite time the substance will reach a finite, subcritical temperature. If $\delta = \delta_c$, then the temperature will reach the critical (runaway) condition, but this will take an infinite time. For $\delta > \delta_c$, the temperature will tend to infinite values after a finite time. For such 'supercritical' systems, the increase of temperature with time does not proceed in a smooth manner. The substance first rapidly heats up to a temperature slightly less than T_c, then it rises in temperature only gradually for a period of time, then finally it again rises rapidly in temperature and shoots up to and past the T_c. Since the runaway condition represents the criticality in the balance between heat generated by a volume and heat lost by the surface, the surface/volume ratio would be expected to be of importance. This is confirmed in Table 4—the Semenov condition is exactly proportional to the surface/volume ratio, and the Frank-Kamenetskii condition is quite close.

The variable δ is sometimes called the *Frank-Kamenetskii number*, but it can also be identified as a type of *Damköhler number*, being a non-dimensional representation of the ratio

$$\delta = \frac{\text{characteristic heating time}}{\text{characteristic reaction time}}$$

PEAK TEMPERATURES UNDER SUBCRITICAL CONDITIONS

The classical theory of thermal ignition also considers in some detail what happens to temperatures in the course of self-heating. The temperature T_p at the center of the body is expressed in terms of a nondimensional temperature θ_p, defined as:

$$\theta_p = \frac{E}{RT_o^2}\left(T_p - T_o\right)$$

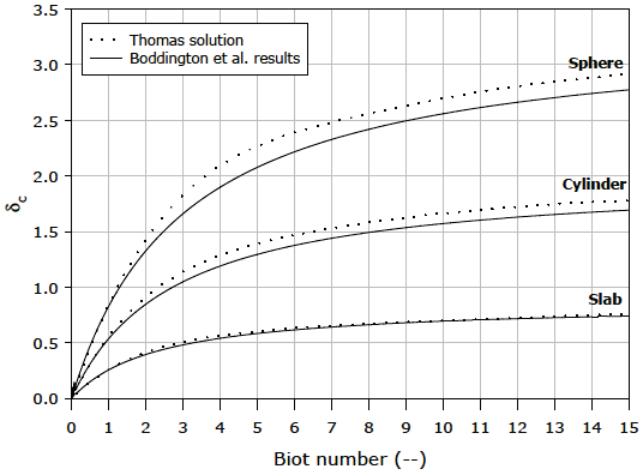

Figure 6 The critical values of the non-dimensional F-K parameter, as a function of the Biot number

Critical values[17,20] of θ_p are given in Table 5—these are the maximum values that can be attained in a stable system. It is interesting to consider an example to gain an appreciation of the magnitude of the values that can be expected. A value of $\theta_p = 1.1$ might be appropriate for moderate cooling. Assume that T_o = 40ºC = 313 K. The value of E will typically be in the range 60 – 140 kJ mol^{-1}. If E = 60 kJ mol^{-1}, then $(T_p - T_o)$ = 14.9ºC degree rise. For E = 140 kJ mol^{-1}, then $(T_p - T_o)$ = 6.4ºC. With small-scale testing, the value of T_o will typically be higher while the Biot number will be higher and the $Bi \rightarrow \infty$ condition might be approximated. Figure 17 shows laboratory data obtained by Read et al. for wool specimens in an equicylinder container. These indicate that if T_o = 155.5ºC = 429 K, then $(T_p - T_o) \approx$ 31ºC was possible prior to reaching criticality. Chapter 14 indicates that E = 91.5 kJ mol^{-1} for wool; and taking θ_p = 1.78, gives a predicted value of $(T_p - T_o)$ = 29.8ºC. The agreement is quite close but, because of various neglected effects, the theory somewhat underestimates the permissible rise. Bowes[10] showed examples of wood sawdust sustaining a subcritical rise of 31ºC and wood sawdust covered with olive oil a rise of 98ºC. The sawdust + olive oil case showed complex reactions not conforming to the assumptions of F-K theory, but the 31ºC rise for sawdust alone is identical to that found by Read for wool. Nugroho et al.[21] presented some more data showing that the actual temperature rise that can be sustained is generally under-predicted by theory.

Table 5 Critical temperature values

Geometry	θ_p		Θ_s
	$Bi \rightarrow 0$	$Bi \rightarrow \infty$	$Bi \rightarrow \infty$
slab	1.0	1.19	0.252
infinite cylinder	1.0	1.39	0.254
equicylinder	1.0	1.78	
sphere	1.0	1.61	0.257
cube	1.0	1.89	

Table 6 Constants for other body geometries

Geometry	j	$F(j)$	$(r/R_o)^2$	(r/R_s)	$\theta_{p,c}$
infinite slab, thickness $2r$	0	0.857	0.3333	0.3333	1.187
thin circular disk, thickness $2r$, radius $10r$	0.4370	0.9243	0.3340	0.4000	1.241
infinite cylinder, radius r	1	1.0000	0.6667	0.6667	1.386
long circular cylinder, radius r, length $10r$	1.418	1.050	0.6671	0.7333	1.489
infinite square rod, side $2r$	1.443	1.051	0.5455	0.6667	1.492
sphere, radius r	2	1.111	1.0	1.0	1.622
equicylinder, radius r, height $2r$	2.728	1.178	0.8047	1.0	1.778
cube, side $2r$	3.280	1.222	0.7009	1.0	1.888
regular tetrahedron, side $2\sqrt{6}\ r$	4.187	1.284	3.4702	2.449	2.058

In some cases, it is useful to estimate the self-heating for much smaller sizes than necessary to reach criticality. Thomas and Bowes[22] showed that for r values small enough so that δ is significantly less than δ_c, T_p for a sphere is given by:

$$T_p - T_o \approx \frac{2+Bi}{Bi}\frac{r^2 Q\rho A}{6\lambda}e^{-E/RT_p}$$

This is not an explicit equation, but knowing all the pertinent constants, the value can be found by a few iterations of trial-and-error. Similar expressions are not available for other shapes, although a reasonable estimate for a cube may be made by replacing the 6λ in the denominator with 4λ.

Of additional interest is the surface temperature. The best solution for that is probably from Gill and coworkers[23]. Their nondimensionalization is different from other authors, however, and uses the absolute temperature value, rather than the temperature rise above ambient. Their relationship for the critical values of the surface temperature, T_s, are also given in Table 5, expressed in terms of the non-dimensional surface temperature Θ_s:

$$\Theta_s = \frac{RT_s}{E}$$

The maximum stable temperature values are of practical import, in that if a temperature at the center of a body (or at the surface) is measured which is greater than the critical value, it indicates that according to the theory, at least, the substance is already in the process of thermal runaway. This is sometimes used in monitoring industrial stockpiles of materials that have a propensity for self-heating. To make this comparison, of course, the relevant nondimensional temperature first should be converted to the dimensional temperature T_p or T_s. The limitation to this strategy is that, at least for small-scale testing, theory may underestimate the permissible temperature rise, however, this at least makes the strategy conservative.

BODIES OF OTHER SHAPES

Closed-form solutions are possible only for some very simple geometric shapes. Even so, there are significant mathematical complexities, regardless of how simple the shape is. Yet, in some applications it is desirable to estimate the self-heating potential of other shapes, for instance, a short cylinder. For this purpose, Boddington and coworkers[24] developed generalized expressions which are able to treat a wide variety of shapes. The method is an approximation, albeit a very good one. For perspective, even 'exact' solutions for this class of problems tend to vary among different researchers, since simplifications must be made in order to obtain any closed-form solutions.

Boddington's general expression for δ_c is in terms of $\delta_c(R_o)$, which is defined in terms of a 'mean radius' R_o, rather than the conventional physical distance r:

$$\frac{1}{\delta_c(R_o)} = \frac{1}{3F(j)} + \frac{e}{j+1}\frac{1}{Bi(R_S)}$$

It is standard in many differential equation solutions to generalize the geometry by the use of the j parameter, where j = 0 is the infinite slab, j = 1 is the infinite cylinder, and j = 2 is the sphere. Boddington's innovation is to extend this 'dimensionality index' concept to other geometries, where it assumes non-integral values. His values are given in Table 6.

Converting then to the physical dimension r, the expression becomes:

$$\delta_c(r) = \frac{(r/R_o)^2}{\frac{1}{3F(j)} + \frac{e}{j+1}\frac{1}{Bi(R_S)}}$$

The final conversion which has to be made is for the Biot number. Boddington gives it as a function of the 'Semenov radius' R_S, but we need to have it in terms of the physical dimension r. This relation is simply:

$$Bi(R_S) = \left(\frac{R_S}{r}\right)Bi(r)$$

Thus,

$$\delta_c(r) = \frac{(r/R_o)^2}{\frac{1}{3F(j)} + \frac{e}{j+1}\left(\frac{r}{R_S}\right)\frac{1}{Bi(r)}}$$

where values of $(r/R_o)^2$ and r/R_S can be found in Table 6. The asymptotic behavior for large and small Bi is:

$$\delta_c = (r/R_o)^2 3F(j) \qquad Bi \to \infty$$

$$\delta_c = \frac{\left(\frac{r}{R_o}\right)^2}{\left(\frac{r}{R_S}\right)} \frac{(j+1)Bi(r)}{e} \qquad Bi \to 0$$

For some common geometries, Boddington's method works out to:

Sphere $$\delta_c(r) = \frac{1}{0.3 + \frac{0.906}{Bi(r)}}$$

Infinite cylinder $$\delta_c(r) = \frac{1}{0.5 + \frac{1.359}{Bi(r)}}$$

Infinite slab $$\delta_c(r) = \frac{1}{1.167 + \frac{2.718}{Bi(r)}}$$

Equicylinder* $$\delta_c(r) = \frac{1}{0.3516 + \frac{0.906}{Bi(r)}}$$

Cube $$\delta_c(r) = \frac{1}{0.3892 + \frac{0.906}{Bi(r)}}$$

A comparison between Boddington's approximations and Thomas' results is shown in Figure 6. For the $Bi \to \infty$ condition, the comparative results are given in Table 7; for the $Bi \to 0$ condition, Boddington's results are essentially identical to Thomas'.

Table 7 Accuracy of Boddington's approximations for δ_c as $Bi \to \infty$

Geometry	Exact	Boddington
slab	0.88	0.857
infinite cylinder	2.0	2.0
sphere	3.32	3.333
equicylinder	2.76	2.84
cube	2.52	2.57

Boddington's simplified method pertains to bodies which can be described by use of only a single dimension, identified here as r. Many practical bodies, however, do not have such a high degree of symmetry. For such more general shapes, Bowes[10] has provided additional results, applicable specifically to the $Bi \to \infty$ condition:

General cylinder with r = radius and d = half-height

$$\delta_c(r) = 2.0 + 0.84\left(\frac{r}{d}\right)^2$$

and $\delta_c(r)$ denotes that the length dimension to be used in evaluating δ is r.

Hollow infinite cylinder with a = inner radius and b = outer radius

Bowes[10] provides a graphical solution for this problem, to which a good analytic approximation is:

$$\delta_c(s) = \frac{1}{6 - 4\exp(-1/z)}$$

where $z = b/a$ is the ratio of the radii, and $s = (b - a)/2$ is the half-thickness of the solid portion. For a solid cylinder, $a = 0$, therefore $z = \infty$, and $\delta_c(s) = 1/2$. To compare to the results for a solid, infinite cylinder, note that its normal δ_c is defined as a function of the full radius r, rather than the half-radius s. Thus, for the solid cylinder we regain the previous result that $\delta_c(r) = 2$. For a hollow cylinder with a very thin wall, as $z \to 1$, $\delta_c \to 0.22$, which is the same result as for an infinite slab of half-thickness s. This particular solution, however, cannot be applied to the most common practical case of self-heating of an annulus: pipe insulation. The boundary conditions for pipe insulation involve a fixed, elevated temperature at the inner radius, rather than convective cooling. For such conditions, the theory of the next Section, below, must be applied instead.

Rectangular brick with sides = $2a$, $2b$, $2c$

$$\delta_c(a) = 0.840\left(1 + \frac{1}{p^2} + \frac{1}{q^2}\right)$$

where $p = b/a$, $q = c/a$, and the notation $\delta_c(a)$ denotes that the length dimension to be used in evaluating δ is a. Beever[54] gives the same formula, but with the constant being 0.873.

Cone with base radius = a, height = d

$$\delta_c(d/2) = 1.2 + \frac{2}{p^2} \qquad \text{for } p \geq 0.5$$

where $p = a/d$. The above approximate relation is derived from a graph of results given by Bowes. For tall, slender cones, where $p < 0.5$, no comparable simplification is offered; however practical piles of materials are less likely to have such a shape. On the other hand, the short-cone configuration is common, since granular material poured on the ground will assume such a shape.

General bodies

No precise expression is available for bodies of general shape. However, Boddington et al.[25] proved that, for the $Bi \to \infty$ condition, a body of any shape (but without internal cavities) will have a higher critical ambient temperature than does a sphere of the same volume. Thus, determining the results for a sphere of the same volume will give a worst-case limit to the desired solution for critical T_o.

* An equicylinder is one of a height identical to its diameter.

STEADY STATE THEORY FOR UNSYMMETRICALLY COOLED BODIES

INFINITE SLAB

The case of uniform cooling on all surfaces of a body is relatively easy to create in oven tests, as discussed later in this Chapter. However, in actual fires such conditions are rarely encountered. One condition which is often encountered is dust layers accumulating on a hot surface. Such a condition can be well approximated by considering a slab which is at a fixed, elevated temperature on one face and convectively cooled on the other face (Figure 7). The conservation equation to be solved is identical to the one already considered in the symmetrical steady-state, but the problem becomes more complicated because now there are two different temperatures associated with the boundary conditions—T_h, the hotplate temperature, and T_o, the ambient air temperatures. Because of this complication, slightly different definitions of the non-dimensional variables θ and δ must be adopted:

$$\theta = \frac{E}{RT_h^2}(T - T_h)$$

$$\delta = \frac{E}{RT_h^2}\frac{r^2 Q \rho A}{\lambda} e^{-E/RT_h}$$

The boundary conditions are:

$$T = T_h \qquad \text{at } x = 0$$

$$-\lambda \frac{dT}{dx} = h\left(T_s - T_o\right) \qquad \text{at } x = 2r$$

where T_s denotes the temperature of the slab at the surface that is exposed to air. After the equation is non-dimensionalized, the boundary conditions become:

$$\theta = 0 \qquad \text{at } z = 0$$

$$-\frac{d\theta}{dz} = Bi\left(\theta_s - \theta_o\right) \qquad \text{at } z = 2$$

For the symmetrically-cooled case, solutions for δ_c were obtained as a function of just a single variable, Bi. In the present case, solutions for δ_c must involve both Bi, defined as before, and a second variable, θ_o, defined as:

$$\theta_o = \frac{E}{RT_h^2}(T_o - T_h)$$

Thomas and Bowes obtained a numerical solution[26] for this problem, shown graphically in Figure 8.

Note that the values of θ_o are all negative. This is because the problem has been defined for a case where the ambient temperature T_o is less than the hot face temperature T_h. Not shown on the figure is the asymptotic behavior for small Bi. As $Bi \rightarrow 0$, $\delta_c \rightarrow 0.22$, which is different from the symmetric case, where $\delta_c \rightarrow 0$. There is a direct comparison to the symmetric case, however. For the symmetric case, as $Bi \rightarrow \infty$, $\delta_c \rightarrow 0.88$. Now, under those conditions, the symmetric case represents a body which has a fixed boundary temperature, since infinite convective heat transfer means the surface temperature of the body is identical to the (fixed) temperature of the fluid. So we establish that the $x = 2r$ boundary is at a fixed temperature. But, by symmetry, under all conditions for a symmetrically-cooled body, the centerline ($x = r$) position is an adiabatic surface. Thus, in the $Bi \rightarrow \infty$ limit, the symmetrically-cooled body has exactly the same boundary conditions as the unsymmetrically cooled case in the $Bi \rightarrow 0$. However, our unsymmetric case was for a width = $2r$, while the analogue of the symmetric case is to be considered for its half-width, which is = $1r$. But note from its definition that $\delta \propto r^2$. Now, since the unsymmetric problem is twice the width, for the same physical conditions to be

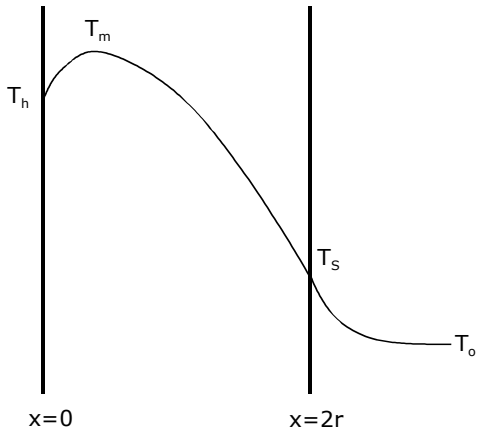

Figure 7 The geometry for the unsymmetric slab with one side (at $x = 0$) at a fixed temperature, the other side (at $x = 2r$) convectively cooled

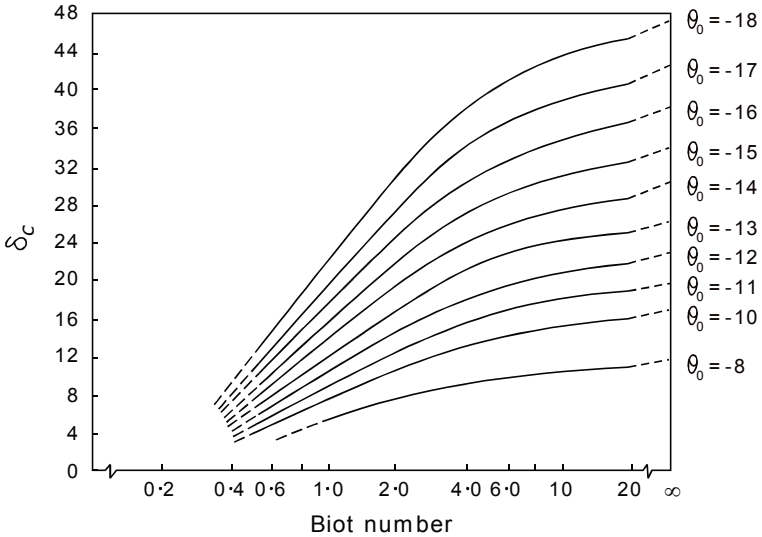

Figure 8 The solution for δ_c in the case of a slab with one face at a constant temperature

(Copyright Royal Society of Chemistry, used by permission)

reached, its δ_c must be = 0.88/4 = 0.22.

There is a closed-form approximation[10] to the results presented graphically in Figure 8 if $\delta_c > 5$:

$$\delta_c \approx \frac{1}{2}\left(\frac{Bi}{1+2Bi}\right)^2 (1.4-\theta_o)^2$$

A somewhat different problem of unsymmetric cooling is when one side is exposed to a constant temperature, but the other side sees a constant heat flux, rather than a heat flux driven by a convective coefficient. This case might occur in practice with a reactive material which is photosensitive, but such problems are not as frequently encountered as convective cooling. A solution was developed by Clemmow and Huffington[27] and is reprised by Bowes[10].

HOLLOW INFINITE CYLINDER

This geometry is most commonly encountered in self-heating of pipe insulation. The pipe insulation is kept at a fixed temperature at its inner radius, while its outer radius is convectively cooled in ambient air. Bowes[29] provides a solution for this geometry. The solution is not exactly parallel to the infinite slab, unfortunately, and is derived in terms of the actual (unknown) outer surface temperature T_s, rather than the known ambient temperature T_a. For pipes of large diameter, the solution perforce must collapse to that of the infinite slab, so the simpler solution given above can conveniently be used. The graphical solution provided by Bowes can be approximated by:

$$\delta_c^* = 0.39|\theta_s|^{1.62} z_s^{0.27+0.49|\theta_s|}$$

where δ_c^* is the critical value of δ^*, and the latter is defined with the space dimension being the wall half-thickness $(b - a)/2$ and the temperature being the inner wall temperature T_h:

$$\delta^* = \frac{E}{RT_h}\left(\frac{b-a}{2}\right)^2 \frac{\rho Q A}{\lambda} e^{-E/RT_h}$$

The nondimensional temperature θ_s is defined as:

$$\theta_s = \frac{E}{RT_h^2}(T_s - T_h)$$

where T_s is the outside surface temperature of the cylinder. The nondimensional distance z_s is defined as:

$$z_s = \frac{b}{a}$$

where b is the outer radius and a is the inner radius. To obtain a solution, T_s is still needed and Bowes points out that, under subcritical conditions, T_s will not be much different from the case where the pipe insulation is chemically inert, thus it can be obtained by solving this equation:

$$h_c(T_s - T_o) = \frac{\lambda(T_h - T_s)}{\ln z_s}$$

where h_c = convective heat transfer coefficient (W m^{-2} K^{-1}). Thus, the practical solution strategy is to first use the above equation to obtain T_s, then use T_s to obtain θ_s, then solve for δ_c^*, and finally solve for δ^*. If $\delta^* < \delta_c^*$, then the system is subcritical, otherwise it is supercritical.

STEADY-STATE THEORY INCLUDING OXYGEN DIFFUSION

The basic steady state theory assumed that there is an infinite supply of both reactants, the fuel and the oxygen. For a porous body, the oxygen must come in from the outside. A certain amount of oxygen is contained within the voids of a porous body, even if its boundaries are sealed and flow cannot take place. Computations typically show, however, that using up all of the local oxygen would allow for a rise of only a few degrees Celsius. Thus, for substances which show exothermicity due to reaction with air, no self-heating hazard will occur unless a continued inflow of oxygen exists.

In a real porous body, however, even if the boundaries are not sealed, there will be limits to how much oxygen can flow into the inside of the body. If this flow is insufficient for the reaction, then the reaction will slow down. To express the oxygen diffusion effect, an equation for the diffusion of oxygen is added[30]:

$$D\left(\frac{d^2c}{dx^2} + \frac{j}{x}\frac{dc}{dx}\right) = \frac{\varepsilon \dot{m}_{ox}'''}{\rho_{ox}}$$

where D = the diffusion coefficient for oxygen in the porous solid (m^2 s^{-1}), c = concentration of oxygen in the gas phase (kg m^{-3}), ε = void fraction (--), ρ_{ox} = density of oxygen (kg m^{-3}), and $\dot{m}_{ox}'''$ = mass consumption rate of oxygen,

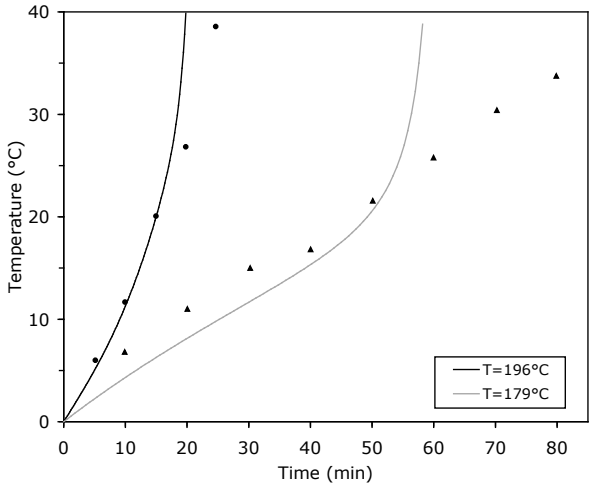

Figure 9 The effect of depletion of reactants on temperature rise[28]. Two different sizes of sawdust spheres were tested—the one exposed to T_o = 196ºC was 37 mm diameter, while the one exposed to T_o = 179ºC was 52.5 mm. The data points are experimental, while the lines are a numerical solution which neglects depletion of fuel.

per unit volume (kg m^{-3} s^{-1}). The dimensionality variable j is: 0 for slab, 1 for cylinder, and 2 for sphere; this simplified notation allows all three common geometries to be represented by a single equation. Numerically, D can be evaluated as $D = 1.8 \times 10^{-5} \varepsilon \left(\frac{T}{273} \right)^{7/4}$.

