This method[177] which never became an official IMO test, but has been widely used in its draft form, is based on a highly simplified version of the FRS oven-basket procedure. The simplification is justified since it is intended for pass/fail rating of products and not for product development or risk management purposes. A single oven temperature of 140ºC and a single basket size of 100 mm are used. The oven test is run for 12 h and failure is declared if the temperature at the center exceeds 200ºC (400ºC in the case of activated carbon or activated charcoal). The method is based on the assumption that a value of $E \approx 77$ kJ mol^{-1}, which has been found to be a good value for US bituminous coals[178], will also hold approximately true for any organic substances. With the assumption that the slope (given by $–E/R$) is a fixed, known value, a single point suffices to establish a straight line. The real-life conditions are presumed to correspond to a shipping package of a 3 m cube and a ship's hold temperature of 38ºC. Thus, if the 100 mm cube does not lead to thermal runaway at 140ºC, neither will the 3 m package at 38ºC. But the range of values of E which can be found for common substances is wide. If the true value is 100 kJ mol^{-1}, then critical conditions will occur for 9 m and not 3 m. Even higher values ca. 130 kJ mol^{-1} are common; for such a case the true critical size would rise to

over 37 m. A scheme which inserts unexpected factors of up to 12× is evidently rather crude.

Oven-basket tests: UN Test N4

The UN version of the oven-basket test generally resembles the IMO test, but with some differences. A unique feature is the basket-inside-a-basket arrangement. The inner basket of 25 or 100 mm cube size is put into an outer wire-mesh cubical basket of 150 mm size. This is ostensibly to keep material from being scattered by air flow velocity. This is contrary to what the many decades of research at FRS indicated as being appropriate and has been criticized by Jones[179]. The outer basket creates a poorly defined convective heat transfer situation, making results less amenable to quantitative interpretation.

In the procedure, a test is first conducted using the 100 mm basket at 140ºC for 24 h. Failure occurs if a temperature rise of ¤ 60ºC is recorded by a thermocouple placed in the center of the sample. If the specimen passes, then no further testing is done and the substance does not need to be classified into Division 4.2. If it fails the 100 mm basket test, then another test is run using a 25 mm basket. If the test using the 25 mm basket at 140ºC also fails, then the substance is classified as requiring Division 4.2 Packaging Group II. If the second test is passed, then a third test is run using a 100 mm basket. The third test is run at 100ºC if it is desired to qualify the substance for shipping in sizes no greater than 450 L. Alternatively, it is run at 120ºC if the substance is to be qualified for shipping in sizes of 450 L to 3 m^3. If the substance passes either of these versions of the third test, then it is classified as requiring Division 4.2 Packaging Group III, with appropriate size limits.

Hotplate tests

A testing strategy is possible where the substance is arranged as a uniform layer on a hotplate. The hotplate provides uniform heating, while the upper surface of the specimen is exposed to ambient cooling. The geometry has been used most commonly for examining the self-heating propensity of dust layers, on the grounds that it closely resembles the end-use geometry. In this context, hotplate tests have normally been used just as a rough pass/fail screening procedure, but the experimental arrangement is sometimes also used to derive quantitative data in the context of the F-K theory. Use of theory for this problem, along with example data, have already been presented above under *Ignition of dust layers*. The precision attainable with hotplate testing is lower than with oven-basket testing, but the tests can be conducted quicker[180]. Since the test methods typically use layer thickness of 25 mm or less, higher temperatures must be used in conducting the test in order to reach critical conditions. Consequently, correction for reactant depletion may be needed. The test apparatus must provide for a specimen diameter which is much greater than the depth. Limited testing[181] showed that reported layer ignition temperatures for a 20 mm depth decreased when going from a diameter of 100 mm to 140 mm, but did not further decrease on going to 180 mm. This suggests that, for a 20 mm depth, 140 mm is the minimum diameter for obtaining accurate results. Another study[182] showed that, for layers of 10 – 25 mm depth, in going from 100 mm to 150 mm diameter test specimens the critical hotplate temperature decreased by ca. 10ºC. The accuracy of this work is not clear, however, since the authors reported erroneous critical heat fluxes for ignition.