The rate of oxygen consumption can be expressed as:

$$\dot{m}'''_{ox} = \varepsilon A c^n e^{-E/RT}$$

where the Arrhenius rate expression is written to the general power n of the concentration. Since the units for the mass consumption term must be kg s^{-1} m^{-3}, the units of the pre-exponential factor A are seen to depend on the order of the reaction and are: $(kg/m^3)^{1-n}$ s^{-1}. In the same format, the steady-state energy conservation equation is written as:

$$\lambda \left(\frac{d^2T}{dx^2} + \frac{j}{x} \frac{dT}{dx} \right) = -\dot{q}'''$$

Here, the expression for the heat release rate term becomes:

$$\dot{q}''' = \frac{Q_{ox} \varepsilon \dot{m}'''_{ox}}{\rho_{ox}}$$

where Q_{ox} = heat of reaction per mass of *oxygen* consumed (kJ kg^{-1}). The energy conservation equation is then:

$$\lambda \left(\frac{d^2T}{dx^2} + \frac{j}{x} \frac{dT}{dx} \right) = -\frac{Q_{ox} \varepsilon \dot{m}'''_{ox}}{\rho_{ox}}$$

This formulation puts into parallel form the energy conservation equation (diffusion of heat) and the equation for diffusion of oxygen. The simplest boundary conditions are:

$$\frac{dT}{dx} = \frac{dc}{dx} = 0 \qquad \text{at } x = 0$$

$$T = T_o$$

$$c = c_o \qquad \text{at } x = \pm r$$

Note that in this simplified theory, the convective coefficient is *not* taken into account; thus, only a solution for $Bi \rightarrow \infty$ is sought. Thus, this theory relaxes the assumptions of infinite oxygen supply and of zero-order kinetics, but introduces a new limitation of a fixed temperature at the boundaries. To obtain a solution to the above theory, the classical approach has been to make a series expansion of the Arrhenius term around the ambient temperature T_o. Takeno and Sato[31] improved the accuracy by developing a series expansion around the to-be-solved maximum temperature T_m, instead. For their analytical solutions, they also introduced an additional approximation incorporating the diffusivity term. Their analytical solution for the slab case is shown in Figure 10.

The definition of δ_c for the limited-oxygen case is:

$$\delta_c = \frac{E}{RT_o^2} \frac{r^2 c_o^n \varepsilon Q_{ox} A}{\lambda} e^{-E/RT_o}$$

Note that, unlike for the base case, the heat of reaction is here on an oxygen basis and the porosity ε also enters into the equation. Figure 10 indicates that two variables affect

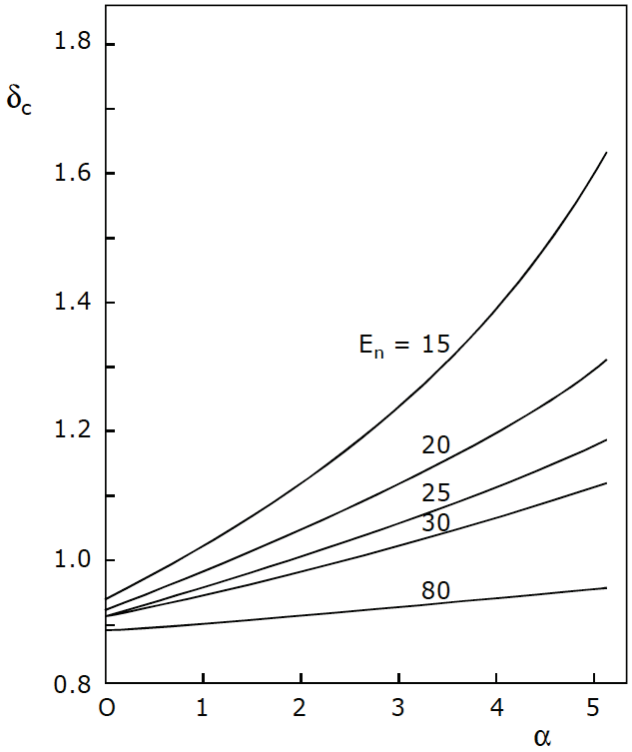

Figure 10 Effect of limited oxygen supply in raising δ_c according to the solution of Takeno and Sato
(Copyright The Combustion Institute, used by permission)

the oxygen-diffusion-limited value of δ_c: α and E_n. These new non-dimensional variables are defined as:

$$\alpha = \frac{n \lambda T_o}{c_o Q_{ox} D}$$

$$E_n = \frac{E}{RT_o}$$

and c_o, as before, is the initial concentration of oxygen. When oxygen supply does not limit the reaction, effectively $D \rightarrow \infty$. This corresponds to the classical solution, thus the $\alpha \rightarrow 0$ limit here should recover the Frank-Kamenetskii limit (i.e., $Bi \rightarrow \infty$). For the slab case, this value was 0.88. Here, one can see a value of $\delta_c \approx 0.9$. The slight difference is due to the different nature of the exponential approximation made by Takeno and Sato. A similar theory was also offered by Nakajima and Takeno[32].

STEADY-STATE THEORY INCLUDING FUEL DEPLETION

Fuel exhaustion occurs in all cases where an ongoing reaction can continue. This causes temperatures to be lower than a numerical solution of the heat flow equation would indicate (Figure 9). The bulk of the fuel depletion occurs after very rapid heating (i.e., runaway) has started. But if reactant depletion is significant, the onset of criticality will be estimated in an over-conservative way, thus a method to take reactant depletion into account is advantageous. The mathematics of the case which includes reactant depletion

changes in a fundamental way[33]. By ignoring reactant depletion, a limiting condition is computed whereby the system temperature →∞. This simplified result is then taken to correspond to thermal runaway, where large but not infinite temperatures will occur. The mathematical solution when reactant depletion is included does not show this same trait. Instead, temperatures run up to a high value, then proceed downward. Physically, this corresponds to the fact that temperatures must start dropping when fuel becomes scant.

Solutions which fully incorporate fuel depletion do not lend themselves to tractable, closed-form approximations. But Thomas presented a theoretical analysis[34] which was obtained by assuming that the fuel depletion case is a perturbation upon the no-depletion case. In his solution, he also generalized the Arrhenius Law reaction rate used to include reactions of arbitrary order. This gives the initial heat release rate as:

$$\dot{q}''' = c_f^n QA e^{-E/RT_a}$$

The fuel concentration c_f can be expressed either in mole units (mol m^{-3}) or density units (kg m^{-3}). The units of A depend on the value of n. For c_f in mole units, they are mol^{1-n} m^{3n-3} s^{-1}, while if c_f is in density units, then A is in units of kg^{1-n} m^{3n-3} s^{-1}. For a first-order reaction, the units of A are s^{-1}. Then δ is expressed as:

$$\delta = \frac{E}{RT_o^2}\frac{r^2 c_f^n QA}{\lambda} e^{-E/RT_o}$$

where c_f is the initial concentration of fuel. In Thomas' solution, an additional nondimensional term B is needed, which represents the temperature rise under adiabatic conditions:

$$B = \frac{E}{RT_o^2}\frac{Q}{C}$$

The results for the critical condition can be expressed as a 'corrected' δ_c:

$$\delta_c(B,n) = \frac{\delta_c(\infty)}{1 - 2.85(n/B)^{2/3}}$$

where $\delta_c(\infty)$ is the value obtained without considering reactant depletion. The value of n will not be known *a priori* without a detailed study of the material's chemistry, but for rough estimating purposes, it may be reasonable to assume $n = 1$. Small values of B promote a high degree of reactant depletion. A correction may be appropriate if B is less than about 100. Boddington[35] worked out a similar solution and obtained 2.703 instead of 2.85 in the above equation. He points out, however, that all such solutions contain steps which are logically somewhat shaky. Thomas and Bowes[36] have discussed the accuracy which is needed for fuel depletion effects calculations in order to preserve the accuracy of predictions, concluding that very simple corrections are sufficient. A number of alternative, possibly more exact solutions to the problem have subsequently been offered. Bowes[10] reviewed several of them in some detail and concluded that the best approximation is:

$$\delta_c(B,n) = \frac{\delta_c(\infty)}{0.97 - 2.35(n/B)^{2/3}}$$

The permissible temperature rise θ_p that can be incurred before criticality is reached also increases if reactant depletion is considered. Tyler and Wesley[37] offered the following correction equation for this:

$$\theta_p(B,n) = \theta_p \times \left[0.326 + 0.553\exp(3.47\varepsilon) + \left[3.69 + 1.91\exp(16.0\varepsilon)\right](n/B)^{2/3}\right]$$

where $\varepsilon = RT_o/E$. The correction equation was derived only for $B \geq 100$, but in view of the absence of other tractable prediction methods, it may be applied, with lower expected accuracy, even to B values outside this range. It is useful to estimate the magnitude of the correction that might be obtained with this equation. Taking values similar to those of some wood products, for example, E = 100 kJ mol^{-1}, Q = 500 kJ kg^{-1}, C = 1.4 kJ kg^{-1} K^{-1}, and taking T_o = 373 K gives B = 31 and ε = 0.031. Assuming that n =1, then $\theta_p(B, n)/\theta_p$ = 1.63; this is a fairly sizable increase in the permissible temperature rise.

The above discussion assumed that the solid in question was a symmetrically heated sphere, cylinder, or slab. For an unsymmetrically heated slab, some numerically-obtained guidance[38] is also available.

CORRECTION FOR LOW ACTIVATION ENERGY

The standard theory assumes that

$$\frac{RT_o}{E} << 1$$

If the activation energy is not large enough to justify that, then the values of δ_c will not be the standard tabulated values. By making full numerical calculations without approximation, Enig et al.[39] obtained tables for δ_c as a function of RT_o/E. For example, if RT_o/E = 0.25, then the slab δ_c = 1.12 instead of 0.88. In practice, no corrections need to be considered if E > 40 kJ mol^{-1}. For smaller values, Boddington et al.[24] provide the following approximation:

$$\delta_c(\varepsilon) = (\delta_c)_{\varepsilon=0}(1 + 1.07\,\varepsilon)$$

where $\varepsilon = RT_o/E$. This equation is valid for $\varepsilon \leq 0.05$. To make the correction, the value of δ_c is found from the basic theory, then the correction is applied according to the equation above.

For extremely small activation energies, the concept of criticality entirely vanishes. Such systems will self-heat continuously and a small-enough 'safe' diameter cannot be sought. This limit occurs at

$$\frac{RT_o}{E} \geq \text{ca. } 0.25$$

The limit value, in principle, varies with *Bi*, but the whole range of *Bi* numbers is encompassed[40] by about 0.24 to 0.25. For T_o = 20ºC, this limit will occur for E < 9.7 kJ mol^{-1}, which would only be seen for certain highly unstable substances.

MORE COMPLEX REACTIONS

Easily-tractable forms of theoretical treatment are all based on there being only a single, Arrhenius-form reaction. But some real materials show chemical reactions that are more complex. The forms of more-complex reactions include the following:

- A single reaction, but with a temperature dependence that is not of the Arrhenius form.
- Two sequential reactions.
- A substance comprised of a mixture of two pure substances, each of which exhibits a separate reaction chemistry.
- A substance that has two parallel reactions taking place, but those reactions cannot be attributed to two separate constituents of the substance.
- Single-step or multi-step autocatalytic reactions.

It is common to find substances where the best-fit kinetic expression shows a temperature dependence of the following form:

$$k \propto T^{1/2} \exp(-E/RT)$$

Boddington et al.[41] studied this case numerically. The results for δ_c are identical to those for the Arrhenius case in the case of no reactant depletion and nearly identical otherwise. Simple solutions have not been offered for more complex temperature-dependent factors.

If a material shows two sequential Arrhenius reactions, matters become very complicated. Forbes et al.[42] described some of the oscillatory behavior that can occur in a system where:

$$A \xrightarrow{k_1} B \xrightarrow{k_2} C$$

with k_1 and k_2 being two different, Arrhenius-form reaction rate terms.

Sawdust contaminated with an oil is the classical example of a two-component system where the self-heating behavior has been studied in detail for each component. Bowes developed a theory[43] for this case and provided experimental results[44] for the sawdust/oil example. Boddington et al.[45] developed another theoretical treatment for the case of two pure substances mixed together, and a calculational example has been published[46]. Wake et al.[47] discussed the case of two parallel reactions and provided numerical solutions for two example cases. Nunziato et al.[48] presented a theoretical solution, but without practical illustration. All of these theories are mathematically complicated and none are straightforward to apply in practice.

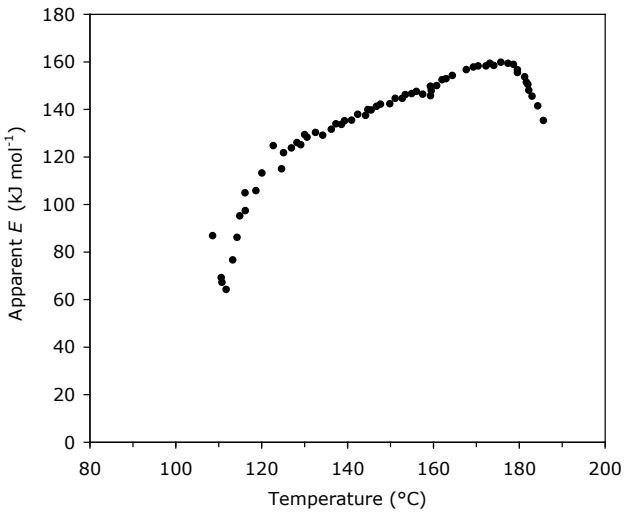

Figure 11 Apparent value of E obtained by analyzing ARC results for di-*tert*-butyl peroxide as having only a single Arrhenius-form reaction

In some cases, several parallel reactions occur in a substance which is a single, complicated substance and the reactions cannot be attributed to components that might be studied in isolation. Analyzing such a substance by assuming a single reaction will produce erroneous results. If a substance has a single, Arrhenius-form reaction, then the value of E must necessarily be a constant. Bowler[49] showed (Figure 11) that presenting data obtained from an accelerating rate calorimeter for di-*tert*-butyl peroxide (which exhibits two parallel reactions) gives an apparent value of E

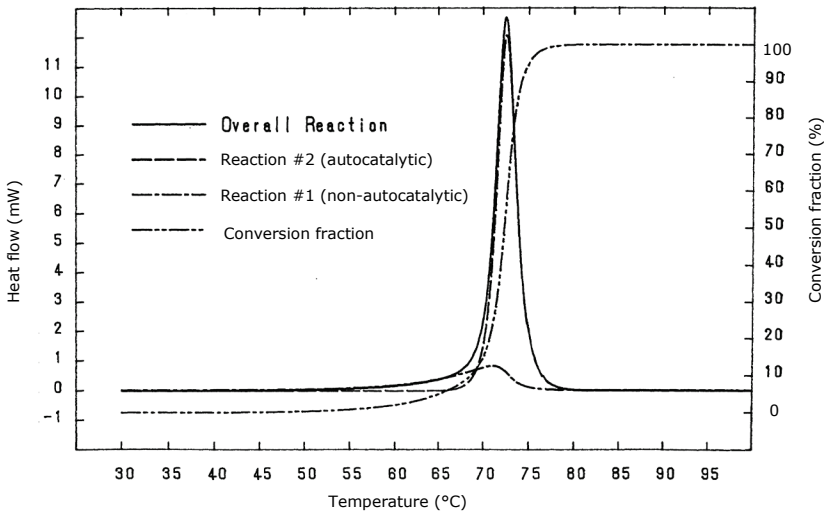

Figure 12 Two reactions during decomposition of bis(2-chlorobenzoyl) peroxide
(Copyright Associacio D'Enginyers Industrials de Catalunya, used by permission)

which is strongly temperature-dependent. A mild case of this has been documented for wood fiberboard[22], although adequate experimental accuracy is obtained by simply treating this material according to a single-reaction Arrhenius expression. Coal exhibits several simultaneous reactions and these cannot be attributed to individual constituents (Chapter 14). In some cases, a practical treatment can ignore the presence of two parallel reactions. A good illustration is provided by some explosives, which often show two temperature regimes (Chapter 10). Within each temperature regime, a single-reaction analysis can be used. This is possible because of the exponential nature of the temperature dependence—for temperatures a little bit away from the breakpoint, one reaction dominates and the second one becomes quantitatively insignificant. For substances of this kind, care must be taken to only use experimental data from the same temperature regime as the proposed environmental temperature into which the substance will be put.

As discussed in Chapter 3, autocatalytic reactions obey somewhat different relationships than do normal bimolecular reactions. In general, if a substance shows a small amount of autocatalytic activity, this may well be ignored. But if the reaction is strongly autocatalytic, extensive research may be needed. Grewer's book[72] examines autocatalytic reactions at great length, but no simple treatment emerges. Li and Hasegawa[50] studied bis(2-chlorobenzoyl) peroxide, whose decomposition has both an autocatalytic and a non-autocatalytic reaction. Allowing for both contributions to be of arbitrary reaction order, they developed an experimental technique for obtaining the kinetic constants from microcalorimeter data. Results can be obtained with a modest amount of trial-and-error because at the very start of the reaction no products yet exist, thus heat production must be solely due to the non-autocatalytic term contribution. Once its kinetic constants are obtained, then the higher temperature regime is used to obtain the constants for the autocatalytic portion of the reaction. The heat release contributions of the two reactions are shown in Figure 12. Another complicated reaction scheme involving autocatalytic reactions was examined by Tyler and Henderson[51], who studied sodium dithionite ($Na_2S_2O_4$), a self-heating powder. The reaction did not conform to a simple autocatalytic reaction, and to obtain agreement with experimental results, they found it necessary to perform numerical calculations using an empirically-derived reaction-rate law.

HOT WORK, COLD WORK, AND HOT SPOTS

Most of the discussion thus far has involved systems with only a single characteristic temperature: a body which is quickly assembled at T_o and placed in an environment which is at T_o. Subsequently, the system can heat up, but only a single temperature is needed to describe the initial system conditions. Apart from the unsymmetrically-heated slab already considered, two other classes of problems occur where there are two different initial temperatures: hot spots and hot/cold work. Theories have been developed to address both these situations. The hot work problem involves a material assembled or stacked which is initially at some elevated temperature T_h, higher than the ambient air temperature T_o. Hot spots may arise as a potential ignition problem in granular material if a hot body (a hot rivet, for example) is dropped into a pile of granular material. The granular material is initially at some lower temperature than the hot body. In such a case, the hot spot itself is inert, but the granular material is reactive. Hot spots may also arise due to non-uniformities of the substance, where localized nuclei of heating develop. The formation of such nuclei appears to still be largely unexplained. However, there has been a fair number of mathematical theories for the self-heating of a system where both the hot body and the surrounding body are reactive. Mathematically, these two problems have only one real difference: The hot work problem comprises a substance which is put into the atmosphere while at an elevated temperature; thus its edges are cooled by *convection*. The hot spot, on the other hand, is immersed in the reactive material; thus its cooling is only by solid-phase *conduction*. Cold work problems are the opposite of hot work, but have received only limited study.

HOT WORK

The problem of the initially-warm material is called the 'hot work' or 'hot stacking' problem. It can arise whenever a heat-treatment of a reactive material is used. For some materials, cooling under conditions of oxygen exclusion may be needed. The hot work problem has some special features, among them is that the upper (unstable) equilibrium point of Figure 2 can serve as a starting point for the process, since heat losses will decrease afterwards. When a system of this kind is placed in the air, there is internal heating but cooling at the boundaries. Thus, inevitably the center of the material rises in temperature. If the system is subcritical, after a modest increase, the temperatures begin to fall. But if the system is supercritical, then temperatures keep growing (Figure 13)[52].

Since there are two different characteristic temperatures, either one can be taken as the reference, but the development of the theory is quite different, depending on the choice. The more intuitively obvious choice is to select the ambient temperature T_o as the reference temperature. This was done by Gray and Scott[52] and the choice leads to δ_c values which sensibly drop as T_h is raised, indicating that if our conventional definition of δ_c is kept, permitted sizes must become smaller as T_h becomes larger. The other choice is to select T_h as the reference temperature. In that case, δ_c rises as T_h increases. The meaning of this is that a certain size would be permitted if both the initial body temperature and the ambient temperature were at the high value of T_h. But since T_o is in fact lower than T_h, a size increase is permitted, with respect to that starting point. This is equally viable as a calculational procedure, albeit less transparent. In the Gray/Scott method, the definition of δ_c is:

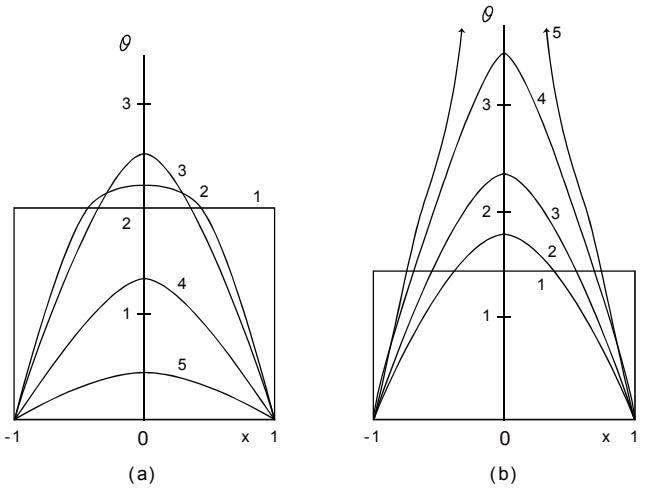

Figure 13 Hot work problem: (a) subcritical and (b) supercritical behavior; shown at time of assembly **1** and at later times **2**…**5**
(Copyright The Combustion Institute, used by permission)

$$\delta = \frac{E}{RT_o^2}\frac{r^2 \rho Q A}{\lambda} e^{-E/RT_o}$$

and the definition of the nondimensional initial temperature is:

$$\theta_i = \frac{E}{RT_o^2}(T_h - T_o)$$

Gray and Scott solved the problem numerically, and obtained results for the slab case as shown in Figure 14. They provided solutions only under the condition of $Bi \rightarrow \infty$, but for several values of ε, where

$$\varepsilon = \frac{RT_o}{E}$$

Note that if $\varepsilon = 0$ and $\delta_c = 0.88$ (that is, the value for the normal, non-hot-work case), then the maximum permitted initial temperature corresponds to $\theta_i = 1.115$, but for smaller δ_c values the permitted θ_i rises rapidly. The authors also provide similar graphs for the infinite cylinder and the sphere. Unfortunately, they did not analyze the case of a cube—which is often the shape of most interest. Griffiths and Kordylewski[53] did treat the case of the cube, but their solution was wholly computational and did not lead to closed-form approximations.

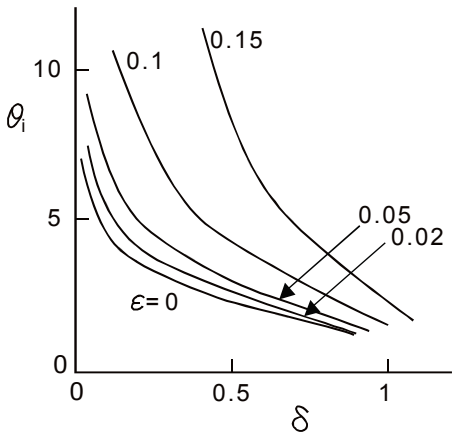

Figure 14 The critical values of initial temperature excess for the infinite-slab case (for values of $\varepsilon = 0$, 0.02, 0.05, 0.1, and 0.15)

An earlier solution to the problem was provided by Thomas[63], who took as a reference temperature the hot work temperature T_h:

$$\delta = \frac{E}{RT_h^2}\frac{r^2 \rho Q A}{\lambda} e^{-E/RT_h}$$

and using the definition of the nondimensional initial temperature as:

$$\theta_h = \frac{E}{RT_h^2}(T_h - T_o)$$

With these definitions, the value of δ_c rises as θ_h rises since, in this case, a rising θ_h must be interpreted as a falling T_o, in other words, T_h is viewed as fixed and that the hot work item is plunged into progressively cooler ambient environments. The Thomas solution was simplified by Bowes[10] and given as:

$$\delta_c = Bi(1+j)\theta_h\, e^{Bi(1+j)/\delta_c}$$

where $j = 0$, 1, and 2 pertain to the cases of the slab, cylinder, and sphere, respectively. This equation allows for finite values of Bi, but the unknown, δ_c, is present on both sides, so the equation can only be solved by trial-and-error. For the case where $\theta_h >> 1$, the very simple approximation can be used:

$$\delta_c \approx Bi(1+j)\theta_h$$

For high rates of convective cooling, where $Bi \rightarrow \infty$, Beever[54] presented graphical solutions. The following equations represent good curve fits to her results in the range $2 < \theta_h < 14$:

Infinite slab $$\delta_c = \frac{1}{0.0544 + 0.3603/\theta_h}$$

Infinite cylinder $$\delta_c = \frac{1}{0.04196 + 0.1382/\theta_h}$$

Equicylinder $$\delta_c = \frac{1}{0.0404 + 0.1180/\theta_h}$$

Sphere $$\delta_c = \frac{1}{0.0366 + 0.0610/\theta_h}$$

Cube $$\delta_c = \frac{1}{0.0458 + 0.1316/\theta_h}$$

All of the solutions above for the hot work problem assume that the substance is not of low activation energy, that is, that $E/RT_o >> 1$. If this condition is not fulfilled, then a simple, closed-form treatment is not available.

Results from a set of validation experiments on the hot work problem have been published[55]. In the experiments, wood sawdust was heated to steady state temperatures of 140 – 160ºC. The material was placed in thin, long cylinders to avoid runaway self-heating while in the oven. After reaching steady state, the sawdust was quickly emptied into cubical wire baskets sitting in open air. A linen lining was used inside the baskets to allow the material to be retained. An agreement within 21% to the theoretical results was obtained. The necessary material properties for the sawdust had been obtained previously from standard oven tests for self-heating of cubes.

COLD WORK

There exists an exact inverse to the hot work problem—a body initially at the temperature T_1 is plunged into an environment at T_o, where $T_1 < T_o$. In practice, this is how oven-basket testing, which is explored later in this Chapter, is done. To conform to simple F-K theory, the material should be dispersed in the oven in the form of an infinitesimally-thin layer, then quickly pulled together at $t = 0$ into a basket. It is rather hard to do this, so normally a basket is prepared at room temperature, then inserted into an oven that is preheated to some elevated temperature. For practical purposes, the time $t = 0$ is then declared to be the time at which the temperature at the center of the specimen first attains the oven temperature. This is entirely acceptable from the point of view of determining the critical size/temperature relationship, but actual temperatures during the initial warm-up period will not correspond to those pertinent to a theoretical treatment where the body is quickly assembled at T_o. The cold work problem has not been studied extensively from a theoretical viewpoint, because assuming that the entire system was equilibrated to T_o at $t = 0$ is a conservative assumption. Chong et al.[56] performed some illustrative numerical calculations for a cube, and these are shown in Figure 15. The substance showed only mild exothermicity, and thermal runaway eventually took place at the center, although early heating showed an initial 'shoulder' rise near the edges. If the substance is strongly exothermic, then runaway will occur close the edge and not at the center. Zinn and Mader[57] made some experiments and provided numerical calculations which illustrates this for the case of a sphere, as shown in Figure 16.

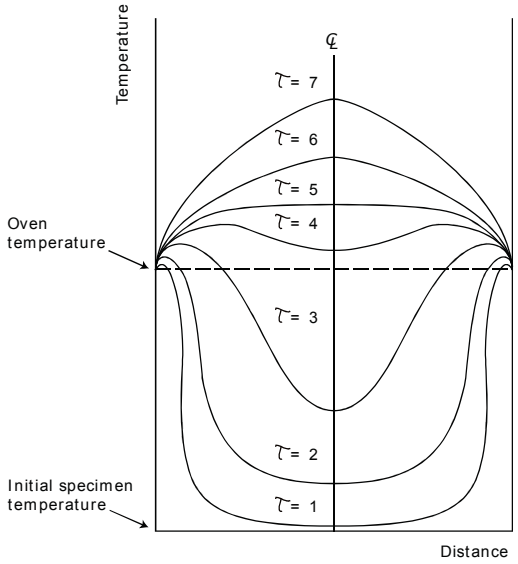

Figure 15 The heating of a cold cube of an exothermic substance after insertion into a test oven held at a hotter temperature; increasing times are denoted by higher τ values

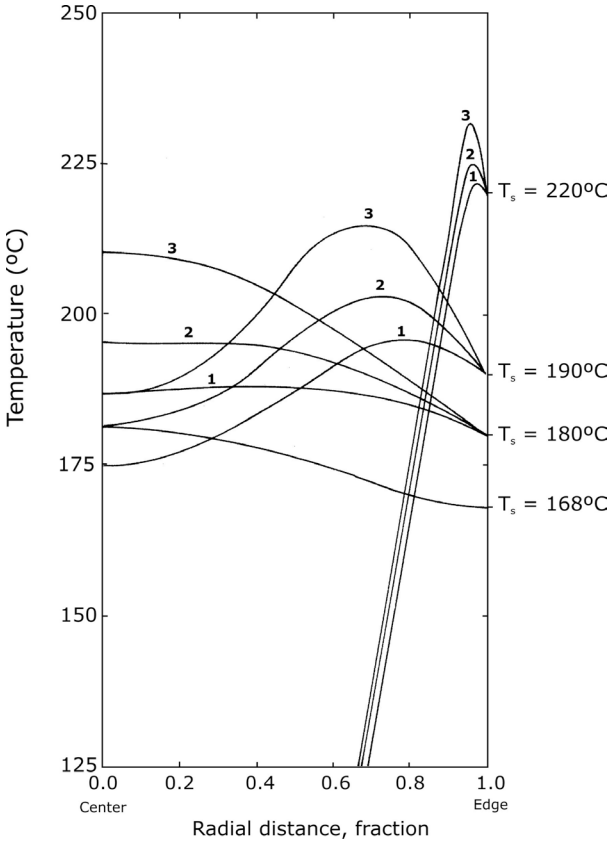

Figure 16 Calculated results for the heating of a 25 mm diameter sphere of RDX, initially at 25ºC, plunged into environments of various elevated temperatures (T_s). Curves shown were obtained for three different times: **1** denotes time which is 90% of critical time, **2** is 95%, **3** is 98%. T_s = 168ºC is the highest subcritical temperature. It is assumed that $Bi \rightarrow \infty$, therefore the surface temperature T_s is identical to the environment temperature T_o.

Abramov et al.[58] obtained example solutions in terms of δ_c', which is the critical value of δ beyond which thermal runaway will no longer occur at the center. Their computed values, obtained only for θ_i = 11.7, are shown in Table 8.

For δ slightly in excess of δ_c', thermal runaway will take place only slightly offset from the center and it requires $\delta \approx$ 1000 before the peak temperature approaches close to the edge.

INERT HOT SPOTS

An inert hot spot can comprise, for example, a piece of hot metal that falls into a bed of ignitable fuel. Whether a self-sustaining reaction is thereby caused in the fuel bed depends on the size and the temperature of the hot spot, along with the properties of the fuel. The problem becomes intrinsically complicated, since now several new variables—those describing the characteristics of the hot spot—are introduced. Of the various proposed solutions, Bowes[10] recommends the use of Gol'dshleger's method[59] as being reasonably accurate, yet still tractable. In the Gol'dshleger method, the critical value δ_c is approximated as:

$$\delta_c = Z\left[1+\frac{(\theta_h-3)^2 b(j+1)}{30k_\lambda^{2/3}(1+3b^{2/3})}\right]^2$$

where

$$\delta = \frac{E}{RT_h^2}\frac{r^2\rho Q A}{\lambda}e^{-E/RT_h}$$

$$\theta_h = \frac{E}{RT_h^2}(T_h - T_o)$$

$$Z = 0.4\left[\theta_h + 2.25(j-1)\right]^2 \times\left[1+0.5\varepsilon\theta_h\right]\sqrt{b^2+0.25\,j(j+1)(b+0.1b^3)}$$

T_h = initial temperature of hot spot
T_o = initial temperature of surrounding body

$$b = \frac{\rho C}{\rho_h C_h}$$

$$k_\lambda = \frac{\lambda_h}{\lambda}$$

$$\varepsilon = \frac{RT_h}{E}$$

and the suffix *h* denotes properties of the inert hot spot.

Finally, j = 0, 1, and 2 for the infinite slab, infinite cylinder, and sphere geometries, respectively. The approximate solution was derived assuming the following range of variables: 7.5 $\theta_h \le 25$; $0.01 \le \varepsilon \le 0.9/\theta_o$; $1 \le k_\lambda \le \infty$; $0.05 \le b \le 10$. An example of the use of the Gol'dshleger method is given in Chapter 14 under *Forest materials, vegetation, and hay*.

Another solution to the same problem was offered by Liñán and Kindelán[60]. Their solution is based on a different definition of a non-dimensional heat generation parameter, which for distinction is identified as δ^{LK}:

$$\delta^{LK} = \frac{2RT_h^2 QAr^2\rho_o}{E(T_h-T_o)^2\lambda_o}\exp(-E/RT_h)$$

where T_h = temperature (K) of the hot spot, T_o = initial temperature (K) of the self-heating body, ρ_o = density (kg m^{-3}) of the self-heating body, and λ_o = thermal conductivity (W m^{-1} K^{-1}) of the self-heating body. The solution is presented in terms of the variable Λ, defined as:

$$\Lambda = \frac{RT_h^2}{(T_h-T_o)(j+1)E}\frac{\rho_h C_h}{\rho_o C_o}$$

where j = 1 for cylinder or 2 for sphere, ρ_h = density (kg m^{-3}) of the hot spot, C_o = heat capacity (J kg^{-1} K^{-1}) of the self-heating body, and C_h = heat capacity (J kg^{-1} K^{-1}) of the hot spot. Over the range $10^{-2} < \Lambda < 10^3$, the solution for the critical value δ_c^{LK} is shown as a graph, which can be expressed as:

$$\delta_c^{LK} = 1.15 + 1.32\Lambda^{-0.5} + 3.47\Lambda^{-1} + 0.302\Lambda^{-2}$$

The solution is valid provided that $\lambda_h\rho_h C_h >> \lambda_o\rho_o C_o$, which will commonly be the case for granular or porous materials.

A simpler solution, but applicable only to the infinite cylinder geometry was obtained by Friedman[61]. His approximation for δ_c is:

$$\delta_c \approx \ln\left[0.608\frac{E}{RT_h}\left(1-\frac{T_o}{T_h}\right)\right]$$

where the definition of δ is:

$$\delta = \frac{E}{RT_h^2}\frac{r^2\rho Q A}{\lambda}e^{-E/RT_h}$$

REACTIVE HOT SPOTS

Theories for reactive hot spots assume that the hot spot and the fuel bed are comprised of the same substance, with the distinction being that the hot spot is smoldering and the main fuel is not (yet). In principle, theories could also be produced for a situation where the two substances are chemically different, but none of this kind have been published. Thomas reviewed in 1965 the early work[62]. Two concerns emerged: (1) predicted values for δ_c varied by close to a factor of ten among the theories. In fact, under the same circumstances, some theories predicted that immediately after t = 0, the hot spot itself will start rising in temperature, while others predicted that it will start dropping. (2) Adequate experimental data were not available for validation. Several years later, additional new theories were available, leading to a second review of the subject by Thomas[63]. In the latter study, Thomas concluded that Merzhanov's[64] approach is the most suitable. The physical assumptions in that theory are:

(1) the hot substance and the surrounding substance are the same material.
(2) a transient solution is needed, therefore, time terms are not dropped in the conservation equation.
(3) Arrhenius kinetics applies.
(4) reactant depletion can be ignored.
(5) the approximation $RT_h/E \rightarrow 0$ can be made.

The theory then considers a hot zone of radius r which is originally at $T = T_h$ at $t = 0$. The nondimensional temperature rise is defined as:

$$\theta = \frac{E}{RT_o^2}(T - T_h)$$

and the nondimensional difference between the initial hot spot temperature (T_h) and the initial temperature of the surrounding body (T_o) is defined as θ_h:

$$\theta_h = \frac{E}{RT_h^2}(T_h - T_o)$$

A further approximation is then made that $\theta_h >> 1$. The nondimensional heating rate δ is defined as:

$$\delta = \frac{E}{RT_h^2}\frac{r^2 \rho Q A}{\lambda} e^{-E/RT_h}$$

Note that in this formulation the value of temperature used to define δ is T_h (the initial hot spot temperature), not the ambient temperature of the surrounding body. The mathematics of the solution is complex and we will proceed straight to the engineering approximation:

$$\delta_c = M(\ln \theta_h)^N \quad \text{for } 4 < \theta_h < 25$$

where the constants M and N, for various geometries, are given in Table 9.

infinite cylinder	7.39	0.83
sphere	12.1	0.60

APPLIED HEAT FLUX

A related problem is the ignition of a self-heating material by the application of a specified heat flux at a boundary. Brindley et al.[65] formulated this problem for a slab, a spherical annulus, and a cylindrical annulus; the face not receiving the specified heat flux is, in all cases, subjected to convective cooling. Their method only produced numerical results and did not lend itself to a closed-form solution.

TRANSIENT THEORY

ESTIMATING TIME TO CRITICALITY

The steady state theory tells us only if runaway conditions will result. But it is often of interest to estimate not only *whether* ignition can occur, but *how long* it will take, if the system is one which does lead to ignition. The practical relevance is because many piles of materials prone to self-heating are not being stored indefinitely. If runaway conditions are anticipated to occur in, say 1 month, but the average storage period (before the pile is segregated into small piles and removed) is 3 days, then there is little danger in the process. Since, thus far, time-dependent solutions have not been considered, we first start with an example of some laboratory data showing histories of self-heating. Figure 17 illustrates the temperatures obtained for several equicylinders (height ≡ diameter) of wool, placed in an oven at various temperatures[66].

To estimate the ignition time from theory requires either a numerical computation of the governing equation, or approximations, or both. For the problem of constant surface temperature, Zinn and Mader[57] solved the time-dependent equations for the non-dimensional ignition time τ as a function of the ratio δ/δ_c. under the assumption that $Bi \rightarrow \infty$. Their definition of τ is:

$$\tau = \frac{t_{ig}\lambda}{\rho C r^2} = \frac{t_{ig}}{t_{Fo}}$$

where t_{Fo} denotes the 'Fourier time,' which is the characteristic time for cooling. Thus, the physical ignition time t_{ig} is computed as:

$$t_{ig} = \tau \cdot t_{Fo} = \tau \frac{\rho C r^2}{\lambda}$$

A closed-form approximation to their results is:

$$\tau = \frac{1}{a + b(\delta/\delta_c) - c(\delta/\delta_c)^{-1/2}}$$

where the numerical constants are given in Table 10. A graph of Zinn and Mader's original results (x's) and the curve fits (lines) are shown in Figure 18. Note that only points for $\delta > \delta_c$ are shown, since there is no thermal runaway if $\delta < \delta_c$.

sphere	3.90	0.0390	3.46

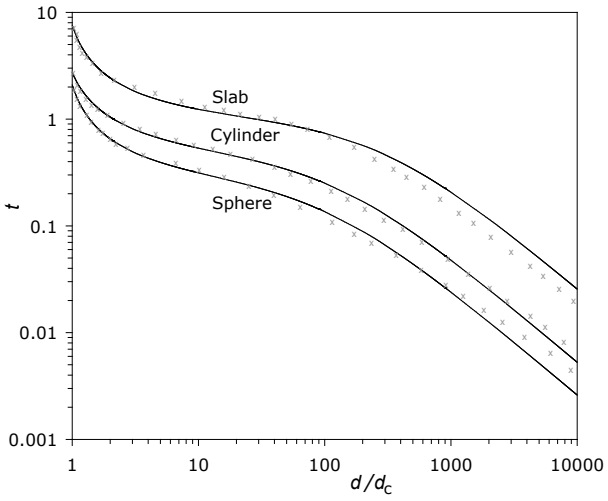

Figure 18 Estimating of the ignition time, Zinn and Mader method

Another method for estimating the ignition time was developed by Boddington et al.[67]. Using the same nomenclature as above, their expression is:

$$\tau = \frac{M(Bi)}{(\delta/\delta_c - 1)^{1/2}}$$

with values of the function M (Bi) given in Table 11. In their paper, Boddington et al. also provide values of M for intermediate values of Bi. However, since the limit values are quite similar, it should suffice to simply select either the $M(0)$ or the $M(\infty)$ value.

The calculations can be alternately presented, as Boddington et al. did in their original work, by using the concept of the *adiabatic induction period*, which pertains to a system with no heat losses. The adiabatic induction period is defined as:

$$t_{ad} = \frac{C}{AQ}\frac{RT_o^2}{E}\exp\left(\frac{E}{RT_o}\right)$$

where C = heat capacity of the reactants (kJ kg^{-1} K^{-1}) and T_o is the initial temperature (K). But, according to definition of δ_c,

$$\delta_c = \frac{t_{Fo}}{t_{ad}}$$

The ignition time t_{ig} can then be expressed as a function of t_{ad}:

$$\frac{t_{ig}}{t_{ad}} = \frac{M(Bi)}{(\delta/\delta_c - 1)^{1/2}}$$

Table 11 Estimating ignition time by Boddington's method: limiting values of $M(Bi)$

Geometry	*M* (*Bi*)	
	Semenov condition (*Bi*→0)	**Frank-Kamenetskii condition (*Bi*→∞)**
slab	1.6344	1.5336
cylinder	1.6344	1.4288
sphere	1.6344	1.3160

This method presumes that the actual conditions are only marginally supercritical, i.e., that δ is not vastly greater than δ_c. For strongly supercritical systems, Boddington et al. provide another expression:

$$\frac{t_{ig}}{t_{ad}} = \frac{M(Bi)}{(\delta/\delta_c - 1)^{1/2}} - 0.8 + 0.8(\delta/\delta_c - 1)^{1/2}$$

Boddington provided an experimental validation of the above equation[68], although the system studied was a highly explosive gas, where criticality times were all less than 5 s. A comparison of the results of Zinn and Mader to those of Boddington et al. indicate that for $1.05 \le \delta/\delta_c \le 5$, where most practical problems are likely to occur, differences of about a factor of 2 are found.

Thomas[34] derived several estimates for the induction period. The most useful is a simple lower limit:

$$\tau \ge \frac{0.89}{\delta}$$

Or,
$$t_{ig} \ge \frac{0.89}{\delta}\frac{\rho C r^2}{\lambda}$$

Another method for estimating the lower bound was developed by Gray et al.[69] They used the assumptions of a slab geometry, no reactant depletion, and $Bi \to \infty$, but performed a full numerical solution, without making approximations for the exponential term. Numerical solutions were obtained, to which they provided an analytical approximation*:

$$\tau_{ig} \ge u^2 \exp(1/u)[1 - \exp(-\Delta/u^2]$$

where $u = RT_o/E$, $\tau_{ig} = \frac{QAR}{CE}t_{ig}$, $\Delta = RT_p/E$, and the units of QA are W kg^{-1}. Here Δ is the nondimensional temperature rise corresponding to runaway, and Gray suggests that for practical purposes it is sufficient to set $\Delta = 0.003$. Since all of the constants can be determined from tests, a conservative estimate can be computed for any desired ambient temperature T_o. Note that the actual size of the pile does not enter into the expression, thus it is indeed a conservative bound. Even though the expression was specifically derived for slabs, Gray suggests that it is equally applicable to other shapes. Gray recommends[70] that for accurate results, an experimental data point for ignition time should be used.

* The equation given here corrects a misprint in the original paper's expression for τ_{ig}.

The procedure, then, is as follows. Conduct standard oven-basket tests (see below), from which a value of E is determined. Select one of the test temperatures, $T_{o,x}$, where the subscript x denotes experimental value. The observed time to runaway at that temperature is found to be $t_{ig,x}$. Then for that condition $u_x = RT_{o,x}/E$. Knowing u_x, the equation can be solved to determine $\tau_{ig,x}$. Finally, the needed group of constants is solved for as:

$$\frac{QAR}{CE} = \frac{\tau_{ig,x}}{t_{ig,x}}$$

Actual computations of t_{ig} for end-use temperature conditions are then made using this value for the group of constants.

A number of other approximate solutions (of much higher complexity) have been reviewed by Bowes[10]. Squire[71] has pointed out that predicted times from all theories will generally be shorter than actual, since fuel depletion is not taken into account in any of the simplified formulas.