Analysis of data from hotplate tests according to a theoretical model is more complex than that for oven-basket tests, since there are two temperatures that must be considered—the ambient temperature and the hotplate temperature—whereas with oven-basket testing only a single temperature enters the problem. Thus, theory-based calculations are fairly onerous. For practical purposes, it can be sufficient to plot $\ln\left(T_h^2 / d^2\right)$ as a function of $1/T_h$, where T_h = hotplate temperature (K) and d = layer depth (m). Example plots are shown in Figure 33 using the sawdust data of Bowes[30] and Palmer[183]. Reasonably straight lines are usually produced, and these plots can be used to estimate the value of d for a given T_h. In the example graph, values of d ranged from 5 mm to 100 mm. This includes most of the depth range likely to be encountered in practical testing and a deviation is only seen for the 100 mm data point; the experimental accuracy of the latter is questionable, since the reported value is identical to that given for the 75 mm depth. The value of E might be estimated by assuming that the slope = $-E/R$, but this is a crude estimate. For the given data, a value $E \approx 140$ kJ mol^{-1} would be estimated, but the actual value is around 100 kJ mol^{-1}.

The reason for the poor accuracy is because, same as for oven-basket testing, the value that should be plotted on the

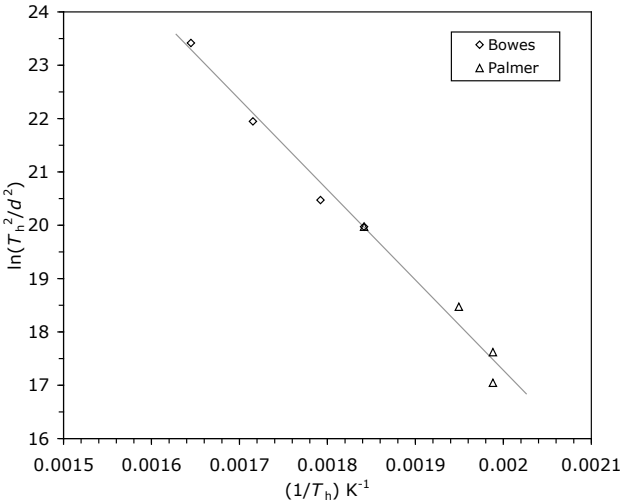

Figure 33 Sawdust hotplate results plotted according to simple correlation

y-axis is $\ln\left(\frac{\delta_c T_h^2}{r^2}\right)$ and not $\ln\left(T_h^2/d^2\right)$ or $\ln\left(T_h^2/r^2\right)$. For oven-basket testing at the $Bi \rightarrow \infty$ limit, the value of δ_c is a simple geometric constant for a given shape. Consequently, whether it is included or omitted simply changes the y-axis intercept of the plot but does not change the slope. For the hot-surface problem, however, the value of δ_c is never a constant, consequently, omitting it causes an incorrect slope to be obtained.

To obtain an accurate solution from theory is cumbersome. As shown above in the theory section, a non-dimensional variable θ_o is needed, which is defined as:

$$\theta_o = \frac{E}{RT_h^2}(T_o - T_h)$$

The value of ambient temperature T_o and hotplate temperature T_h are known. But the value of E is generally not known a priori, and using the slope in a simple data correlation plot will give the wrong result. Thus, the value must be obtained from some other test results, e.g., oven-basket testing. Having a value for θ_o, the value of δ_c is found from Figure 8; note that for each experimental point where a different value of T_h was used, a different value of δ_c will be obtained. Now, the same procedure as involved in plotting oven-basket test results can be used. Using that procedure, $\ln\left(\frac{\delta_c T_h^2}{r^2}\right)$ is plotted on the y-axis, versus $1/T_h$ on the x-axis. But the only useful output of that exercise is that a value for *QA* can be computed; the procedure will also give an improved estimate of *E*. This suggests that hotplate testing has only very limited value as a tool for obtaining material self-heating properties. Because of this, it is not a suitable alternative to oven-basket testing, but does have utility for simple interpolating and extrapolating of data.

With some materials, additional difficulties are encountered if hotplate tests are to be used to impute material properties. Henderson and Tyler found that two criticality temperatures can be reported for sodium dithionite, depending on whether testing proceeds from high temperatures to lower, or vice versa[184]. This is due to two exotherms that the material possesses, one at a higher temperature and one at a lower. When temperatures starting at 400ºC and going down were used, a pseudo-critical temperature at ca. 380ºC was found. But when starting testing at 185ºC, a lower critical temperature at ca. 188ºC was seen. It appears that in the high temperature regime, the low-temperature exotherm is lost in the very rapid temperature rise during the 'assembly' of the dust layer.

Tyler and Henderson[51] further tested sodium dithionite in hotplate tests where they measured the Biot number. Apart from the fact that this substance shows non-Arrhenius kinetics, they discovered a complication in representing the heat transfer at the upper surface. Using the highest ventilation velocity that was possible without scattering the powdery sample, they found that the Biot number varied greatly with layer depth, going from 0.42 for a 5 mm depth to 4.3 for 40 mm. Conversely, if no forced ventilation was used, then the air temperature above the sample rose to very high values (ca. 60ºC), making it impossible to assume a fixed, known ambient temperature value. Thus, they concluded that plots based on the assumption of a constant δ_c value would be in serious error, since δ_c is strongly affected by the value of *Bi*, and *Bi* is notably dependent on layer depth. To obtain data on real material properties, they concluded that it was necessary to measure *Bi* and evaluate δ_c for each data point using the measured *Bi* value for that test run.

Ohlemiller and Rogers[185] presented a detailed analysis of cellulose insulation tested with a hotplate method. They encouraged its use, but with the proviso that predictions from the method to end-use situations be considered, at best, semi-quantitative. Nagy and Verakis[92] claimed that a correlation exists between the critical hotplate temperature when dusts are tested in a 13 mm layer hotplate test and the AIT, as determined in the Godbert-Greenwald furnace (see Chapter 5). This claim was based on only 7 data points and an examination of larger data sets[186] shows that no general correlation exists (nor should one be expected).

ASTM E 2021 test

The rather recent ASTM E 2021 test[187] for self-heating of dusts uses a standard hotplate (Figure 34), on top of which is placed an aluminum plate, 200 mm dia. and 20 mm thick. Due to the plate's high thermal conductivity and high mass, its top surface is much more nearly isothermal than is the surface of the hotplate itself. A steel ring of 100 mm dia. and 12.7 mm depth is placed on top of the aluminum plate and filled with the dust to be tested. The dust tested is to be sub-200 mesh (< 75 μm). The test is discontinued if, after 60 min, self-heating is not apparent. The maximum test temperature is 390ºC. Three standard substances have been characterized with this test. Fine-flake brass dust (sub-325 mesh) coated with stearic acid gives 144 – 160ºC, Pittsburgh coal dust gives 230 – 240ºC, and lycopodium spores give 240 – 250ºC. It is not intended that the data from this test method be used for calculation purposes. Instead, if the assumption is made that dust layers will not exceed 12.7 mm in real life, then the results (adjusted by some prudent safety factor) are simply to be used to limit maximum temperatures of devices upon which dust layers may accumulate. Some of the background of this test has been described by Miron and Lazzara[115] and by the National Academy of Sciences[188]. The test, as specified in the ASTM standard, is very simplistic in that no variations in layer depth are examined. In addition, as mentioned above, several experimental studies exist showing that, to avoid excessive edge effects, a diameter of at least about 140 mm should be used. Thus, for most purposes apart from strict regulatory compliance, it is more appropriate to construct rings of 150 – 200 mm diameter and to vary the layer depth over a significant

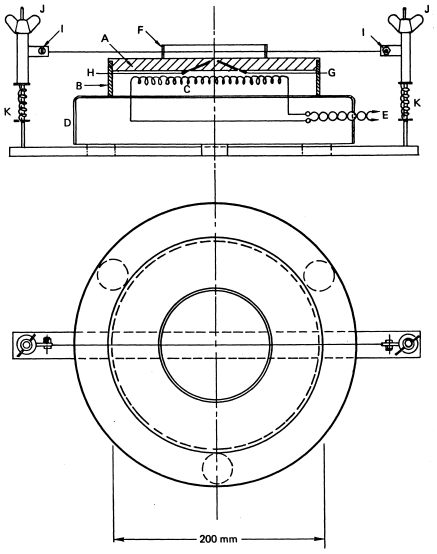

Figure 34 Hotplate test, general arrangement[188]

range. The European standard[189] EN 50281-1-2 is similar but uses a very small layer depth of 5 mm.

SCALING ACCORDING TO SEMENOV THEORY

Tests based on Semenov theory are mostly Dewar-type tests. For convenience, all Dewar tests are grouped into this section, even though the regulatory ones do not have much relation to theory.