For Newtonian cooling of the surfaces with a convective heat transfer coefficient h of finite value, Grewer[72] provided a solution based on knowing the half-time, $t_{1/2}$ (s), of the container, which is defined by the equation:

$$\frac{1}{2} = \exp\left(-\frac{hS}{\rho CV} t_{1/2}\right)$$

where S = surface area, and V = volume. The half-time is then obtained as:

$$t_{1/2} = 0.693 \frac{\rho CV}{hS}$$

Physically, the half-time is determined by taking a block made to the same dimensions as occurs in the problem in question, but of a non-reactive, high thermal conductivity material having a well-known value of C. Suitable materials can be aluminum or copper. The block is heated (or cooled) to equilibrium at some temperature, then quickly removed and plunged into an environment (typically, air) at another temperature. The half-time is simply determined by finding time that it takes for the block to fall (or rise) by ½ of the ultimate value of its temperature change. Grewer then obtained a relation for t_{ig}/t_{ad} as a function of $t_{ad}/t_{1/2}$. This can be numerically represented as:

$$\frac{t_{ig}}{t_{ad}} = \left(\frac{1 + 0.0012\, t_{ad}/t_{1/2}}{1 - 0.255\, t_{ad}/t_{1/2}}\right)^{0.65}$$

The half-time can also be expressed as:

$$t_{1/2} = 0.693\, t_N$$

where $t_N = \dfrac{\rho C}{hS}$ and is identified as the Newtonian cooling time—it is the time scale representing the cooling. We may also note that the Semenov number, ψ_c, is defined as: $\psi_c = t_N / t_{ad}$. Thus, Grewer's relation could have equally well been expressed by replacing $t_{ad}/t_{1/2}$ with 0.693 ψ_c.

Grewer's method is useful in connection with a number of UN tests (see at the end of this Chapter) where $t_{1/2}$ is determined. One would naturally expect that if one "blows harder" on a pile of self-heating material, that the time to criticality would be delayed. Grewer's expression is perhaps the one which most clearly illustrates the effect, since $t_{1/2}$ is decreased with increased cooling, while the expression for t_{ig} increases monotonically (albeit non-linearly), with $1/t_{1/2}$ (Figure 19). Apart from this alternate solution for problems with Arrhenius kinetics, Grewer also developed[72] a numerical solution for the ignition time in the case of autocatalytic reactions.

The above presentation focused solely on the simplest classical case, a body reacting to a uniform ambient temperature. Practical predictions are not available for other situations. For example, a theoretical model[38] was developed to predict the runaway time in systems with one face held at an elevated temperature (e.g., hotplate tests), but comparison with experimental data indicated that success was not achieved.

In practice, it may be best to simply extrapolate from experimental data, and this is what Thomas[73] and Bowes[10] both recommend. Figure 20 illustrates results from Mitchell[161]. In his tests, he used octagonal parallelepipeds with height = face width. The times plotted all pertain to the $\delta \equiv \delta_c$ condition. The lines drawn represent $t_{ig} \propto r^2$. Thomas points out that a dependence on r^2 will be found for any system which is diffusion-limited, and it is not necessary for Arrhenius kinetics to be applicable. Thomas also examined the effect of reactant depletion on the criticality time[74]. He concluded that there is a strong effect, unless the conditions are such that $\delta > 2.5\delta_c$.

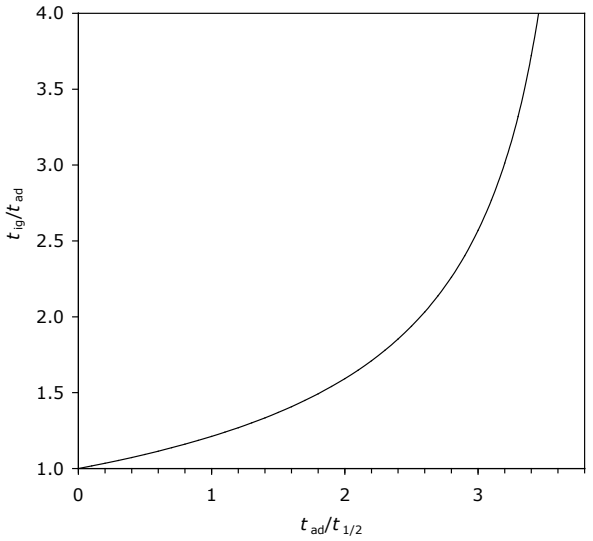

Figure 19 Grewer's method for estimating time to ignition
(Copyright Elsevier Science, used by permission)

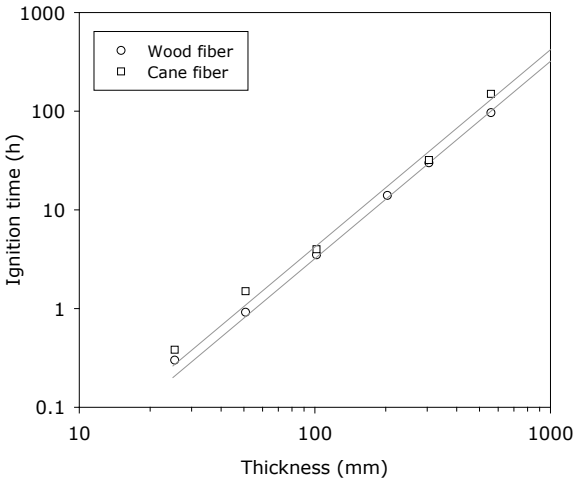

Figure 20 Times to criticality for 'equi-octagons' of two different fiberboards (the oven temperature is different for each data point, in each case corresponding to the critical temperature for the particular thickness)

Gray[75] has pointed out that all methods of computing or estimating time to criticality may be subject to gross errors. The basic reason is that few substances truly possess only a single exothermic reaction. Instead, various chemical reactions (e.g., catalytic reactions) may be important towards establishing the early time scale, but these same reactions are not ones that determine the actual temperature/size criticality relationship. No form of clever mathematical treatment can overcome this potential difficulty.

LINEARLY INCREASING SURFACE TEMPERATURE

In some situations, the boundary conditions for a self-heating substance can be approximated by assuming that the exposed surface temperature is rising at a linearly increasing temperature. Creighton[76] considered a slab with its face subject to the boundary condition

$$T_s = T_o + \beta t$$

and obtained numerical solutions for the cases (a) simple Arrhenius kinetics; and (b) more realistic 3-step reaction kinetics suitable to the explosives HMX and TATB. Unlike bodies with Newtonian cooling conditions at the edges, when peak temperatures are found at the center, the peak temperature rise for this problem is close to the surface. The critical surface temperature T_c at ignition was found in all cases to obey a relation of the form:

$$T_c = \frac{a}{1 - b \ln \beta}$$

where a and b are constants to be fitted.

MORE ADVANCED MODELS

The models discussed so far have largely been simplified sufficiently so that either approximate closed-form solutions could be obtained or, at least, that the number of variables be small enough so that some 'universal' graph could be obtained. This means that important physical/chemical factors had to be ignored. A more comprehensive treatment would include not only transient effects, but also encompass 3-dimensional bodies not having symmetry; more detailed chemistry, variation of thermophysical properties with temperature and degree of charring, flow of moisture, etc.

The disadvantage of comprehensive numerical models is that they lack instructive value. If all the necessary input data can be assembled (and that may be a very large "if"), then a precise, specific result can be computed. However, it is difficult to develop an intuitive understanding how the physics and chemistry really work, when such a model is used. Brute-force, numerical modeling has been used for a very long time in computational fluid dynamics (CFD), in civil engineering thermostructural studies, and in a plethora of other disciplines. Thus, perhaps it is a bit surprising that there have not been a great number developed of multi-component, multidimensional, fully-featured numerical models of self-heating. There has been a handful, however.

Nordon[77] presented a computational model for coal. His initial model was 1-dimensional, but included conservation equations for heat, oxygen, and water vapor. One aspect that Nordon was able to study which is not incorporated into the classical model is forced convection blowing through a porous pile, for example, due to effects of wind. Large amounts of *air flow* reduced self-heating below the no-forced-convection case. On the other hand, a small amount of forced convection, with velocities of the order of 10^{-5} m s^{-1}, served to greatly increase the temperature rise of the pile. More recent work reformulated the model to be 3-dimensional, with the objective of examining the effect of porosity[78]. Under the standard theory, porosity would only be accounted for by the density term of the substance. But increasing porosity decreases the density and, according to Frank-Kamenetskii theory, would decrease the self-heating. Instead, the detailed modeling showed that increasing the porosity from 0.2 to 0.3 caused a significant increase in self-heating. This result indicates that at the lower porosity the coal's heat generation was limited by insufficient oxygen access. A much more comprehensive model for the self-heating of coal was developed by Schmal[79], and it is discussed in Chapter 14.

Another numerical model was illustrated by Takeda and Akita[80], who investigated the case of symmetric bodies having a boundary condition at the edges consisting of a steady rate of temperature rise. The number of variables in such a case exceeds what can be readily represented in closed form, but the authors provided computational results showing that increasing the heating rate raises the computed value of T_c. The effect is not major, however, and in their example increasing the boundary rate of rise by 10× caused only about a 9ºC increase in T_c. A two-dimensional, transient model for self-heating of powders in a silo has been described[81]. Despite the fact that a few models have been

documented in the literature, it does not appear that there are any that are available to the public in the form of a computer program.

Applications

IGNITION FROM SELF-HEATING

When a critical condition occurs in a substance undergoing self-heating, the question becomes: What happens then? In general, one can expect a smoldering type ignition. If the substance is homogeneous and its initial temperature is identical to that of its environment, then the temperature rise will be highest in the center, therefore, this is where the ignition is expected to occur. But if a body is plunged into a very hot temperature environment, then ignition must occur at the edges, since heating only a surface layer of small thickness will suffice to cause thermal runaway. For this to happen requires the system to be greatly supercritical. Bowes[10] provided some practical guidance on this topic. For a sphere, if $\delta > 14.25$, then runaway will occur at the edges first. For an infinite cylinder the transition value of δ is 12.25, and for a plane slab it is 9.25.

In general, flaming ignition is not expected to occur—if it occurs at all—until a substantial amount of fuel is consumed and either a large inside cavity is formed or else the smolder front breaks through to the surface. The reason that flaming conditions are not expected inside a pile of material has to do with the quenching distance, discussed in Chapter 4—the porous material effectively acts as a flame arrester. With sufficient material being consumed, this may no longer be true and flaming ignition can occur inside the cavity. The topic of transition from smoldering to flaming is discussed in Chapter 7.

The aftermath of a spontaneous combustion fire can have some surprising features. One aspect may be the presence of multiple 'chimneys' of burned material; these tend to follow paths of least air resistance[75]. Another is that virgin material may remain unburned at the lowest level of the origin of the fire; this is due to poor access of oxygen downward into the material.

EFFECTS OF DIFFERENT VARIABLES ON SELF-HEATING

In the theory sections, the primary variables influencing self-heating were developed on a quantitative basis. Here we examine the effects from a simple qualitative viewpoint, and also provide experimental data, where available, to guide the individual making an application to fire incidents. Additional variables are considered in the Section *Oven-basket tests: FRS method*.

CHEMICAL AND PHYSICAL NATURE OF THE SUBSTANCE

These factors cannot be controlled by the user, but they may be controllable by the maker of the material. The effects can be determined by referring to the basic equation for the non-dimensional heat release rate:

$$\delta = \frac{E}{RT_o^2}\frac{r^2 \rho Q A}{\lambda} e^{-E/RT_o}$$

Thus, lowering the heat of reaction Q or raising the thermal conductivity λ of the substance will decrease the self-heating tendency. Also, any changes which lower the reactivity of the substance (lowering the pre-exponential factor A, or raising the activation energy E) will reduce the self-heating tendency. The activation energy effect is dominated by the exponential factor.

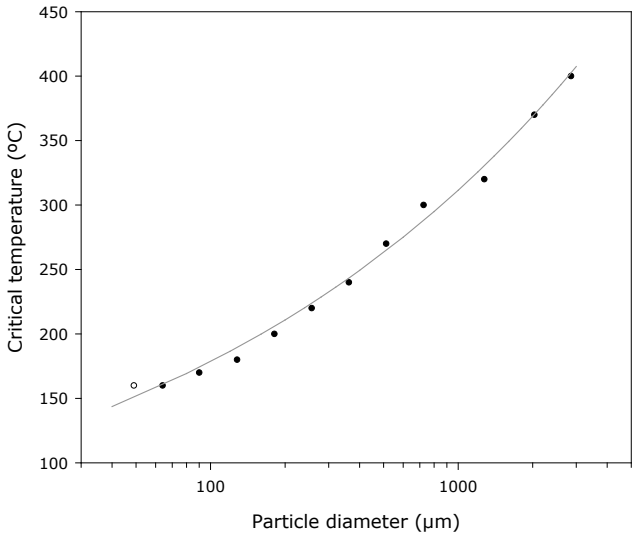

Figure 21 Effect of particle size on hotplate critical temperature for Pittsburgh coal dust

PILE SIZE AND SHAPE, AND POROSITY OF THE SUBSTANCE

The larger the pile of substance, the less efficient is the cooling from the ambient environment, which can only occur at the edges. The heat generation is proportional to the volume of the substance, while the amount of cooling is proportional to the exposed surface area. Thus, the propensity to self-heat is proportional to the volume/surface ratio V/S. This ratio is the highest for the most compact possible body shape, a sphere. It is progressively lower for various elongated shapes, such as a thin, long layer of material.

The most common solids which exhibit self-heating problems are porous materials. Thus, porosity clearly may come into play. In the basic F-K theory, porosity is not a factor, since its primary effect relates to inflow of oxygen and the theory assumes there are no reaction limits due to oxygen insufficiency. Higher-order effects, however, can come into play. Moisture uptake, which can be significant under some circumstances, is affected by porosity, as are surface reactions of various kinds. Materials may change their porosity as chemical reactions take place. Wood is a good example of this. The porosity of virgin whole wood is very small.

This limits the amount of oxygen that can be made available for self-heating, but self-heating nonetheless can proceed, albeit slowly. As oxidation further progresses, the material becomes more porous and oxygen availability becomes greater. No theory is available to treat such a 'self-modifying' substance, but some experimental data are cited under *Wood* in Chapter 14.

PARTICLE SIZE

If the chemical reaction occurred on the surface of the particles (heterogeneous reaction), then particle size would be the most critical variable. F-K theory assumes the opposite extreme, that the reaction occurs evenly dispersed through the volume (homogeneous reaction). The latter assumption appears to be well suited to most substances. But there are exceptions. Coal particles are largely impervious and unreactive except at the surface. Thus, it is not surprising that coal dust tests show a particle size dependence. In testing Pittsburgh coal in a hotplate test, Nagy and Verakis[92] found a strong influence of particle size. Figure 21 shows that the relation was found:

$$T_h = 7.8 + 54\, d^{1/4}$$

where T_h = critical hotplate temperature (ºC) and d = particle diameter (μm). Akgün and Arisoy[82] reviewed a number of other studies on the effect for coal and conducted tests of their own. They concluded that the HRR can be represented as:

$$\dot{Q} \propto Y_{O_2} d^n$$

namely that it depends linearly on the oxygen mole fraction and to a fractional power on the particle diameter d. Their results showed that n itself was temperature-dependent, going from –0.33 at 25ºC up to –0.74 at 75ºC, but this partial expression did not lead to a full calculational method. Their literature review indicated that no diameter effect is present when the particles are very small, but there is wide disagreement as to the limit for this regime (ranging from 0.05 to 5 mm).

Even less data exist for other substances. Demidov[83] reports that in one series of experiments, sulfur pyrite showed a $T_c \approx 400$ºC for various particle sizes > 0.10 mm, but the value dropped to 340ºC for a particle size of 0.086 mm. For wood-bark chips, the size of the particles was found not to affect the self-heating behavior[84].

TEMPERATURE

The cooler the ambient air is, the more effective is the cooling. Thus, a pile of substance which may be stored without reaching critical conditions in the winter may undergo spontaneous combustion in the summer. Similarly, self-heating tendencies are exacerbated if the material is originally stored at an elevated temperature, instead of at ambient temperature.

A factor which should not be overlooked for outdoor storage is *solar heating*. On a clear day, solar heating radiant flux may approach 1 kW m^{-2}, and this is not insignificant. If solar heating is expected to be a factor, numerical evaluation schemes need to be used, since boundary conditions involving natural convection cooling and an external radiant flux are not amenable to closed-form solutions.

TIME OF STORAGE

If conditions for a substance (size, temperature, cooling, etc.) are such that it is sub-critical, then indefinite storage time may be acceptable*. Otherwise, the time to inception of high heating rates—which occurs before the actual point of runaway—must be greater than the storage time. From heat transfer principles, the ignition time may be expected to scale with the size r and the thermal diffusivity α as:

$$t_{ig} \propto \frac{r^2}{\alpha}$$

In practice, the exponent is not necessarily identical to 2, so correlations of the form

$$t_{ig} = b r^n$$

should be sought, where the constants b and n are determined from the data fit. Read et al.[85] recommend a similar form of correlation:

$$t_{ig} \propto \left(\frac{r^2}{\alpha} \right)^{2/3}$$

For practical purposes, Bowes[10] points out that if a series of experimental data is available, extrapolations may be simply made since a plot of r versus t_{ig} will usually produce straight lines on a log-log scale. Or, volume can be used, as shown by the data of Leuschke[86] in Figure 22. A plot of this type is based on test data where each data point was obtained at a different temperature: the minimum temperature needed to exhibit criticality for the particular size being tested. Thus, it can only be used to extrapolate criticality times for just-critical conditions. If the storage temperature is greater than the critical temperature, then the allowable time will be shorter.

In many practical cases, it may be more relevant to plot the time to criticality at a fixed ambient temperature, rather than at the critical one. Such data obtained from a finite-element model of the self-heating of milk powder[87] are shown in Figure 23. The data appear to have a sigmoid shape rather than following a straight line. Thus, extrapolation should not be done and interpolation must be done cautiously.

ACCESS OF AIR

Many—but not all—substances prone to self-heating need oxygen for the chemical reaction to occur. Any conditions which limit oxygen access to the material can, therefore, reduce the self-heating tendency. For example, air infiltra-

* Some substances, e.g., certain agricultural products, may be ruined due to elevated temperatures, even without thermal runaway.

tion into porous substances can be greatly reduced by wrapping them in plastic film (but note that plastic films differ widely in their permeability to air). A more subtle variation of this effect is observed for substances such as linseed-oil soaked rags. It is possible to saturate rags with such a high amount of oil that air is effectively blocked from flowing in. Thus, if one keeps adding linseed oil to a pile of rags, the self-heating propensity will first increase (because the heat of reaction per unit volume is being raised, due to the increased amount of oil), but then with further addition the propensity will start to drop due to difficulties being created for oxygen diffusion.

In most cases of self-heating, air will be pulled through the material by diffusion and natural convection. But air can also be moved through the material by forced ventilation. Apart from allowing oxidation reactions to contribute heat, moving air through the material has an opposite effect also, in that it carries away heat. Thus, especially if a forced ventilation is established, it is not necessarily evident whether air movement will increase or decrease self-heating. A few experiments have been described on this effect. Bowes[88] used a modified Mackey apparatus, where he tested jute fibers soaked in linseed oil. An optimum air flow rate, as defined by the maximum temperature achieved, was found. Gibson et al.[89] reported statistical results from tests on a series of unidentified industrial powders where they conducted self-heating tests with and without forced air movement through the material. Both positive and negative results were obtained, but there were more specimens for which blowing air through the material led to a temperature increase. Neither of these studies led to any systematic guidance and the user will have to tackle the problem experimentally if air movement through the material is considered to be of possible importance.

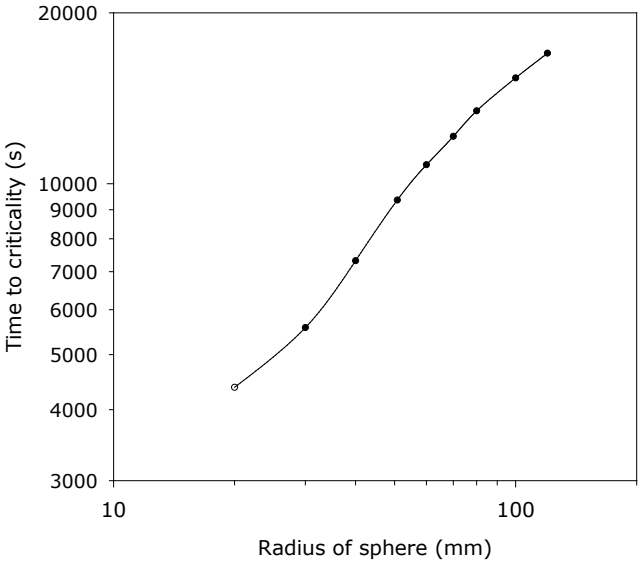

Figure 23 Times to criticality for milk powder spheres of various radii placed in an environment at 195ºC

OXYGEN CONCENTRATION

In addition to the theory refinement which considers limitation of oxygen diffusion, a related effect can be considered: the value of the oxygen concentration for systems not at 21% oxygen. The effects of oxygen concentration are primarily two: (1) lowering the oxygen concentration lowers the HRR of the reaction; and (2) lowered O_2 concentration serves to raise the effective value of δ_c. The value of E is unchanged by changing the oxygen concentration, however.

Bowes and Thomas[30] conducted oven experiments on cubes of wood sawdust at various oxygen concentrations. With the material properties of sawdust having been characterized, they concluded that at an oxygen concentration of 4%, the value of δ_c is raised by 9% over its value in ambient air. In view of general uncertainties of such experiments, this increase can readily be ignored. The effect of oxygen concentration on the heat release rate, however, is noteworthy. In their studies, they observed that the reaction rate should include the factor c_o^n. A value of $n \approx 2/3$ was found for substances as diverse as foodstuffs and coal[90], suggesting that this value has a certain generality. Thus, changing the concentration from 21% to 4% causes a decrease in the reaction rate to $(4/21)^{2/3} = 0.33$ of its ambient-air value. In the standard plot of oven-basket test results (see below), when oxygen concentration is changed only the value of P changes; the slope remains constant since E does not change. Other authors, however, have reported different values for n. Zimbardi[91] examined a variety of powdered agricultural materials and concluded that $n = ½$, irrespective of botanical details. In simple empirical hotplate testing of coal dust, Nagy and Verakis[92] found that over the oxygen concentration range 11.5 –

100%, the critical temperature stayed at 160 – 170ºC, implying that $n \approx 0$ over this range. Below 11.5%, the critical temperature rose sharply, reaching 250ºC for 9.7% oxygen. Conversely, Akgün and Arisoy[82] concluded that, for coal dust, $n = 1.0$.

Bowes[10] concludes that for typical organic substances which show $n \approx 2/3$ and have values of E/RT that are not unusually low, the effect of oxygen concentration on the value of δ_c will be negligibly small and that use of standard values will normally suffice. Thus, for example, in the case of a slab $\delta_c = 0.88$ is taken and use of Figure 10 is not necessary. Under those circumstances, the beneficial effects of partial-inerting can readily be calculated since then $\delta_c \propto c_o^{2/3} r^2$ and consequently the critical value of r varies as $c_o^{-1/3}$. For example if at a given temperature the maximum sub-critical size of a cubical pile of material at 21% O_2 is 1 m, then if inerted down to 5% O_2, and all else remains the same in the expression for δ_c, the critical size will increase to $1.0(0.21/0.05)^{1/3} = 1.63$ m. Care should be taken in extending this arithmetic down to very low values of oxygen concentration, however, since not all organic substances will be devoid of exothermic peaks at zero-oxygen conditions.