General Dewar flask testing

A Dewar flask is a laboratory vessel similar to the well-known Thermos bottles. The sides and bottom of the container (Figure 35) are made of silvered glass in a double-wall construction, with a small vacuum gap in between. Conduction and convection do not exist in a vacuum, but radiation still occurs; thus, the silvered coating is intended to reflect the bulk of the radiation back into the contents. The top cover is typically a lightweight foam plug.

Dewar tests are commonly used for liquids, but one of the earliest devices was developed by the Bureau of Mines in the 1920s for the studying of coal[190]. A 4 L Dewar was filled with oil and in the center was inserted a small glass tube holding 35 g of coal sample. The tube also contained one junction of a thermopile, with the other end being immersed in the oil. The oil bath also contained a heater and a stirrer, with a temperature controller operating the heater so as to maintain very close to zero temperature difference between the coal sample and the enveloping oil bath. The system could maintain an accuracy of 0.15ºC per hour. Thermal explosion theory was not yet developed at that time, so the authors did not analyze their results in the context of a theory.

While the heat losses from a Dewar flask are low, they are high enough that they must be explicitly modeled. It is assumed that the temperature of the liquid within the Dewar flask is uniform. This allows analysis according to Semenov theory. For a small flask, it would seem to be a reasonably accurate assumption, but no error analysis exists. If the substance in the flask is at a uniform temperature, then the cooling of the flask can be represented by a lumped capacitance model. In that case, the only resistance to heat transfer is at the boundary via the convective heat transfer coefficient h_c. If the ambient temperature is T_o and the initial temperature of the Dewar's contents is T_i, then the temperature of the contents at any time t is T, given by:

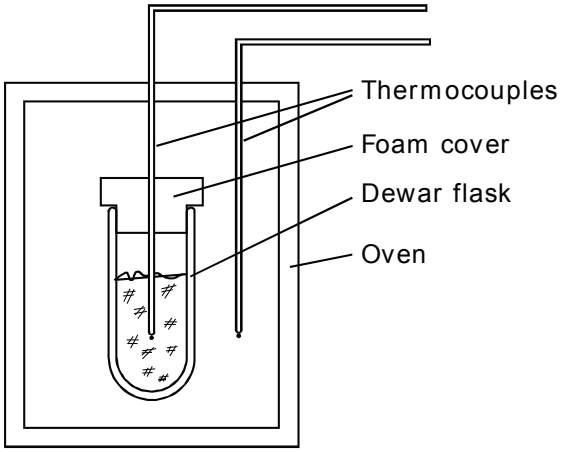

Figure 35 Dewar flask test
(Copyright Elsevier Science, used by permission)

$$T - T_o = (T_i - T_o)\exp\left[-\frac{h_c S}{\rho V C}t\right]$$

where S = surface area, ρ = density, V = volume, and C = heat capacity. It is not necessary to determine all of the factors within the exponential separately, however. Heat losses from Dewars are normally characterized by the half-time $\tau_{1/2}$, that is, the time it takes for a substance to cool to half its original temperature elevation above ambient. Experimentally, a hot liquid (commonly, a low heat capacity substance such as dimethyl phthalate) is poured into the Dewar and its temperature monitored. When $T - T_i$ has dropped to $\frac{1}{2}(T_i - T_o)$, the half-time has been reached. The relation according to the above equation then gives:

$$\frac{h_c S}{\rho V C_p} = \frac{\ln(2)}{\tau_{1/2}}$$

and

$$T - T_o = (T_i - T_o)\frac{1}{2}\exp\left[-\frac{t}{\tau_{1/2}}\right]$$

Thus, $\tau_{1/2}$ is the only property of the Dewar that one needs to know in order to compute how the starting-point temperature decays over time. Values of $\tau_{1/2}$ for an 0.5 L Dewar flask may be on the order of 7 h.

The laboratory-scale results would be directly usable, without additional hypotheses or mathematical manipulation, if

the ratio $h_cS/\rho VC$ in the laboratory test were the same as in the large-scale. The surface/volume ratio S/V will, by definition, be much greater for a small-scale experiment. But since the (heat loss)/(heat generation) ratio actually goes according to $h_cS/\rho VC$, the role of the convective transfer coefficient h_c can be exploited. In a Dewar vessel convective losses are much smaller than the convective losses from a cube, sphere, etc. which is simply exposed to air. Thus, by using the low h_c of the Dewar, the high S/V ratio of the bench-scale experiment can be largely overcome, and the data—approximately at least—taken to be representative of large-scale conditions.