INSULATION

A substance prone to self-heating will have this tendency exacerbated if it is wrapped in any form of thermal insulation, since this will diminish the cooling available at the edges. In some cases, the substance may be wrapped in something which both provides thermal insulation and restricts the access of air. In such cases, the analysis is not simple, since the two effects are in opposite directions.

MULTIPLE PACKING

In many cases, self-heating goods are packed into boxes, drums, etc., but the package is not exposed in open air. Instead, multiple units of the package are packed into a larger container, e.g., an intermodal shipping container. Any particular package is obviously receiving poorer cooling at the boundaries because (a) the heat transfer coefficient is likely to be lower when inside an environment where convective flows are interfered with; and (b) the air circulating past one package has already been preheated by another. This problem is only beginning to see some study. Gray[93] proposed that the effective Biot number for such packages be derived as:

$$Bi' = \frac{Bi}{1 + nsh/SH}$$

where Bi' = effective Biot number, Bi = Biot number for a single package in well-stirred air, n = number of packages, s = surface area of each package, h = heat transfer coefficient for a single package, S = surface area of outside container, H = heat transfer of outside container. Gray also developed a more evolved theory[94] which led to the conclusion that thermal runaway will occur if the number of packages n inside the container exceed a certain value:

$$n \geq \frac{SH}{sh}\left\{\frac{shR}{vEQA}u^2 \exp\left[1/u(1+u)\right] - 1\right\}$$

where $u = RT_o/E$, v = volume of each package, T_o = ambient temperature.

MOISTURE AND RAIN

Moisture has an influence on the self-heating of most granular materials. For piles not sealed against air flow, there will be convective and diffusion moisture flows. These can be in or out, depending on the relation of the moisture inside the pile versus that in the environment. In addition, piles of self-heating material such as coal may be stored outdoors. In such case, they may be subject to periodic rains and undergo wetting/drying cycles with large moisture fluctuations. Rain falling on haystacks has been known to cause rapid self-heating; this is discussed in Chapter 14.

The main effects of moisture on self-heating fall into three groups:

(1) the effect of moisture in raising the thermal conductivity λ of the material;
(2) the direct effects of heat loss/gain due to evaporation/condensation of water; and
(3) any chemical or biological reactions which are water-dependent.

Walker[95] examined these effects in some detail and presented extensive historical information. In the theory of self-heating, λ enters into the expressions for both δ and Bi. While expressions exist for the moisture contribution to λ under precisely-specified conditions, a simple correction cannot be included in self-heating computations, because of the gradients of moisture and temperature that exist within the material. For materials such as wet wood chips, the effect of moisture on thermal conductivity is enormous[96]. Moisture effects can be very pronounced in the range 60 – 90ºC, but once the temperatures exceed 100ºC, moisture contribution to self-heating may not be significant. Thus, oven-basket tests, which, due to size limitations, are almost always run at temperatures over 100ºC, can only capture the behavior of a dry specimen in a dry atmosphere. Even apart from this issue, Gray and Wake[97] have demonstrated that scaling does not apply to criticalities induced by wetting. In other words, samples smaller than a certain size will be unconditionally stable against wetting-induced ignition, while larger ones may not.

Heat loss/gain due to evaporation/condensation of water will have the opposite effect depending on whether a hygroscopic material is initially dry or moist. If it is initially at a moisture content which is equilibrated to the RH of the environment, and then is aggregated into large piles which can self-heat, the main effect of the moisture will be an endothermic evaporation term as self-heating proceeds to raise the temperature. This endothermic effect will serve to

delay the self-heating process. Using a computational model, Chong and Chen[98] showed that even a small amount (3% MC) can lead to large delays in time to criticality. McIntosh[99] analyzed some additional features of the problem. He discovered that, depending on the heating regime, conditions can occur whereby vapor is condensing in certain regions of the sample—this would add to the heat evolution.

If the material is originally dry, however, and is then introduced into a moist atmosphere, the chemical self-heating will be augmented by the exothermicity associated with moisture uptake. This heating involves two contributions: (1) the heat of condensation, and (2) the heat of sorption of liquid water. The heat of condensation is sizeable, varying from 2443 kJ kg^{-1} at 20ºC to 2265 kJ kg^{-1} at 100ºC. This is the heat which is released upon converting an amount of water vapor to liquid water at the same temperature. The heat of sorption is the heat which is released when free water at a given temperature becomes sorbed onto the surface of a solid. The heat of sorption is not a constant, but depends both on the substance and on its pre-existing moisture content. For wood materials, it has a value of 1170 kJ kg^{-1} *of water* for completely dry material. But for a material with 8% moisture content, it drops to about 15% of its dry-substance value. If wood is taken from an oven-dry to a fiber-saturated condition, then the amount of heat gained can also be expressed as being 78 kJ *per kg of wood*. Back[100] calculated that if a wood product originally at 5% moisture content were raised to 9.5% moisture under adiabatic conditions, its temperature would rise from 20ºC to 100ºC due solely to the exothermicity of the moisture uptake process. But Hallström and Werling[101] pointed out that Back did not properly account for the sorption isotherm of wood and, if that is done, the temperature will only rise to a maximum of 34ºC under adiabatic conditions, and to a much smaller value if heat losses are included. Real products, of course, are not stored under adiabatic conditions, but Back provides some details of several cases where such self-heating is said to have led to smoldering or charring. This included dry wood fiberboard which ignited a day to a week after being produced and then stored in a high humidity area. This was also observed with rolls of freshly produced cardboard. What Back's analysis apparently overlooks is that the material was not cooled before being stored. If its internal temperature was significantly above ambient, then the self-heating will directly correspond to a 'hot work' problem, and will not necessarily reflect any moisture problems.

Coal is another substance whose self-heating can be affected by moisture. The heat of sorption has also been measured for coal[102] and it is smaller than for wood, being 670 kJ kg^{-1} of water at 0% MC. Introducing completely dry coal dust into an atmosphere at 65% RH will lead to a temperature increase of 2.5ºC. McIntosh[103] considers that moisture is, overall, favorable to avoiding runaway self-heating of coals, and that about 8% water, by weight, would be adequate to prevent it. Complicating testing and analysis somewhat is the observation[104] that, in certain circumstances where significant moisture is present, self-heating to ignition can occur in a substance which has been showing a temperature *decrease* up to a certain point. With exceedingly moist coals, significant problems were noted in analyzing oven-basket test data[105]. These results for coal suggest a relatively modest effect, but one study found a very large effect for coke; this work is discussed in Chapter 14 under *Charcoal, coke and activated carbon*.

Chen and Wake[106] developed a simplified theory for estimating the effect of the RH of the environment on self-heating of a wet, porous material, when hydrolysis or other chemical reactions involving moisture are not present. They suggest that an RH-modified value of δ_c be used, to be computed as:

$$\delta_c^* = \delta_c \exp\left[- RH \frac{E}{RT_o^2} \frac{Q_L \varepsilon D_w C_{w,sa}}{\lambda} \right]$$

where δ_c^* = the RH-modified value of δ_c; RH = relative humidity (on a 0 to 1 scale); Q_L = latent heat of condensation = 2443 kJ kg^{-1}; ε = porosity (--); D_w = diffusion coefficient of water vapor in gas stream = 0.25×10^{-4} m^2 s^{-1}; and $C_{w,sa}$ = density of water vapor in saturated gas ≈ 0.173 kg m^{-3}. Use of this correction factor lowers the value of δ_c, in other words it shows thermal runaway occurring at a lower ambient temperature. The correction is intended to give only a conservative bound, not an exact answer, since the time-varying moisture remaining in the material is not modeled. Physically, Chen and Wake explain the reduction in temperature as occurring since a high ambient RH will reduce the driving force available for drying, and consequently reduce the dissipation into the environment of the heat generated by oxidation. McIntosh et al.[107] gave solutions for the time-dependent heating, but these did not lead to any simple equation. Chong et al.[98] developed another numerical model for self-heating which includes the effects of moisture.

Chemical and biological effects from moisture are only seen with certain classes of products, but these can dominate the self-heating behavior for that type of substance. The most detailed example which has been studied is hay, as presented in Chapter 14. Gray et al.[20] discussed moisture problems in connection with the self-heating of bagasse and pointed out that moisture makes possible hydrolysis reactions, which is precluded if the material is fully desiccated. Their studies are presented in Chapter 14 under *Bagasse*. In general, the effect of moisture on self-heating may be very complicated and simple treatments may be insufficient. Gray[108] has presented a theory which includes a moisture-dependent reaction, in addition to an oxidation reaction. Its results show that regimes with oscillations and other complex behavior will occur under certain combinations of problem conditions.

DENSITY

Increasing the density of a porous, self-heating material will increase the amount of substance available to chemically react, per given volume. Thus, this will increase the reaction. Noting that

$$\delta_c = \frac{E}{RT_o^2}\frac{r_c^2 \rho Q A}{\lambda} e^{-E/RT_o}$$

it is evident that increasing ρ decreases the critical size r_c, and vice versa. Thus, if data were obtained at a density ρ_1 and now it is desired to compute the critical size for material of density ρ_2, the relation is:

$$r_2 = r_1\sqrt{\frac{\rho_1}{\rho_2}}$$

This is illustrated in Figure 24 by some old and only semi-quantitative data on wood fiberboard and jute[109]. Also shown are some experimental data on linseed-oil soaked jute[10], tested in the Mackey test. At high densities, it also follows the same trend; for lower densities, there is an opposite trend, details of which have not been modeled. Data on coal dust were published by Hardy[110]. His data showed a density/thickness interrelation: raising the density always lowered the critical temperature, but the effect was sizeable only for very small layer thicknesses (3 – 6 mm); for 12 mm layers, the density effect became minimal.

With moist substances susceptible to microbial heating, increased density decreases ventilation, diminishes the rate of drying, and thereby can increase the rate of self-heating. This was observed by Frandsen for wood-waste-chip piles[111]. Quantification or modeling is not easy for situations involving both chemical and microbial heating, however.

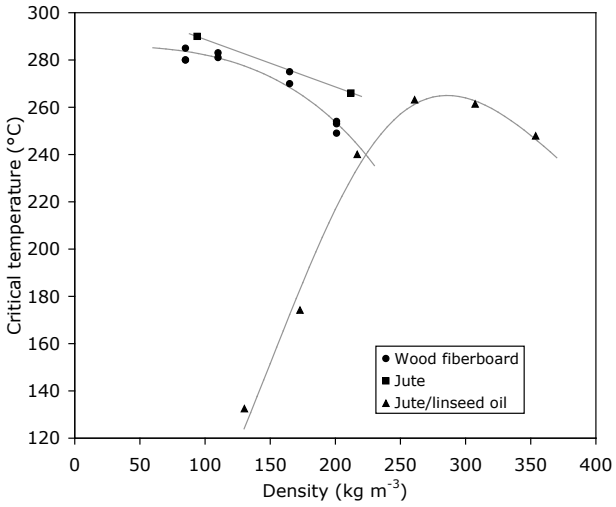

Figure 24 Effect of density of the critical ambient temperature for several materials

ANTIOXIDANTS

Some substances (e.g., foodstuffs, polymers) are formulated with antioxidants. A wide variety of chemicals (e.g., phenols, amines) can serve this role. These will effectively suppress oxidative self-heating, but only until the antioxidant is used up. This effect can be seen in oven heating tests[112]. Figure 25 shows a thermal arrest period t_b during which the antioxidant is being consumed. Oven temperature #1 was slightly below the critical temperature for the given size of sample and criticality did not occur. Oven temperature #2 was slightly above the critical temperature, but an accelerating rise towards criticality did not occur until the time that the antioxidant was used up.

An antioxidant is consumed with the passing of time and eventually offers no protection. Thus, it may be necessary to estimate the duration of time during which protection will remain available. Beever[113] suggests that the following procedure be used. For oven baskets tested at various temperatures, plot $\ln(t_b)$ as a function of $1/T_o$. The data points should fall onto a straight line. Extrapolate to the temperature T_o at which storage is to be done. This will give the approximate length of time for which the antioxidant will remain effective. If additives against deleterious reactions involving more than just oxidation are employed, the broader term *stabilizers* is used. The effect of stabilizers on explosives is discussed in Chapter 10.

CONTAMINANTS

Although the topic has received only minimal study, there are substances which increase the self-heating reactivity of different substrate materials, if introduced as a contaminant. Among compounds which have been identified as playing that role for various substrates (see Chapter 14) are fatty acids and vegetable oils, iron, iron oxides, iron sulfides, cobalt, copper, magnesium, manganese, lead carbonate, potassium carbonate, lead acetate, sodium acetate, and vanadium pentoxide. Consequently, results of testing on specimens, whether small-scale or real-scale, will not be properly indicative of product behavior if criticality in a particular case occurred due to contamination and exemplars are test-

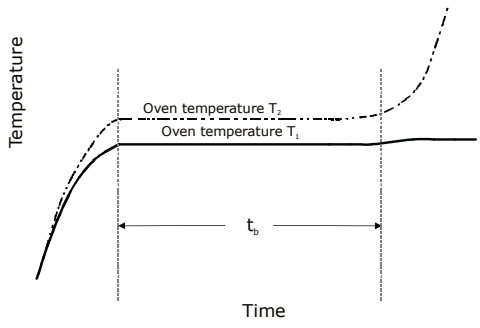

Figure 25 Oven heating results for specimen with antioxidant

ed that are uncontaminated. A case is described in Chapter 14 under *Paper* where a roll of sealed paper towels was found smoldering in the storeroom of a government laboratory. An uncontaminated product would have required an enormously larger volume for critically to occur, and the investigation determined that the product had become contaminated either in manufacture or in packaging.

MULTIPLE-COMPONENT SUBSTANCES

In the common case of the self-heating of linseed-oil soaked cloth, there are two components to consider: the oil and the cloth. Neither a 0% nor a 100% fraction of oil will constitute the worst-case condition. By itself, cotton cloth shows negligible exothermicity compared to linseed oil, so cloth alone would not be the worst case. Oil, however, is not porous if in bulk, so the 100% condition is also reasonably benign. Somewhere in between the worst case condition can be found. A ratio of approximately 1 part oil (by mass) to 1 part cloth is found to be the worst case.

If a large pile is assembled of a material which has two components, each moderately exothermic, then a two-component system has to be considered. An example is sawdust coated with an oil of modest self-heating propensity, which was studied by Bowes[44]. By running oxygen consumption experiments on control samples comprising oil on an inorganic substrate, he was able to demonstrate that the oxidation of the two components is not additive. Both make a positive contribution, but the wood additionally acts as an antioxidant for the oil, with the oil not contributing as much (on top of the wood's contribution) as it would on an inorganic substrate. This he considered to be plausible chemically in terms of what is known of the chemical constituents of wood. No general procedures for such cases are available and, if needed, research would have to be done on the specific system.

IGNITION OF DUST LAYERS

A common problem in many industrial installations is the ignition of dust layers which have accumulated on a hot surface. This usually occurs as a self-heating process. The theory to be used for analysis is the unsymmetric slab problem, presented above. Testing to determine the material properties can be done by any of the tests suitable for engineering determination of self-heating properties. In addition, hotplate tests are sometimes recommended on the grounds that their results can be used without recourse to theory.

Defining the actual ignition event is not necessarily trivial, since the process starts at the hidden surface. Bowes[10] considers the ignition to have occurred when at least one of the following has been observed:

- visible evidence of flaming or glowing in the layer
- melting of the dust layer
- a temperature rise of 50ºC above the hot surface temperature.

A *layer ignition temperature* (LIT) is commonly defined as being the lowest temperature of the hot surface that can cause an ignition according to the above requirements. Some results[10,114] of hotplate tests on several types of dust layers are given in Table 12. Additional data[115] are shown in Table 13 and in Figure 33.

Table 12 Results of some dust layer ignition tests conducted by Bowes

Layer depth (mm)	Ignition temperature (ºC)			
	Beech sawdust	Coal	Cork	Lycopodium
5	350	235	350	283
10	315	205	315	261
20	285	173	280	217

Table 13 Results of some dust layer ignition tests conducted by the Bureau of Mines

Pittsburgh coal		Brass	
Layer depth (mm)	Ignition temp. (ºC)	Layer depth (mm)	Ignition temp. (ºC)
6.5	310	13.3	160
10	265	26.7	140
12.7	240	40	135
25.4	210		

Some additional data on dust layer self-heating ignitions were reported by Reddy et al.[116] They examined Pittsburgh coal, Prince coal and sodium dithionite ($Na_2S_2O_4$). The latter is an interesting material since its exotherm does not require the presence of oxygen. They obtained values of E and QA from hotplate experiments by developing a computer program for the data analysis. From the hotplate tests and additional experiments, the material properties were found to be as shown in Table 15. Note that in the case of sodium dithionite, the Arrhenius-kinetics parameters are, in fact, a poor representation of the actual reaction that takes place, as was shown in detail by Tyler and Henderson[51].

In some cases, the physical condition may be better represented by a surface through which there is a constant power flow into the porous material, rather than there being a hot surface of a fixed temperature. A closed-form solution is not available, but Hensel et al.[117] presented 1-dimensional finite element computations for coal dust and cork dust under such conditions. A heat flux of ca. 0.18 kW m^{-2} was

Table 14 Results for reactive hot spot ignitions

Substance	Bulk density (kg m^{-3})	Min. dia. of hot spot (mm)
cork dust (< 100 μm)	59	19-24
cork dust (500-3000 μm)	171	40
beech wood dust (<400 μm)	382	34
cocoa powder (<40 μm)	369	15

found necessary to cause thermal runaway of a 50 mm thick layer, 0.46 kW m^{-2} for a 25 mm layer, and 1.5 kW m^{-2} for a 10 mm layer. Such values are rather low and might readily be found near motors or heat-producing equipment.

There is no theoretical treatment of induction times for ignition of an unsymmetrically heated slab. Thus, apart from fully-numerical solution strategies[118], it is appropriate to use a data-fit extrapolation as described above.

ELECTRICAL HEATING PROBLEMS

An interesting special case is the deposition of a layer of dust on electric *power cables*. Gray et al.[119] showed that ignition can occur due to two separate phenomena: (1) a non-combustible dust simply acts as insulator and prevents the effective cooling of the wire by convection; this can lead to overheating, melting, or ignition of the wire insulation. (2) If the dust is combustible, the dust layer itself can ignite. Gray showed that formulation of the problem is not particularly difficult, but solutions have to be obtained numerically and these are complicated by the presence of a large number of independent variables. In addition to the variables present in all self-heating problems, this problem adds:

- wire insulation thickness
- electric current
- electric resistance of the copper conductor
- thermal conductivity of copper
- thermal conductivity of the wire insulation.

The authors provided a table giving solutions for selected values of the problem parameters. They also calculated an example case showing that an 0.15 m dust layer thickness can suffice for thermal runaway, given some reasonable problem parameters. They also showed an example of the insulation effect for a wire carrying 14 A. With no dust, the temperature rise was 36ºC; with a dust layer thickness equal to the wire insulation thickness, 77ºC; and with a dust layer thickness of 9× the wire insulation thickness, 300ºC. The latter condition would likely suffice to short out a cable, if not to ignite it. Similar calculations were reported by Dong and Yang[120].

The case of asymmetric accumulation of dust has also been studied[121]. It was shown that, provided the thermal conductivity of the dust is much smaller than that of the cable, the asymmetric case is more conservative than the symmetric, thus, the symmetric results can be used to develop an upper bound.

Another type of electrical heating problem is an electrically heated hot spot (sphere) inserted into a body of smolderable material. Brindley et al.[122] formulated a problem where an electrically heated sphere of radius r_o is embedded at the center of a sphere of granular material having a radius r_1. The problem has no closed-form approximations, so they provided some example calculations using a numerical solution. The problem turned out, at least using a first-order theory, to have an unusual trait. Over a certain range of r_o values, there were multiple zones of stability and runaway, when plotting electric input power as a function of r_o. Validation was not undertaken, so it is not clear if this multiple-zone behavior is real or an artifact of the theory. Nelson[123] considered the same problem and used a purely numerical solution of theory, accompanied by validation experiments. His modeling indicated that:

- r_o – raising it greatly increases the required power, but does not change the surface temperature of the hot spot needed for criticality
- r_1 – changing it has a very small effect on required power
- thermal conductivity – raising it produces a near-linear increase in required power
- heat capacity – no effect
- activation energy – raising it produces a near-linear increase in required power
- heat of reaction – raising it gives a hyperbolic decrease in required power
- ambient temperature – raising it causes a decrease in required power, but the effect is not as large as when raising thermal conductivity or activation energy

Experiments did not support the first of the theoretical predictions and indicated, instead, that the power needed to achieve criticality is roughly independent of r_o. The effects of r_1 and of ambient temperature were found to be broadly consistent with theoretical calculations; other predictions were not investigated experimentally.

HOT SPOTS

Self-heating due to hot spots has only rarely been measured experimentally, thus in this Section we discuss some available results. Krause and Schmidt[124,125] reported data on hot-spot ignitions of cork dust, beech wood powder, and cocoa powder. For an inert hot spot, they used porcelain spheres of various diameter and initial temperatures. The powder was held in a 6 – 12 L cylindrical basket which was always originally at room temperature. For a 25 mm diameter sphere placed in cork dust, a minimum initial temperature of 496ºC was needed to initiate self-sustained smoldering. Larger spheres required lower temperatures: 454ºC for 35 mm, and 427ºC for 40 mm. Sphere size notwithstanding, however, a minimum ignition temperature of 400ºC was observed. Using a 30 mm sphere in beech dust, an initial temperature of 550ºC was needed.

Table 15 Self-heating data for some dust layers

Material	***E*** (kJ mol^{-1})	***Q*** (kJ mol^{-1})	***A*** (s^{-1})	***QA*** (W kg^{-1})
Pittsburgh coal	65.4	N.A.	N.A.	3.04×10^{9}
Prince coal	95.7	N.A.	N.A.	7.0×10^{12}
$Na_2S_2O_4$	177	78.5	2.70×10^{16}	7.7×10^{22}

In a parallel experiment, they buried a 25 W rated electric heating coil in the center of an 0.8 L volume of fine cork dust. The coil produced a surface temperature of ca. 600ºC. They found that a minimum heating time of 5 min, in other words, 7.5 kJ of energy, was needed to cause sustained ignition of the whole volume.

The authors also explored the effect of a reactive hot spot (their term is a 'glowing nest'), wherein a preheated small cubical wire basket of the same substance was inserted into the center of the ambient-temperature specimen. The initial temperature of such a reactive hot spot could not be experimentally varied, they discovered. This is because the smoldering body assumes a characteristic smoldering temperature which is a trait of the material itself. The results for the minimum hot spot diameter needed to cause continuing self-heating of the bulk substance are given in Table 14.