A rigorous analysis of the data according to Semenov theory can be done, as outlined in Chapter 10. But many chemical manufacturing processes involve a relatively short time for which the material exists in a heated state. Thus, time to thermal runaway is often the needed information, not a determination that thermal runaway can/cannot occur. For those cases, Grewer[72] suggests that results of adequate accuracy can be obtained simply by plotting $\log(t_{ig})$ on the y-axis and $1/T$ on the x-axis, where t_{ig} is the thermal runaway time (s) and T = temperature (K). The results should fall along a straight line and the maximum permitted temperature at any desired storage time can be picked off the plot. For comparing substances, the value ADT_{24} is commonly reported. This is the Adiabatic Decomposition Temperature for a 24 h period of exposure. It can be determined by simply reading the temperature at t_{ig} = 24 h from the graph. If the ρVC ('thermal mass') of the Dewar is not small in comparison to thermal mass of the sample, then a correction for the thermal mass of the Dewar may be needed before data are plotted. A more accurate treatment of the data can be made by using the Semenov ψ variable, as explained in Chapter 10.

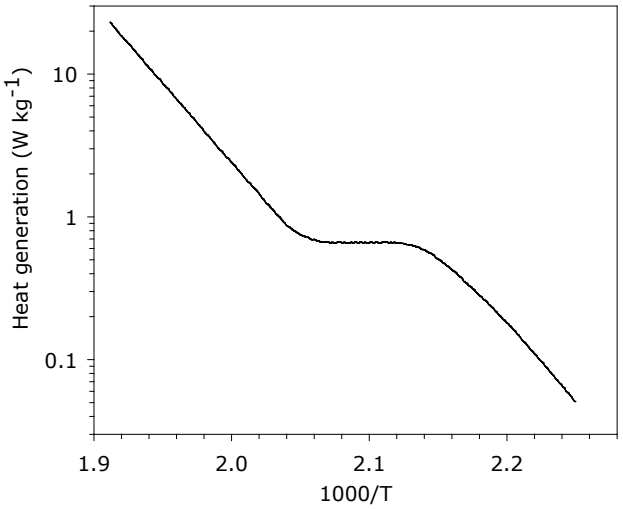

Figure 36 Ammonium nitrate (liquid) tested in the adiabatic storage test (note: this plot is presented using axes best suited for chemical interpretation, not the axes mandated by the test standard)

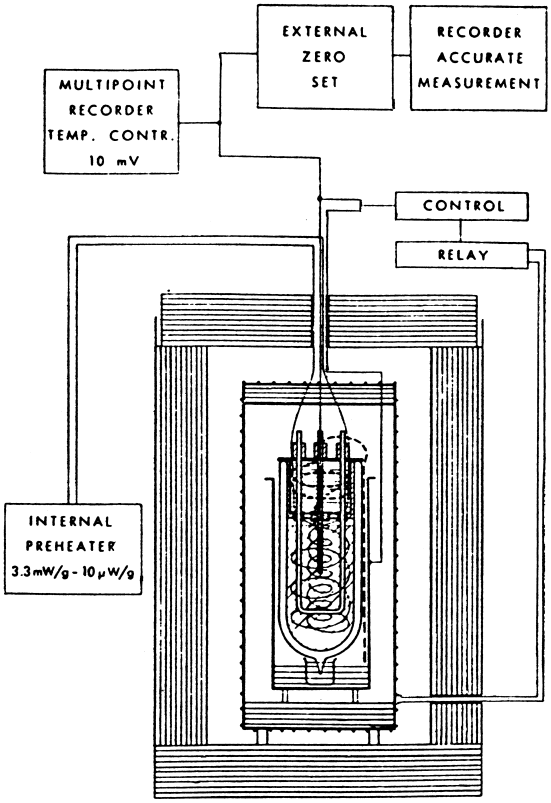

Figure 37 The adiabatic storage test
(Courtesy Elsevier Science, used by permission)

It is important to note that tests are expected to be destructive of the Dewar, so suitable safety precautions are needed in running Dewar tests. The walls of a Dewar flask are, of course, impermeable. Thus, difficulties would exist if a substance were tested where the self-heating reaction depends on atmospheric oxygen being supplied. Flow-through schemes can be arranged, but such gas flow is a non-adiabatic process, so complex corrections and calibrations can be necessary. In general, Dewar tests are only useful when the exothermicity comes from non-oxidative reactions.