The authors explored the effect of varying the size of the bulk, ambient-temperature specimen into which the hot spot was plunged, but over the range of 6 to 50 L the effects were not pronounced. A very small container of 0.8 L, however, led to substantially greater hot spot diameters being needed for sustained propagation.

Once ignited, the characteristic smolder front temperature varied with both the dust type and the volume of the cylinder. For a 12 L cylinder, fine cork dust showed a temperature of ca. 355ºC, while cocoa powder showed ca. 280ºC, with the other substances giving intermediate values. A 1.5 L cylinder of fine cork dust showed 375ºC, while a 200 L cylinder gave 310ºC. The authors attributed the size effect due to oxygen depletion; this was verified in one experiment.

SELF-HEATING IN LIQUIDS

Self-heating in liquids is treated in detail in Chapter 10, where reliance is placed primarily on Semenov theory. A few studies have been made using an adaptation of Frank-Kamenetskii theory, and we consider one of these here. Liquids differ from the porous solids that have more commonly been the subject of self-heating studies in that the bulk material can be subject to convective currents. In a detailed numerical study of a vertical cylindrical tank, Sheu et al.[126] found that, in addition to δ, the Rayleigh number Ra needs to be taken into account to determine limits of stable regimes. For this problem, they define

$$Ra = \frac{gH^3RT_o}{\alpha\nu E}$$

where g = gravitational acceleration (9.91 m s^{-2}), H = height (m), R = universal gas constant (8.314 J mol^{-1} K^{-1}), T_o = initial temperature (K), α = thermal diffusivity (m^2 s^{-1}), ν = kinematic viscosity (m^2 s^{-1}), and E = activation energy (J mol^{-1}). Solving a cylinder with $H = r$, they found that $\delta \approx 5.4$ for Ra = 0, that is, if the fluid cannot move due to buoyancy. As buoyant effects increase, however, the system is stabilized, and $\delta \approx 17$ for Ra = 150,000. For all greater values of the Rayleigh number, however, three regimes become possible: steady stable, stable oscillatory, and thermal explosion. The limits of the steady stable regime shrink for large Ra numbers, going down to $\delta \approx 10$ at Ra = 500,000. Thus, the conclusion is that by ignoring possible buoyancy effects, a conservative prediction value will be obtained. Shtessel et al.[127] also investigated the problem by numerical computation. Their recommendation was to use an internal-convection-modified value δ_c^* which is obtained as:

$$\delta_c^* = \delta_c\left(1+\frac{0.062Ra^{4/3}}{11{,}000+Ra}\right)$$

LIQUID-SOAKED POROUS SOLIDS

In industrial environments, it is common for a liquid to leak and to soak into pipe insulation, for instance, mineral wool (rock wool). There has been at least one disastrous large fire[128] due to self-heating ignition of ethylene oxide soaked insulation (also known as *thermal lagging*). More common, but less spectacular, fires have occurred on ships when diesel fuel permeated porous insulation. The self-heating problem is similar to that in solids, with the exothermicity being oxidation of the liquid. A number of experimental studies were conducted by Bowes[29]. Two different types of experiments were made: oven-basket tests, and tests in a pipe simulator, where a heated pipe was covered with insulation and raised to various temperatures. To apply the results, Bowes endeavored to use conventional self-heating theory. According to his procedure, one first determines E and P from the oven-basket tests. Next, to apply the theoretical treatment pertinent to the hollow infinite cylinder (p. 383) a value of the outer surface temperature is estimated from:

$$T_s = \frac{hT_o + \dfrac{\lambda}{b\ln(b/a)}T_h}{h+\dfrac{\lambda}{b\ln(b/a)}}$$

This allows θ_s to be determined. Knowing θ_s and z_s (= b/a) the theory gives the value of δ_c^*. Then, using the definition of δ^* one determines whether thermal runaway is expected to occur, depending on whether $\delta^* \geq \delta_c^*$.

Bowes' treatment ignores the evaporation of the liquid. But evaporation is an important process, and it shows up both in the energy balance (as an endothermic contribution) and as a depletion of reactant. Evaporating substances do not behave in a way treatable by F-K theory, since initially there is a time period where no appreciable heating occurs and the main manifestation is evaporation of the liquid. When oven-cube tests are conducted, a long time period is observed during which the sample's temperature shows a steady-state plateau value which is below the oven temperature and does not forebode thermal runaway[129]. Yet thermal runaway can occur later on, and can occur quickly. A theory has been developed by McIntosh et al.[130-133] which takes these additional effects into account. The theory is mathe-

matically complex, even with numerous simplifications of physics. The systems are complex partly because it is not sufficient to consider whether an ultimate steady state is achievable. Conditions exist where calculations would indicate a steady (no thermal runaway) ultimate state, yet the transient temperature behavior earlier is one which is basically an ignition. Matters are also complicated because oxygen availability is poor, especially in the early stages of heating, and diffusion of oxygen needs to be explicitly taken into account[134]. The authors conducted oven-basket experiments with a series of alcohols (C_6 to C_{11}) soaked into cubes of insulation and noted that it was possible to get each one of the alcohols tested to self-heat. They did not report a procedure whereby experimental test results could be used to make calculations based on their theory. The procedure would need to be more complex than Bowes', since additional Arrhenius terms are used in their model to express the evaporation process, and constants for these terms would also need to be obtained. In a later study[135] they considered the limiting case where there is so much liquid that it covers all of the fibers. In that case, the amount of liquid is no longer a problem variable. Even the simpler problem did not have closed-form solutions, but the authors noted that such a system can behave in a deceptive way. Under some conditions, the system may start showing a temperature drop, even though it is super-critical and a while later temperatures will again increase and go towards thermal runaway.

It was also noted that, under some circumstances, ignition within thermal insulation can occur as the autoignition of the liquid's vapor within the void spaces. McIntosh et al.[136] considered here the case where the fibers are fully soaked in liquid (so the amount of liquid does not matter) and determined that a critical size exists for the assembly beyond which vapor ignition is predicted. They express the maximum safe size as a critical volume/surface ratio, so that to avoid criticality the size $\ell \equiv V/S$ must not exceed the following critical value:

$$\ell_c = 1.847\left(\frac{\Delta h_v}{\Delta h_c - \Delta h_v}\right)\frac{hW}{A\rho_L R}$$

where V = volume of insulation (m^3), S = exposed surface area (m^2), Δh_v = latent heat of vaporization (J mol^{-1}), Δh_c = heat of combustion of the vapor (J mol^{-1}), h = convective heat transfer coefficient (W m^{-2} K^{-1}), W = molar mass of the fluid (g mol^{-1}), A = pre-exponential factor for reaction of vapor (s^{-1}), ρ_L = density of the liquid (kg m^{-3}), and R = universal gas constant (= 8.314 J mol^{-1} K^{-1}). The value of A can be estimated from the reaction of the vapor which is usually a hydrocarbon gas. One interesting result of this solution is that the initial temperature does not affect the outcome, and the only variable apart from the chemical constants of the liquid is the size of the system. McIntosh also considered the case where a small leak continually places new liquid into the insulation[137]. For that case, he derived an estimate for the critical feed rate (beyond which dangerous oscillatory temperature behavior develops) as:

$$\dot{m} = \frac{RT_o^2 ShW}{EQ}$$

where T_o = ambient temperature (K), E = activation energy (J mol^{-1}), and Q = heat of reaction (J mol^{-1}), and the Sh product represents the convective heat loss (W K^{-1}) at the surface. This formula is at first sight counter-intuitive since as ambient temperature is increased one needs more supply of fuel to cause critical conditions to occur. This is because at the greater temperature, there is a greater evaporative loss of fuel to be overcome, in order to induce the oscillatory behavior. But of course the equilibrium temperature solution (without oscillations) may in fact already be dangerously high. The formula has greatest practical relevance for low ambient temperatures where the oscillatory behavior is deceptively slow. If the loss of heat at the surface (Sh) is poor, then even a small leak (on the order of grams per hour) is dangerous.

DETONATION OR DEFLAGRATION UPON SELF-HEATING

As mentioned in Chapter 7, certain solid substances, upon self-heating, are capable of undergoing deflagration or detonation, not merely thermal explosion. Ammonium dichromate is a substance which can undergo deflagration; Grewer[72] provides color illustrations of this process as it occurs. Detonation upon self-heating is encountered with explosives and unstable substances and is further considered in Chapter 10.

PREVENTIVE MEASURES

Measures to prevent ignitions due to self-heating can take a wide variety of forms.

1. Chemical modification of the substance. Changes in the chemical makeup of the substance are often limited by the fact that the substance has some practical use and arbitrary changes in formulation may negate its primary function. For oxidative self-heating, one simple strategy often used is to add antioxidant agents, commonly seen in foodstuffs and in synthetic polymers. Such antioxidants have a primary benefit which transcends self-heating issues. For foodstuffs, antioxidants retard spoilage; for polymers, they slow down degradation processes such as yellowing, hardening, or crazing.

2. Inerting. If placed in an inert atmosphere, reactions dependent on atmospheric oxygen will stop. For general storage, this is not practical, but it is employed in specialized applications, including agricultural products where inerting, typically with nitrogen, helps retard spoilage.

3. Reduction in size of piles. This is probably the most common and practical tactic. Since size of pile is a dominant variable in governing the self-heating, a good

preventive measure is to reduce the pile size. This has the advantage that no other modification of the substance nor the environment is necessary.

4. Sealing of the substance. Porous substances only contain a very limited amount of oxygen within the bulk material. For self-heating which depends on atmospheric oxygen, most of the oxygen comes from diffusion or convection through the pile. If packed into airtight containers or otherwise sealed, only the most unstable of substances will be able to self-heat to critical conditions by using the available oxygen sealed in. The most economical form of sealing may be use of impermeable plastic film wraps or bags. In practice, such bags cannot be guaranteed to be 100% intact. Thus, in a fascinating study, Bowes[10] examined activated charcoal packed in plastic bags which were damaged by tears or by cutting away rectangular strips of material. Even with a 613 × 51 mm strip removed from a 25 kg bag, self-heating in the damaged bags did not reach critical conditions at 75ºC, while comparable-size permeable bags were shown to reach thermal runaway if stored at 65ºC. Smaller damaged areas produced undetectable self-heating.
5. Monitoring of temperature rise or products of combustion. A study on grain dust heating showed that an ionization detector can detect conditions quite early, before thermal runaway has commenced[138].

Tests for self-heating or reactivity

In this Section we present an overview of the test methods most commonly used for assessing self-heating or reactivity. Some methods are suited only for solids or only for liquids, etc., while others are of wider applicability. Since there is a some overlap between the theme of this Chapter and the following one, all of the self-heating tests, including those on unstable substances, are discussed as a group here. There has been a huge variety of tests invented for characterizing self-heating materials. The ones discussed in this section are modern tests based on fundamental theory, or are well-known tests used for regulatory purposes, or tests commonly used in industry for exploratory studies. Grewer[139] has reviewed a number of additional tests, which are mainly empirical self-heating tests used in Germany and showed the very wide spread of data obtained in comparative testing.

Hazardous materials basically can be viewed as having two aspects of hazard: (1) the potential for ignition, reaction, explosion, etc.; and (2) the consequences of an ignition, reaction, explosion, spill, etc. When hazardous materials are in transport, governmental regulations commonly apply. The United Nations publish the Recommendations on Transport of Dangerous Goods[140,141] based on recommendations of a Committee of Experts. This work comprises two volumes, first being a model regulation, while the second being a collection of test methods. By itself, the Recommendations do not have a special standing. They acquire the force of law when adopted by treaties or regulations. Treaties have resulted in adoption or partial adoption of the Recommendations for various modes of transport. Transport by ship is governed by the International Maritime Dangerous Goods Code, administered by the International Maritime Organization; air transport by the International Civil Aviation Organization's Technical Instructions for the Safe Transport of Dangerous Goods by Air; and European road transport by UN's European Agreement Concerning the International Carriage of Dangerous Goods by Road. In the US, the Department of Transportation has adopted many of the UN tests for interstate transport requirements. The UN Recommendations are revised rather frequently, and worldwide harmonization efforts are expected to result in substantive technical changes. There is no official commentary to the Recommendations which might provide a rationale for the classification and testing decisions taken; however, a recent symposium[142] was devoted largely to discussions of various aspects of these test methods. Some comments from a test laboratory on certain of the methods are especially valuable[143].

The UN Recommendations propound the concept of a *self-accelerating decomposition temperature*, SADT, defined as "the lowest ambient temperature at which self-accelerating decomposition may occur in the packaging as used in transport." In practice, the Recommendations offer numerous tests for determining the SADT and substantially different definitions are found among the individual test method requirements. As the theory portion of this Chapter makes clear, it is illogical to seek a handbook value of a temperature at which self-heating or decomposition begins. This is because the actual temperature at which runaway occurs depends not just on the chemical nature of the substance, but on the way it is held (e.g., insulated or well-cooled convectively), and most especially, on the amount of substance that is aggregated. The UN regulations try to respect these variables in a rough way by making classifications limits according to sizes of packages and by requiring that a quantity L be measured. L is defined as the heat loss per unit mass (W kg^{-1} K^{-1}) and is to be determined by filling the package with "another substance having similar physical properties" and then observing the half-time of cooling, $t_{1/2}$. The user must also determine the heat capacity of the substance, then compute $L = (C_p \ln 2)/t_{1/2}$. Despite these attempts to provide some realism, Whitmore pertinently concludes[144] that "SADT is not universally the most useful measure." This is because the methods do not produce fundamental data, on the basis of which, the behavior of any desired package might be computed. Part of the problem in providing a solid tie-in to theory is that many of the potentially 'hazardous' substances that need to be considered have complex reaction mechanisms and do not conform to Arrhenius kinetics, specifically, many reactions are autocatalytic.

The UN Recommendations provide four SADT tests, H1, H2, H3, and H4, which are described below. If the SADT is 50ºC or less for self-reactive substances (55ºC for organic peroxides), special temperature control measures are mandated for shipping. Test H1 is a real-size test method, while Tests H2, H3 and H4 are reduced-scale tests, but even these may be unsuitable for initial examination of potentially very unstable substances, thus a number of screening tests have been developed and these are also considered below.

REAL-SCALE TESTS

The size of the substance involved plays a very strong role in determining its self-heating behavior. Thus, the best self-heating test, by far, is a real-scale test. The substance is configured in the shape and with the boundary conditions that it will experience in its end-use application and is placed in an environment at the maximum temperature it is expected to encounter. The results then are directly indicative and require no theory, computations, or extrapolations to produce the final answer. In many cases, due to limitations of cost, time, or supply of material, real-scale testing is impossible and reduced-scale testing must be undertaken. Even the best of these methods leave larger doubts, since the theory according to which extrapolations are undertaken is invariably simplified and certain phenomena are neglected.

UN TEST H1—THE US SADT TEST

UN Test H1 is a real-scale test, where specimens of the actual size are tested in an oven. The oven is intended to be a disposable device, which may be lost in case of explosion. The SADT is defined arbitrarily as the lowest oven temperature for which the specimen shows a 6ºC rise. A substantial safety factor is built into this definition, since, as explained previously in this Chapter, a substance that is approaching thermal runaway will normally show a temperature rise several times greater than 6ºC. The test is run for 7 to 10 days; the exact time is not fixed due to a complicated specification of the start of the data-taking period. The test method is poorly designed, since the air velocity within the oven is not controlled and so results can be irreproducible and susceptible to large unconservative errors[152]. The test method also does not make clear that the "packaging" to be tested should be the full shipping container and not an individual container within it, since grossly unconservative results will be obtained if only the latter is tested. In fact, the test method explicitly limits the test specimen size to no more than 220 L. Finally, if larger packages, such as a rail car, were tested, the time limit of the test would be much too short, since train voyages can be longer and thermal runaway can take place beyond the time limit set in the test.

GEOMETRIC-SCALING TESTS

SCALING ACCORDING TO FRANK-KAMENETSKII THEORY

Most of the test methods based on using the Frank-Kamenetskii theory are oven-basket tests, and these are all presented in this section. A number of regulatory oven-basket tests also exist where the connection to theory is limited, at best. Nonetheless, for convenience these are also described in this section.

Oven-basket tests: FRS method

The most common technique for conducting bench-scale tests with an objective of predicting large-scale behavior is an oven-basket test and, in turn, historically the most common way of doing those has been as developed by the Fire Research Station. The method requires that the sample be held in a wire-mesh basket, thus it is only suitable for solids. Each individual test run is made at a fixed oven temperature, thus the method is classified as an isothermal oven test. This test condition is sometimes described as *isoperibolic*. The technique was refined over several decades of research by Philip Bowes and coworkers[10] and has been described in summary by former FRS researcher Paula Beever[54]. In this technique, a powder, granular, etc. specimen is prepared by packing it into a wire gauze basket; the latter is usually in the form of a cube. Stainless steel wire gauze having openings of ca. 0.25 mm is used. The basket is placed in an oven where the temperature can be controlled accurately to better than ±1ºC. The oven must also be equipped with a fan to keep the temperatures uniform and to provide a reasonably high convective heat transfer coefficient to the specimen. Runaway fires must be expected to occur, so the oven construction should be able to withstand fire temperatures, even though a controlled-heating range of only up to about 400ºC is needed.

The sample is normally prepared at room temperature, then inserted into the oven which is at a desired test temperature substantially above room temperature. As a consequence, the specimen heats up to the oven temperature, but if it is not inert, it also continues to heat to a higher temperature. The initial heating occurs near the edges, but subsequent heating is mainly at the center (see Figure 15). This actual problem is the cold-work problem and is theoretically more difficult to treat than the simple F-K theory, which assumes that initially the substance is already at the oven temperature, but is thinly spread out so it does not self-heat. Within the simple F-K theory, at $t = 0$ the specimen is then assembled instantaneously into the desired oven-basket configuration. In analyzing oven-basket results, it is customary to ignore all times prior to the instant that the central thermocouple reaches the oven temperature, and to declare $t = 0$ to occur at that moment. This is illustrated in Figure 17.

As a minimum, two thermocouples are required—one at the center of the specimen, and the second monitoring the oven

air temperature. In many cases, a third thermocouple is used, located at the surface of the specimen. This third thermocouple is used to monitor whether the $Bi \rightarrow \infty$ condition is reasonably fulfilled, that is, to see if the specimen surface temperature is very close to the oven air temperature. A Type K thermocouple made of 0.19 to 0.27 mm dia. wires and having a bare junction is used. Experiments must be conducted on a number of different-sized cubes. Commonly, cubes of 25, 50, 100, and 200 mm dimensions ($2r$) are used. The density must be controlled so that it is nearly identical for all the specimens tested, and it should approximate the density to which the substance is packed in the real-scale environment. The material must be carefully tamped or shaken in order to ensure that the packing is uniform throughout the sample.

The basic procedure is to determine by trial and error the critical value of T_o for each basket size. For any given size and oven temperature (T_o) setting, there are two possible results: (1) the temperature at the center of the sample rises only a modest amount over the oven temperature (if indeed it reaches it), establishes a plateau, then eventually decreases*; or (2) either initially or after possibly some plateau is reached, a very sharp increase in temperature occurs and the temperature climbs way over the oven temperature. The first event and second event temperatures are denoted as subcritical and supercritical, respectively. By means of bracketing, it is eventually possible to find a subcritical and a supercritical temperature separated by only 1 or 2ºC. The critical value of T_o is then deemed to be halfway in between the two. When a critical T_o has been found for one basket size, experiments are started for the next size. A table is then compiled of r versus critical values of T_o. Since repeated testing (which may take days or weeks) is needed for each specimen size and at least 3—preferably more—sizes must be studied, the procedure is somewhat lengthy.

Simple form of analysis

Once a set of data has been obtained for critical size vs. temperature, the simplest form of analysis is that recommended by Leuschke[146]. The volume/surface ratio (m) is obtained for each specimen and these values are plotted on a log-scale x-axis. The quantity $1000/T_o$ is plotted on the y-axis, where T_o is the oven temperature (K). Leuschke demonstrated (Figure 26) that the results fall into a straight line. In addition, he demonstrated empirically that the shapes of the test containers, provided they are reasonably compact, do not make a significant difference.

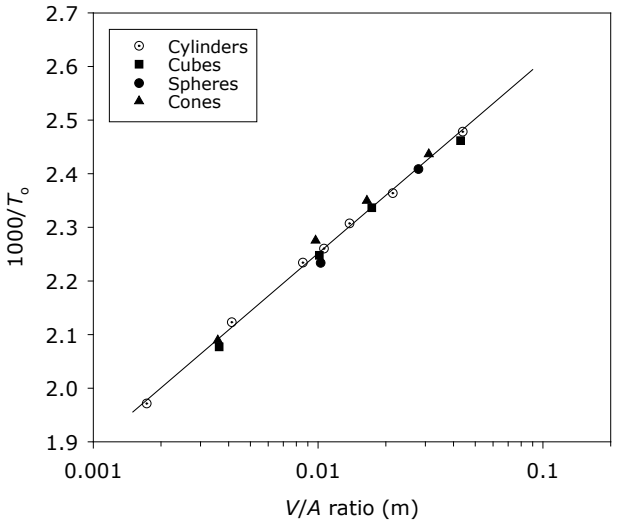

Figure 26 Analysis of cork dust oven-test data using the plot recommended by Leuschke

Example

Using the data of Leuschke in Figure 26, determine what would be the maximum permitted storage temperature for a 2 m conical pile of cork dust.

Solution. The volume of a cone is $\frac{1}{3}\pi r^2 L$, where L = height. We will assume that $L = r$. The area of the base of a cone is πr^2, and the area of the slant surface is $\pi z r$, where z = slant length. For the case $L = r$, $z = \sqrt{2}r$. Then $A = \sqrt{2}\pi r^2$. In the case of an oven-test specimen, the specimen can exchange heat convectively on all sides. For the case of the pile on the ground, there will be no convective cooling of the bottom (of course, conduction heat transfer will exist, but we will ignore this in solving the problem). Thus, the value of A will be taken as only that which comprises the slant-sides. Then, $V/A = \frac{r}{3\sqrt{2}}$. Since in this problem $r = 2.0$ m, $V/A = 0.47$ m. The value of $1000/T_o$ could be determined graphically, by simply extrapolating the data fit line. Instead, we will compute numerically the extrapolated value. The straight line shown in Figure 26 corresponds to the equation:

$$y = 2.97 + 0.156 \ln(x)$$

For $x = 0.47$ m, $y = 1000/T_o = 2.852$, giving $T_o = 351$ K = 78ºC.

FRS method of analysis

The analysis method recommended by FRS and Beever involves using a fair bit of theory to interpret and extend the data, not just making a straight-line plot. As a result, a more refined and accurate estimation can be made, and several corrections incorporated where needed.

After collecting the data, to perform the analysis, one must first determine the value of δ_c that is pertinent to the exper-

* In most oven basket tests, when a specimen is tested at a subcritical oven temperature, the temperature reaches a peak then drops down to about the oven temperature value. Some drop is expected, since a steady-state value would be achieved only if no reactants were consumed. However, questions have been raised[145]—but not answered—as to how it is possible for the excess temperature to drop to near zero, if after removing the specimen from the oven very little is found to have been consumed.

imental situation. To present the data in a form suitable for analysis, we start with the definition of δ

$$\delta = \frac{E}{RT_o^2}\frac{r^2 \rho Q A}{\lambda} e^{-E/RT_o}$$

Taking logarithms of both sides, re-arranging, and noting that the values of δ to be obtained are the critical ones, δ_c, the following relation is obtained:

$$\ln\left(\frac{\delta_c T_o^2}{r^2}\right) = P - \frac{E}{RT_o}$$

where T_o = the critical oven temperature value found for a particular size r, and P is a material constant, since it is a grouping of variables which, under the assumptions of the theory, are neither dependent on T nor r:

$$P = \ln\left(\frac{E}{R}\rho\frac{QA}{\lambda}\right)$$

This suggests that it is appropriate to plot the experimental results by putting $1/T_o$ on the x-axis and $\ln\left(\frac{\delta_c T_o^2}{r^2}\right)$ on the y-axis. This gives a straight line, with a slope of $-E/R$ and a y-axis intercept of P.

To evaluate whether a product stored at a given temperature will exhibit thermal runaway, one first finds the value of δ_c that is given by theory. Note that the end-use geometry need not be the same as the test geometry. For instance, the tested configuration may be a cube, while the end-use product is in the shape of a rectangular box. However, all necessary theoretical corrections to δ_c (for finite Bi number, fuel depletion, etc.) must be made. Then, one can express δ as:

$$\delta = \frac{r^2}{T_o^2}\exp(P)\cdot\exp\left(-\frac{E}{RT_o}\right)$$

where P and E/R were obtained from the plot of experimental data, while the values of r and T_o to be used are those that pertain to the end-use condition. The above equation gives the value of the actual δ. This is to be compared to the value of δ_c obtained from the theory. If the $\delta < \delta_c$, then thermal runaway is not expected; otherwise, it is.

A value of QA is also needed if some of the methods for estimating time to runaway (assuming the system is found to be supercritical). It can be obtained from the values of P and E/R by the relation:

$$QA = \left(\frac{1}{E/R}\right)\frac{\lambda}{\rho}\exp(P)$$

Treatment for initially-hot substances

Using Thomas' hot-work theory, oven tests on cubes or cylinders are conducted in the standard manner and from these results, a value of E/R is found. The value of θ_h can then be solved for:

$$\theta_h = \frac{E}{RT_h^2}(T_h - T_o)$$

where T_h is the initial temperature of the hot material, and T_o is the temperature of the environment. Knowing θ_h, a value of δ_c is then found from the theoretical expression for to the geometrical shape being used. As usual evaluation is made by comparing the δ_c with the value of δ for the actual system.

Treatment for substances varying in density

In some cases, density of a particular substance can vary significantly. Thus, test data may be available from specimens of diverse densities, or else, application of test results needs to be made to substances of various density. In the latter case, it may be simplest to just use the correction:

$$r_2 = r_1\sqrt{\frac{\rho_1}{\rho_2}}$$

If test data of diverse densities are to be used, however, it is possible to modify the standard data correlation procedure and plot $\ln(\delta_c T^2/\rho r^2)$ on the y-axis, instead of $\ln(\delta_c T^2/r^2)$. A consistent treatment may be achieved in this way, but it is important to realize that the y-axis intercept will no longer be the value P, and thus the intercept value cannot be directly compared to P values reported in the literature.

This type of data treatment, while recommended by a number of authors, leaves out the important issue of thermal conductivity. For most organic solids, the thermal conductivity is roughly proportional to the density, although reliable data quantifying this dependence are not necessarily common. If $\lambda \propto \rho$ then *no* correction should be made, since $\delta \propto \rho/\lambda$, and thus the joint density/conductivity dependence would cancel out. In any case, for a given substance, judgment should be used as to whether to correct for ρ alone, to do no corrections, or to correct for both ρ and λ. If for some substance accurate data are available for both the density and the conductivity, then the process is simply generalized and $\ln(\delta_c T^2 \lambda/\rho r^2)$ is plotted on the y-axis when samples of diverse densities are to be correlated.

Variations in loading

In some cases, systems are considered where there is a reactive component which is dispersed on an inert component. Spokoinyi and Eidukyavichus[147] treated a case of mineral wool where the active component is the phenolic binder, while the inert matrix is the mineral wool itself. They concluded that the effects of varying the loading of binder can be represented by taking $Q = \beta Q_p$, where Q_p = heat of reaction of pure reactive component, and β = mass fraction of reactive component in total mass. An estimating rule of this kind can be applied to other substances, keeping in mind that it will only be valid within the context of the F-K theory. Thus, for example, estimates should not be made of a

high enough loading of the reactive component that the reaction becomes oxygen-limited.

Estimating the Biot number

It is generally quite difficult to determine the Biot number, especially for a real-scale commodity. There are no known studies of the transfer coefficient for large stacks of sundry goods and, even if there were, to obtain the Biot number would require knowing the thermal conductivity of the material, which is, again, rarely known or easily determined. Beever[54] suggests that for large piles the assumption that $Bi \rightarrow \infty$ is appropriate. Presumably the justification for this is that, if h_c is size-independent, Bi will increase directly with increasing size and will, in some sense, become 'large.' Thus, the assumption that $Bi \rightarrow \infty$ is commonly applied to the real-scale situation.

For the small-scale oven tests, the choice is to either determine the Bi value quantitatively, or else set the experiment up in such a way the $Bi \rightarrow \infty$ asymptote is valid. Bowes suggests[10] that if the flow velocity is greater than 10 m s^{-1}, then the $Bi \rightarrow \infty$ can be assumed. This advice is important, since oven-basket testing has indicated that, unless high velocities are achieved, significant errors will occur if $Bi \rightarrow \infty$ is assumed[148]. In the procedure described above for evaluating the chemical constants from oven basket testing, if $Bi \rightarrow \infty$ is assumed for a case where a finite Bi value should have been used, the consequences will be: (1) a higher-than-true value of E will be reported; and (2) a higher-than-true value of P will be reported.

The Biot number is expressed as a convective effect, but in actuality there is also radiant heat exchange at the surface. Thus, 'effective' values must be derived for the heat transfer coefficient (which we will denote as h_{tot} here for clarity) that include an extra contribution from radiation. In the general case, for a body of arbitrary shape and arbitrary surface radiant absorptivity, the calculations become unwieldy (and probably unjustified by other approximations already being made in the problem). As a practical approach, when there is natural convection only and no wind, Bowes[10] offers the following equation:

$$h_{tot} = \frac{\lambda_{air}}{D}\left[2.0 + 0.6\left(\frac{gD^3RT_o}{\nu_{air}\alpha_{air}E}\right)^{1/4}\right] + 4\sigma T_o^3$$

where D = diameter or other critical dimension of specimen, λ_{air} = thermal conductivity of air, ν_{air} = dynamic viscosity of air, α_{air} = thermal diffusivity of air, g = 9.8 m s^{-2}, R = 8.314 J mol^{-1} K^{-1} and $\sigma = 5.67\times10^{-8}$ W m^{-2} K^{-4}. The needed values of the thermal properties for air at a particular temperature T_o can be found in Incropera[151]. Bowes also worked an example where h_{tot} was computed for various specimen sizes r. An analysis shows that a good fit through his data can be obtained by a simple expression:

$$h_{tot} = 13 + 1.033\,r^{-0.7}$$

where the units of r are m and the units for h_{tot} are W m^{-2} K^{-1}. This approximation should only be applied to 'compact' shapes, that is, ones where no one dimension is very different from the other two. Gray and Halliburton[149] reviewed available measurements and procedures for determining the Biot number pertinent to testing specimens in wire baskets in ovens having reasonable circulation rates and recommend that the constant value h_{tot} = 14 W m^{-2} K^{-1} can be used as a general expression.

In oven testing, for best accuracy, the value of h_{tot} should be determined in the oven used. To do this, a series of cubes (or whatever shape is used) is made up in copper or aluminum. The internal thermal resistance of these two metals is low enough that it can be ignored. A cube originally at room temperature T_i is plunged into the oven which is at T_∞ and the cube's temperature T is measured as a function of time. A solution for h_{tot} can then be obtained from the lumped-capacitance equation:

$$h_{tot} = \frac{\rho VC}{St}\ln\left(\frac{T_i - T_\infty}{T - T_\infty}\right)$$

where V = volume of cube (m^3), C = heat capacity (J kg^{-1} K^{-1}), S = surface area (m^2), and t = time (s). An example of this kind of experiment has been given by O'Connor[87]. Jones[150] proposed a similar technique, but using an inert substance of arbitrary, but known thermal diffusivity, instead of a metal which has effectively infinite diffusivity. The analysis of results using a low thermal diffusivity block is less straightforward but can be done with the help of Heisler charts, which are given by Incropera[151] and in other heat-transfer textbooks. Having a value for h_{tot}, the value of Bi can then be computed from:

$$Bi = \frac{h_{tot}r}{\lambda}$$

where λ is the thermal conductivity of the substance being investigated and has the units W m^{-1} K^{-1}. The problem is not finished, however, because a value for λ is needed for the substance being evaluated for self-heating.

A simpler but less general technique for finding the Biot number was proposed by Bowes[10]. Oven test specimens (see below) normally require only a central thermocouple (T_m) and a thermocouple recording the oven air (T_a). However, a specimen surface thermocouple, T_s, may also be fitted. In that case, the value of Bi can be estimated directly from steady-state readings (for specimens that did not lead to thermal runaway):

$$Bi = \beta_\infty \frac{T_m - T_s}{T_s - T_o}$$

and the value of β_∞ is 2.36 for a cube and 2.70 for a long cylinder. In the case of hotplate tests for a dust layer,

$$Bi = 0.5\frac{T_p - T_s}{T_s - T_o}$$

where T_p is the hotplate temperature[51]. Determining steady-state temperatures may not be trivial, since some substances

show multiple peaks or significant reactant depletion effects rather than smoothly approaching a steady state.

Halliburton[152] measured the heat transfer coefficients of shipping drums, tested in open air. For an 0.35 m diameter drum, h_{tot} = 10.3 W m^{-1} K^{-1} was found, while for an 0.55 m diameter drum, h_{tot} = 7.9 W m^{-1} K^{-1}. The smaller drum was then measured inside a test oven, where it showed a higher value of h_{tot} = 16.4 W m^{-1} K^{-1} due to the forced-air stirring. Halliburton additionally measured the heat transfer coefficient of a standard shipping container (2.4 m wide × 2.6 m high × 6.0 m long) in open air and found h_{tot} = 3.5 W m^{-1} K^{-1}. If the functional form derived above for forced convection is used, this gives

$$h_{tot} = 1.13 + 2.78\, r^{-0.7}$$

for free convection results in open air. This relation should of course be viewed only as a qualitative trend, since quantitative curve-fitting cannot be done on the basis of only 3 data points.

Estimating the thermal conductivity

For *powders, dusts, and granular materials*, the thermal conductivity is highly dependent on the porosity ε. The extreme cases are trivial, as $\varepsilon \to 0$, $\lambda \to \lambda_s$, where λ_s is the density of the bulk solid. Conversely, as $\varepsilon \to 1$, $\lambda \to \lambda_g$, where λ_g is the conductivity of air. These extremes are not particularly helpful in estimating the actual λ value and unfortunately the relation is not linear. Numerous relations have been proposed for estimating λ, but none is universally valid or applicable. Gorring and Churchill[153] and Dawson and Briggs[154] reviewed a number of studies on the subject. One of the more usable expressions is the Maxwell-Eucken formula[155]:

Table 16 Thermal conductivity of dry air, λ_g

Temperature (ºC)	λ_g (W m^{-1} K^{-1})
0	0.024
20	0.026
40	0.027

140	0.035
160	0.036
180	0.038
200	0.039
220	0.040
240	0.041
260	0.043
280	0.044
300	0.045

$$\lambda = \lambda_s \frac{1 - \varepsilon\left(1 - a\lambda_g / \lambda_s\right)}{1 + \varepsilon\left(a - 1\right)}$$

where

$$a = \frac{3\lambda_s}{2\lambda_s + \lambda_g}$$

Values of λ_g are shown in Table 16. Intermediate values can be computed as:

$$\lambda_g = A + BT + CT^{3/2}$$

where A = 0.0240, $B = 9.24\times10^{-5}$, $C = -1.28\times10^{-6}$, and T = temperature (ºC). The effect of moisture on the conductivity of air is small, raising the value by 1% for a 5% MC.

If a granular material is wetted, thermal conductivity can rise drastically, with a factor of 10 increase not being rare. Palosaari and Cornish[156] discuss thermal conductivity estimating techniques for wet granular materials.

When materials with void spaces are involved, conductive heat transfer can be augmented by radiation and convection. These effects present notable complications for materials of high porosity (e.g., glass fiber thermal insulation), but for relatively compact powders, dusts, grains, etc., usually can be ignored.

For *non-granular cellulosic and lignocellulosic materials* (e.g., cotton, wood products, paper, etc.), the data of Sauer[157] indicate that a good correlation can be produced on the basis of the material's density. Figure 27 gives the experimental data points, along with two fitted lines. On the basis of these results, a practical strategy can be:

If $\rho < 300$ kg m^{-3}, then $\lambda = 0.043$ W m^{-1} K^{-1}.

If $300 < \rho < 1100$ kg m^{-3}, then $\lambda = 1.6\times10^{-4}\,\rho$.

This is indicated as the dashed straight line on the graph.

If $\rho > 1100$ kg m^{-3}, then $\lambda = 0.042 + 1.14\times10^{-7}\,\rho$.

This is indicated as the solid-line curve on the graph. These data only pertain to room-temperature conductivity values, but self-heating theory itself does not provide for changes in λ with temperature, so this should not be a major limitation. A rather similar, but slightly lower curve has been obtained for wool products by Baxter[158]. Most materials of interest in self-heating problems will typically have densities greater than 50 kg m^{-3} or so, but for extremely lightweight materials, effective thermal conductivity rises, since convective and radiative effects begin to dominate[159].

For *granular cellulosic materials*, Bowes et al.[160] concluded that $\lambda \propto \rho$ is a good assumption, at least within the range studied, $250 < \rho < 450$ kg m^{-3}.

Worked examples

Bowes[10] has given a detailed example how data for low-density wood fiberboard are analyzed and presented. Here, we work three versions of this example, following generally

Table 17 Data on low-density wood fiberboard

Shape	Size r (m)	Critical temp. T_o (K)	δ_c for $Bi\to\infty$	$\varepsilon = RT_o/E$	B	h_{tot} (W m^{-2} K^{-1})	Bi	Corr. δ_c

	0.021	435	0.88	0.036	16.2	28	11.9	1.29

the method* used by Beever[54]. The example is especially illustrative, since experimental data from three different geometries of oven-test specimens are combined: Mitchell's[161] data on octagonal piles and on cubes, and the data of Thomas and Bowes[22] on cubes and on vertical slabs. The experimental data are given in Table 17. We first solve an example problem where no corrections are made, then solve it again with corrections, and finally compute a hot-work example.

Simple problem

Problem: Using the data obtained, compute the critical height of a layer of wood particleboard placed on the ground, if the stack width and depth are very much greater than the height.

Solution: The first step is to obtain the material properties from the oven test data. This is done as a plot presenting $1/T_o$ on the x-axis and $\ln\left(\delta_c T_o^2 / r^2\right)$ on the y-axis. The values of T_o to plot are simply the critical temperature of the oven environment which was recorded for each different specimen size. The values r are the half-thickness for the slab, the half-edge-length for the cube, etc. The data from experiments on different shapes can be combined in one plot, making sure to use the δ_c pertinent to each geometry. It is assumed that the oven tests were well stirred, so that in the oven the condition $Bi \to \infty$ was fulfilled.

The plot is shown in Figure 29; note that neither of the axes is extended to the zero origin, in order to present the data more legibly. The straight line of best fit was found to be:

$$y = 47.54 - 12053\,x$$

The slope is –12053 and has the units of K. The slope is equal to $-E/R$, thus the activation energy E = 12053 K × 8.314 J mol^{-1} K^{-1}, or 100.2 kJ mol^{-1}. The y-axis intercept is 47.5; the units are ln(K^2 m^{-2}) and it is identified as the variable P in Beever's nomenclature.

The problem to be solved is that of a plane slab. Since the material is placed on the ground and there is no cooling along the bottom surface, it is appropriate to assume that the height of the physical slab is r, and not $2r$. With this assumption, the bottom surface is then equivalent to the midplane of a 'logical' slab which is twice the thickness of the actual slab. The reason is made clear by remembering that zero heat transfer occurs across the midplane of a slab with symmetrical heating and boundary conditions. We will assume that cooling is unrestricted at the top surface and that $Bi \to \infty$ there. If we want to compute the just-critical value of size, then we must evaluate δ under conditions that

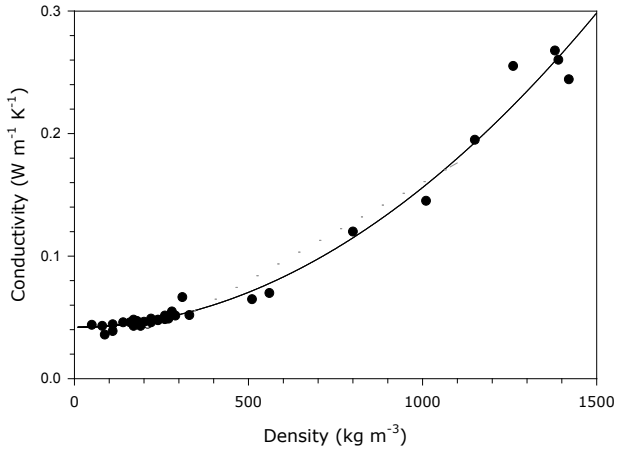

Figure 27 Estimating the thermal conductivity of lignocellulosic solids on the basis of density

* For consistency, we adopt the nomenclature and units used by Beever. Bowes defines $-E/R$ as P, and defines the y-axis intercept (our P) as M. Also note that he uses mm and not m as the unit of measure, with the result that his values of M are lower than our values of P by $\ln(10^6) = 13.82$.

(a) δ is exactly equal to its critical value, δ_c; and (b) T_o is the initial ambient temperature, which we will take as 20ºC = 293 K. For a slab, the critical value $\delta_c = 0.88$. Now

$$\delta_c = 0.88 = \frac{r^2}{T_o^2}\exp\left(P - \frac{E}{R}\frac{1}{T_o}\right)$$

and since all the values are known, we directly get r = 11.4 m. This means that the pile would have to be 11.4 m high for runaway self-heating to occur. This is substantially higher than would normally be stacked in any facility. Thus, if the pile is stacked with its initial temperature being 20ºC, no spontaneous combustion would be expected. Note also that if the pile had been stacked on pallets which permitted good access of cooling air to the bottom, then an even higher critical condition of 2×11.4 m would be computed.

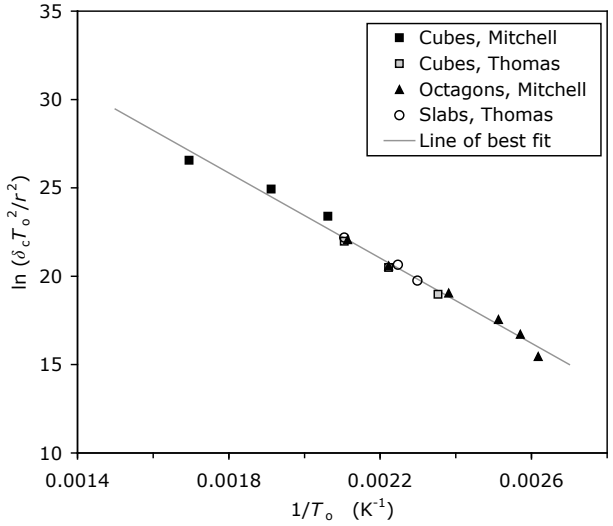

Figure 28 Simple analysis of wood fiberboard data

Problem using corrections

Problem: Using the above experimental data, make corrections for finite Biot number and reactant depletion, check if a correction for low activation energy is needed, then apply the results to determine if a 3 m cube of material, stacked on pallets at 20ºC, is safe.

Solution: Estimates of E and P were already obtained in the previous problem. To correct for a finite Bi, a value of the thermal conductivity λ of fiberboard is needed, which can be taken as 0.050 W m^{-1} K^{-1}. Knowing the size and the thermal conductivity, Bi can be estimated as:

$$Bi = \frac{\left(13 + 1.033 r^{-0.7}\right) r}{\lambda}$$

These values are listed in Table 17. Then values of δ_c corrected for finite Bi values can be obtained from Boddington's relationships. Very little error is introduced if the octagonal parallelepiped is treated as a cube, so two shapes only need to be considered:

$$\delta_c(Bi) = \frac{1}{0.3892 + \dfrac{0.906}{Bi}} \qquad \text{for the cube}$$

$$\delta_c(Bi) = \frac{1}{1.167 + \dfrac{2.718}{Bi}} \qquad \text{for the slab}$$

Reactant depletion correction is computed by first evaluating the nondimensional temperature rise B:

$$B = \frac{E}{RT_o^2}\frac{Q}{C}$$

A good estimate of E was already obtained in the preceding Example problem. A value for the heat of reaction, Q, is difficult to determine without a thermal analysis study of the material. Bowes recommends a value of 350 kJ kg^{-1}, based on a detailed investigation of wood pyrolysis. A knowledge of C for wood fiberboard is also required, this being 1400 J kg^{-1} K^{-1}. A value of B can then be computed as $\left(E/RT_o^2\right)\left(Q/C\right) = 3.0\times10^6/T_o^2$. The reactant-depletion correction factor is:

$$\delta_c(B,n) = \frac{\delta_c(\infty)}{1 - 2.85(n/B)^{2/3}}$$

where n = 1 is appropriate for a first-order reaction.

A low-activation-energy correction is needed if E < 40 kJ mol^{-1}. In the present case, $E \approx$ 100 kJ mol^{-1}, so a correction is not needed.

Thus, the final expression for δ_c, using the two corrections needed, becomes:

$$\delta_c(corrected) = \delta_c(Bi) \times \frac{1}{1 - 2.85\,B^{-2/3}}$$

The final results are shown in Figure 29.

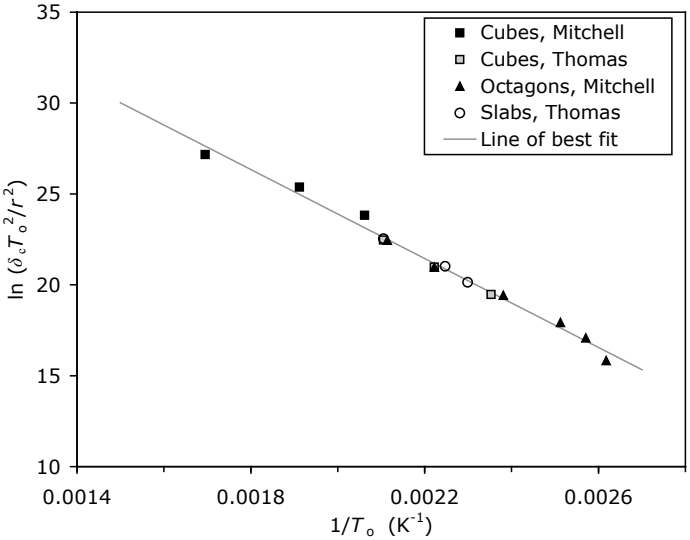

Figure 29 Analysis of wood fiberboard data with corrections included

The line of best fit has a y-intercept (that is, P) of 48.38 and a slope of –12,242 K. Since the latter = $-E/R$, a final value for E of 101.8 kJ mol^{-1} is found. These values are not noticeably different from the ones computed in the preceding problem. To apply the results to a 3×3×3 m cube of wood fiberboard stacked in 20ºC ambient temperature, first we find the value of r is 3/2 = 1.5 m. To estimate Bi:

$$h_{tot} = 13 + 1.033\, r^{-0.7} = 13 + 1.033\,(1.5)^{-0.7}$$
$$= 13.78 \text{ W m}^{-2} \text{ K}^{-1}.$$
$$Bi = \frac{h_{tot} r}{\lambda} = \frac{13.78 \times 1.5}{0.05} = 413$$

This is a very large value, so the $Bi \to \infty$ results (for a rectangular brick with all sides identical) can be used: δ_c = 2.52. As computed above, $B = 3.0\times10^6 / T_o^2$ and n = 1. This gives

$$\delta_c(corrected) = \delta_c \times \frac{1}{1 - 2.85\,(n/B)^{2/3}}$$
$$= 2.52 \times \frac{1}{1 - \dfrac{2.85\,(293)^2}{3\times10^6}} = 2.74$$

Now, the value of δ for the actual conditions is computed as:

$$\delta = \frac{r^2}{T_o^2} \exp\left(P - \frac{E}{R}\frac{1}{T_o} \right)$$
$$= \left(\frac{1.5}{293}\right)^2 \exp\left(48.38 - \frac{12{,}242}{293}\right) = 0.020$$

Since 0.020 << 2.74, the pile is much too small for criticality to occur. The critical condition will occur at:

$$\frac{r^2}{T_o^2}\exp(6.60) = 2.74$$

Which can be solved to give r_c = 18.0 m, in other words, a cube of 36.0 m on a side, which is a large value indeed. Thus, the hazard from storing such piles in 20ºC temperature air should be minimal.

Problem in estimating criticality time

Problem: A very large storage compartment is filled with milk powder to the depth of 2 m. The ambient temperature is 321 K and the self-heating constants have been determined for the product as ρ = 508 kg m^{-3}, λ = 0.127 W m^{-1} K^{-1}, C = 2000 J kg^{-1} K^{-1}, E = 99.6 kJ mol^{-1}, P = 48.1, and $QA = 1.46\times10^{13}$ W kg^{-1}. How long will it take for the bin to reach criticality.

Solution: In order to be able to use any of the time-to-criticality formulas, it is first necessary to determine whether thermal runaway will occur. We will assume that the bottom of the layer represents an adiabatic surface, then r = 2 m. Using the given values, δ = 1.69. Ignoring any corrections for reactant depletion, δ_c = 0.88. Since 1.69 > 0.88, criticality is expected. Using the Zinn & Mader method, $t_{Fo} = \rho C r^2 / \lambda = 3.27\times10^7$ s. Also, δ/δ_c = 1.69/0.88 = 1.92. From Figure 18 or from the equations, $t_{ig} = 8.0310^7$ s = 930 days. Using Boddington's method, take M = 1.53. Then, $t_{ad} = 1.90\times10^7$ s and $t_{ig} = 1.60 t_{ad} = 3.04\times10^7$ s = 352 days. Using Thomas' method for estimating the lower limit, $t_{ig} \geq (0.89\rho C r^2)/(\delta\lambda) = 1.69\times10^7$ = 195 days. Using Gray's method for estimating the lower limit, $u = RT_o / E$ = 0.0268. This gives $\tau_{ig} = 1.14\times10^{13}$. Then, $t_{ig} \geq \tau_{ig} CE / QAR$ = 1.87×10^7 s = 217 days. Note that Gray does *not* recommend that the numerics be worked by substitution in this manner. Instead, his preferred procedure is based on scaling from an experimental datum point for critical time. Unfortunately, this example problem illustrates that theoretical treatments of criticality time are widely divergent.

Hot work problem

Problem: The same wood fiberboard material is now emerging from a manufacturing plant at 80ºC and is then immediately stored at an air temperature of 20ºC. Will a 3×3×3 m pile stacked on pallets reach critical conditions? If so, how long will it take?

Solution: First, a value for θ_o is computed as:

$$\theta_o = \frac{E}{R}\frac{T_i - T_o}{T_i^2} = 12{,}242\frac{353 - 293}{353^2} = 5.90$$

Then, the expression for the δ_c of a hot-work cube is evaluated:

$$\delta_c = \frac{1}{0.0458 + 0.1316/\theta_o} = 14.68$$

Next, the expression of δ is evaluated, with the temperature to be used being the hot-work temperature T_h and not the ambient temperature T_o:

$$\delta = \frac{r^2}{T_h^2} \exp\left(P - \frac{E}{R}\frac{1}{T_h} \right)$$
$$= \left(\frac{1.5}{353}\right)^2 \exp\left(48.38 - \frac{12{,}242}{353}\right) = 16.09$$

Since 16.09 > 14.68, the pile is expected to sustain thermal runaway. Under such circumstances, we wish to estimate the time until critical self-heating will occur. To evaluate this for a slightly-supercritical system, first compute t_{ad}. To evaluate this quantity, we must provide values for QA, but the frequency factor A has not been determined in the solution so far. The product QA can be solved by knowing the value of P and the density ρ, which for wood fiberboard of the present example is 270 kg m^{-3}.

$$QA = \left(\frac{1}{E/R}\right)\frac{\lambda}{\rho}\exp(P)$$
$$= \frac{1}{12{,}242}\,\frac{0.05}{270}\exp(48.38) = 1.55\times10^{13} \text{ W kg}^{-1}$$

$$t_{ad} = \frac{RT_i^2}{E}\frac{C_p}{AQ}\exp\left(\frac{E}{RT_i}\right)$$

$$= \frac{353^2}{12{,}242}\frac{1.4\times10^3}{1.55\times10^{13}}\exp\left(\frac{12{,}242}{353}\right) = 1.06\times10^6\,\text{s} \approx 12.3\ \text{days}$$

The value of $M(Bi)$ for cubes is not given by Boddington, but we can get approximate results by taking the value for a sphere, 1.3. Then, the expected time under real, non-adiabatic conditions can then be computed as:

$$t_{ig} = t_{ad}\frac{M(Bi)}{(\delta/\delta_c - 1)^{1/2}}$$

$$= 1.06\times10^6\,\frac{1.3}{\left(\frac{16.09}{14.68}-1\right)^{1/2}} = 4.4\times10^6\,s$$

= 51 days. This time may be entirely adequate if stock is normally broken up into small shipments within, say, one week.

Limitations and validation of small-scale test procedures

The standard oven-basket test procedure is practical, but it is simplified. For the sake of tractability, the method is based on standard theoretical development which uses a linearized approximation to the Arrhenius rate kinetics, rather than the full expression thereof. Furthermore, the treatment ignores such conditions and factors as:

- irregular product shapes found in practice
- products of more than one material
- materials having more than one exothermic peak; or endothermic and exothermic peaks
- materials having antioxidants
- variation of thermal properties with temperature
- variation of thermal properties with reaction progress (the thermal properties of char are generally different from that of the virgin material)
- mass flow of pyrolysates or water vapor
- natural convection occurring inside the body
- variation of thermal properties with the instantaneous moisture content (this can be an especially strong effect on thermal conductivity when moisture content approaches fiber saturation)
- non-uniform dispersion of the substance if, for instance, finer particles tend to segregate in a pile
- cooling behavior which is not represented by a constant, linear heat transfer coefficient
- forced convection blowing through the porous body
- products that have different exposures on their different sides (e.g., the bottom on a shelf, the sides exposed to air).

Furthermore, to avoid unmanageably large specimen sizes, oven heating typically needs to be conducted at temperatures over 100ºC. Thus, self-heating effects due to biological activity (which ceases at temperatures greater than ca. 80ºC) and due to the presence of moisture cannot be evaluated.

For some of these real-world complications, there has been discussion in the literature, however, none of the above factors lend themselves to any simple correction scheme. Composite products, however, would lend themselves to improved treatment by a modified testing strategy, e.g., by making up cubes of composite rather than cubes of a single material.

A somewhat unanticipated advantage of the oven-basket method is that the results often have a wider range of validity than the F-K theory itself, when it comes to temperature-dependent constants. Material properties, such as thermal conductivity, which vary with temperature cannot be treated by any tractable form of F-K theory. Yet when data are plotted using the FRS procedure for substances having such temperature-dependent properties, it is often seen that straight lines are obtained. This suggests that the effects of various temperature-dependent constants can cancel out sufficiently to produce the linear plots. The FRS procedure, consequently, can be more robust than thermal analysis procedures (see below), which do not provide any satisfactory solutions for situations where the properties are temperature-dependent.

Finally, it is important to point out that oven-basket test procedures, even though they are the most robust form of small-scale testing currently known, have only limited *validation data* and that it may not be prudent to extrapolate to larger sizes. The largest oven-basket sample reported to have been used[44] is 0.9 m, which is much smaller than piles of material are commonly stacked in various industries. Few actual validation studies have been published. A study on activated charcoal[162] concluded that small-scale data followed a linear relationship well up to a size of 0.2 m, but an 0.6 m size oven-basket sample deviated substantially, as did real incidents involving a material size of 2 – 3 m. Both the latter deviations were on the conservative side. For a number of substances, effects such as listed above (e.g., flow of moisture) may dominate in real-scale piles and the effect may be inadequately or incorrectly treated using F-K based extrapolations. In summary, Beever[54] wisely advises of "…risks of extrapolating over orders of magnitude in size" even with this most-refined of the small-scale test procedures.

Oven-basket tests: crossing point methods

This class of tests has often been suggested as quick, small-scale laboratory procedures for self-heating. In a traditional crossing-point scheme, a sample is equipped with at least one thermocouple, located in the middle, and is placed in a temperature controlled oven. The oven temperature is ramped up at a relatively slow rate. If at a certain time the specimen thermocouple reading exceeds the oven temperature, then this is declared to be the 'critical temperature.' The test implicitly relies on the assumption that the small oven sample will undergo thermal runaway at the same temperature as the real-scale pile. As discussed extensively

earlier in this Chapter, both theory and practical experience indicate that the runaway temperature is very strongly affected by the size of the sample, thus simple crossing-point test results are without much value. The results of such testing can, at best, be used to compare the self-heating proclivity of two very similar substances. They are not capable of predicting real-scale thermal runaway conditions[78].

A much improved scheme was proposed by Chen et al.[56] In their scheme, a variant of the crossing-point method leads to quantitative data essentially similar to what is obtained in the standard oven-basket test. In this technique, the oven is held at various constant temperature values and is not ramped. A cubical basket is inserted cold and the temperature is monitored at the center of the specimen and at the edge of the specimen. When the two temperature readings become identical, then, by definition, no heat is being transferred between these two locations within the specimen. Using the equation for conservation of energy and assuming that there are no space-wise gradients gives:

$$\rho C \left.\frac{dT}{dt}\right|_p = \rho\, QA \exp\left(-E / RT_p\right)$$

where the subscript p denotes conditions at the center of the sample. Figure 30 shows results for a coal sample tested at slightly super-critical conditions[21]. The critical value of T_p for 50 mm cubes of this material was 401.5 K (128.4ºC). At 135.6 min, it can be seen that the temperature profile is flat. By repeating the test at various oven temperatures (which do not come explicitly into the above equation), a series of pairs of data points T_p vs. dT/dt is obtained.

Then, by plotting $(1/T_p)$ on the x-axis and ln(dT/dt) on the y-axis, a straight line is obtained according to the relation:

$$\ln\left(\left.\frac{dT}{dt}\right|_p\right) = \ln\left(\frac{QA}{C}\right) - \frac{E}{R}\frac{1}{T_p}$$

The slope is $-E/R$ and the y-axis intercept is ln(QA/C), as illustrated for the same coal material in Figure 32. Often for convenience in dealing with small numbers, $1000/T_p$ is plotted on the x-axis, instead of $1/T_p$. The slope obtained in Figure 32 is –9.378. The actual slope on a graph where $1/T_p$ would have been plotted would be = –1000×9.378 = –9378. Then, E = 9378×8.314 = 77970 J mol^{-1} = 78.0 kJ mol^{-1}. Knowing C, a value for QA may also be obtained. By contrast, in the standard oven-basket procedure, to get QA from the plotted data requires knowing the thermal conductivity λ. Since values of thermal conductivity for porous, possibly moist, substances are generally less certain than their C values, the crossing-point procedure can determine QA more robustly. In the present example, the y-axis intercept of the straight line is found to be 22.32, thus

$$22.32 = \ln\left(\frac{QA}{C}\right).$$

If the value of C = 1000 J kg^{-1} K^{-1} is used, then QA = 1000 exp(22.32) = 4.9×10^{12} W kg^{-1}. Observe that the size of the oven-basket sample does not enter into the calculations. If various sizes are used, the points will all follow the same line. For comparison purposes, the value P, which is the y-axis intercept in conventional plotting of oven-basket data, can be obtained as:

$$P = \ln\left(\frac{E}{R}\right) + \ln\left(\frac{QA}{C}\right) - \ln(\alpha)$$

where we note that the thermal diffusivity α (m^2 s^{-1}) is defined as $\alpha = \lambda / \rho C$. The first two terms in the above equation are directly obtained as results from the plot. The value of thermal diffusivity however, is not determined by the test, and a handbook value needs to be found.

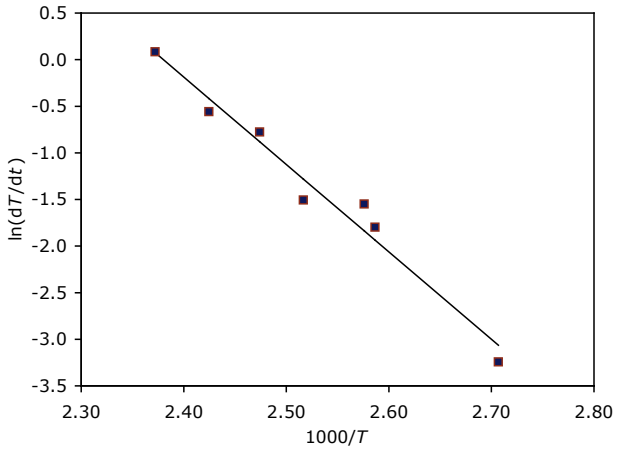

Figure 32 The results for coal self-heating tests plotted according to the crossing-point method of Chen et al.

McIntosh and coworkers[21] also studied coal and found that results using the standard oven-basket method and the crossing-point method were indistinguishable. They further studied the same sample with thermal analysis and obtained a value of E = 109 kJ mol^{-1} from DTA tests. This, they observe, is distinctly erroneous, since the thermal regime in the DTA test did not correspond to the low-temperature chemistry observed in actual self-heating. Sujunti et al.[163] applied the crossing-point method to an Australian coal and demonstrated that (a) the kinetic parameters derived were insignificantly different from the ones obtained from standard oven-basket tests; and (b) the size of the baskets used in the crossing-point tests did not have a noticeable effect on the results.

The best place to put thermocouples using the cross-point method is a crucial issue. Clearly, one thermocouple should always be at or close to the center. Various proposals have been made concerning where the second thermocouple is best located. In the example of Figure 30, it would seem that placing the thermocouple at or near the edge would be best, since greatest sensitivity to a relative difference of temperatures would be had. But in the example shown in Figure 15, placing the thermocouple at the edge does not make much sense, since only the central portion ever gets reasonably flat. In their work, McIntosh et al. recommended that the best place to measure the peripheral temperature is 10 mm away from the center. Chen et al. made many of their measurements using an 8 mm spacing[164].

In doing crossing-point tests, it is important to understand under what conditions and where the temperature profile across the specimen can ever be flat. In general, a theoretical study[165] has indicated that a substance that is originally at a uniform ambient temperature and is then quickly inserted into an elevated temperature environment will never show a flat temperature profile. A specimen quickly assembled of materials that are originally at oven temperature but disaggregated would, of course, show a flat profile, but only for the trivial case at time = 0.

Jones[166] developed an alternative crossing-point method wherein he does not instrument the sample with off-center thermocouples, but rather uses the oven temperature as the second temperature. Figure 31 shows that, at the time that the flat profile occurs in the center of the specimen, the oven temperature is notably lower, being 7ºC less in the example graph. If the Jones method had been used on these data, equality of central thermocouple and oven thermocouple would have occurred at 175 min, which is different from the 190 min at which the temperatures from the two in-sample thermocouples became equal. In making the data plot, both a different temperature and a different dT/dt would have been recorded at that instant. Chen[167] illustrated this in a comparison plot and showed that the kinetic properties that would have been derived would have been different by more than just the amount of data scatter. Chen's examples suggest that the value of the y-axis intercept is more notably altered than the value of E, if the oven temperature is substituted for the specimen peripheral temperature. In addition to Chen's experimental analysis, Gray et al.[165] performed theoretical computations which demonstrated that if the specimen's center has become equal to the oven temperature, the center temperature has to be the *minimum* temperature that is found in the profile of the specimen at that instant. In other words, dT/dx cannot be equal to zero at that time at the central axis of the body.

Comparing among the methods, the Jones method is somewhat easier to use, but the Chen method has better theoretical justification. Comparing either of the crossing-point methods against the FRS oven-basket method, the advantages are:

(a) Only one specimen size is required and no trial-and-error procedure is needed.
(b) Any symmetric shape of specimen (cube, cylinder, sphere, etc.) may be selected without needing to perform computations that are geometry-related.
(c) Because the convective boundary condition drops out[168], it is neither necessary to ensure that $bi \rightarrow \infty$ nor to correct for a non-infinite value.

They also have these drawbacks:

(a) The theoretical foundation for the method is somewhat shaky and Prof. Brian Gray[75], one of the ranking theoreticians on the subject of self-heating, concluded that crossing-point methods "can give dangerously flawed results."
(b) As an entirely separate test procedure, a value of thermal diffusivity must be obtained for the specimen, and this can be difficult, especially for moist materials.
(c) More precise workmanship is required.
(d) The method cannot be used for specimens (e.g., oil-soaked cloth) that show hot spots or other non-uniformities. For this reason, it is desirable with the crossing-point methods to include additional thermo-

couples in the basket so that uniformity can be assessed. Routine testing using only 1 or 2 thermocouples and no visual observation of the outcome should never be done.

(e) A highly accurate specimen center temperature measurement must be made. In the standard oven-basket technique, no quantitative use is made of these data—the reading only has to indicate thermal runaway. In the crossing-point methods, by contrast, errors in measuring that temperature would directly reflect an error in heat balance. This is not a trivial concern, since metallic thermocouple wires may have a thermal conductivity of a thousand times that of the lightweight, porous substances being tested. To avoid significant 'stem loss' errors, a spiral-shape thermocouple has been proposed[169]. In any case, the crossing-point method requires a much higher accuracy of temperature measurement than is demanded in the FRS oven-basket procedure, and this may be quite difficult to achieve[170].

(f) The methods rely on being able to draw a robust straight line through an $\ln(dT/dt)$ versus $1/T$ plot. But Jones[171] found that some materials—sawdust, coconut waste, and bagasse—produce data plots with a high degree of scatter through which a reliable straight line cannot be passed. This is said to be a chemical as opposed to an instrumentation issue, since using the identical equipment and procedures other types of substances do produce good straight lines.

To obtain the needed value of the thermal diffusivity α, several authors[172,173] used the following scheme. Graphical solutions in Carslaw and Jaeger[174] are provided that, with some manipulation, can be used to compute the temperature rise at the center of a cylinder, T, originally equilibrated to a temperature T_i, then plunged at $t = 0$ to an environment at T_f. Defining $\theta = (T–T_i)/(T_f–T_i)$, and knowing the height/diameter ratio of the cylinder, L/D, and its radius r, the value of $\alpha t/r^2$ can be determined for which $\theta = 0.5$, as given in Table 18. Experimentally, the procedure depends on being able to abruptly establish a new temperature on the surface of a cylinder. Consequently, while a cylinder containing the test material may originally be equilibrated to T_i in an air environment, it must be plunged into a water bath and not an air oven at T_f. A thin-walled copper cylinder is typically used which is sealed at one end and contains a removable end-cap made water-tight with an O-ring seal. A thermocouple is passed through the sealed end and fixed at the center of the cylinder. A viable procedure is to equilibrate the specimen in an air oven to a modestly elevated temperature, say 50 – 100ºC, then plunge it into an ice-water bath at 0ºC. The thermocouple output is used to determine the time at which a temperature exactly halfway in between the two endpoint temperatures is attained. Knowing the L/D of the cylinder, a value of $\alpha t/r^2$ is found from Table 18. Since the values of t (s) and r (m) are known, the value of α ($m^2\ s^{-1}$) can be determined. In conducting the experiments, it is important to weigh the cylinder before inserting into the oven and after removal from the ice-water bath. If the weight has increased, it indicates that water has leaked into the cylinder. The specimen should also be examined visually to make sure its condition has not altered, for example, that a lightweight material has not become compacted.

Table 18 Values of $\alpha t/r^2$ which correspond to $\theta = 0.5$

L/D	1	1.1	1.2	1.3	1.4	1.5	1.8	2.5
$\alpha t/r^2$	0.167	0.175	0.182	0.187	0.191	0.195	0.200	0.204

Oven-basket tests: Nordtest method

The Nordic country standards group Nordtest published a novel oven-basket procedure as NT Fire 045[175,176]. Similar to the crossing-point methods, it was developed to eliminate the need for time-consuming, trial-and-error testing. The Nordtest method replaces isothermal heating with a linearly-rising oven temperature regimen. Two specimen thermocouples are used: one at the center, the other halfway between the center and the edge. At least three different specimen sizes are to be used, with the sizes to scale by 2× from each to the next. The test method requires that a suitable heating rate be guessed, or developed by experience, so trial-and-error aspects are not entirely eliminated. There is no published validation of results from this method, nor is there even a comparison to data obtained from FRS-type oven-basket testing. Thus, in view of the fact that at least the latter comparison does exist for Chen's crossing-point method, it would be hard to consider the Nordtest method as the preferred time-saving technique.