A standard Dewar test method does not include any internal heaters. Some schemes have been described[191-193] where an internal heater is associated with the Dewar flask, in addition to the external oven. If properly controlled, a Dewar of this kind is effectively an adiabatic calorimeter.

UN Test H2—Adiabatic storage test

This apparatus comprises a 1.0 – 1.5 L Dewar, located inside a test oven and equipped with a feedback loop control to keep the oven with 0.1ºC of the Dewar contents (Figure 37)[194]. In addition, heating and cooling coils are placed within the specimen area—the former to rapidly bring up the substance to a desired starting point, the latter to help avoid an active explosion, if needed. The apparatus is first calibrated by passing known heating power into the sample

space and using the measured data to determine the heat capacity and the heat loss of the Dewar vessel and the heat capacity of the specimen. The actual testing is done by making numerous 24 h test runs at various temperatures. At each temperature, the heat generation Q_T (W kg^{-1}) is determined as:

$$Q_T = \frac{D(MC + H) - K}{M}$$

where D = rate of rise of temperature (K s^{-1}), M = mass of specimen (kg), C = heat capacity of specimen (J kg^{-1} K^{-1}), H = thermal mass (mass × heat capacity) of the Dewar (J K^{-1}), and K = heat loss (W). The heat loss term K is a temperature-dependent quantity and is obtained in a separate calibration procedure. The presentation of the data is done using the basic Semenov graph (Figure 3). The heat generation curve is simply values of Q_T, plotted as a function of the temperature T. The convective heat loss of the Dewar L (W kg^{-1} K^{-1}) is obtained using a separate test procedure, as described on page 405. Knowing this value of L, the heat loss line on the Semenov graph is plotted as a straight line of slope L and tangent to Q_T curve. The x-axis intercept of the heat loss curve gives T_o, which, upon being rounded to the next higher multiple of 5ºC, is defined in this test as the SADT. The sensitivity of the apparatus is about 10 mW kg^{-1}. An example of results from testing of ammonium nitrate[239] in the adiabatic storage test is shown in Figure 36 (the data in this figure are plotted not on a Semenov graph, but using axes that better illustrate the chemical reactions involved). Three regions are seen in the example graph. For temperatures < 200ºC (the sloping line corresponding to large 1/T values), the water formed from the decomposition reaction remains in the products. Over the range 200 – 220ºC, the water is boiled off; above 220ºC (the sloping line corresponding to small 1/T values), the water content remaining is nearly nil.

UN Test H4—Heat accumulation storage test

The test method is a Dewar test for liquids and wetted solids. An 0.5 L Dewar is used and it is stated that the heat loss characteristics of such a Dewar are similar to a 50 kg package of the intended commodity. The Dewar is inserted into an oven at a given temperature and it is noted whether the sample's temperature rises to 6ºC above the oven temperature during 1 week after the time when the sample's temperature first reached 2ºC below the oven temperature. The SADT is the oven temperature, to the nearest ºC, which turns out to be required to obtain the 6ºC rise within a week.

CALORIMETER TESTS

A calorimeter is any device for measuring energy in the form of heat, commonly heat produced in a chemical reaction. There has been a very wide variety of calorimeters invented, the best known being oxygen-bomb calorimeters used to determine heats of reaction, especially heats of combustion and heats of formation. The four most common calorimeter designs are adiabatic, isothermal, isoperibol, and heat flux meter. Figure 38 shows the basic features of an adiabatic calorimeter. It is based on the principle that, if there is no temperature drop across a body then there can be no heat flow through the body. In the case illustrated, this is the 'bomb,' which is a small vessel holding the sample. Since if $T_2 \equiv T_1$, there is no heat loss from the sample-holding vessel, this adiabatic condition can be created by heating the liquid bath into which the bomb is immersed. The two thermocouples T_2 and T_1 are connected to an electronic controller regulating the power fed to a heater immersed in the oil bath. A stirrer helps keep the oil bath temperature uniform. Practical devices are generally more complex; for instance, the sample bomb is commonly immersed in an inner liquid bath. The temperature measured by thermocouple T_1 is the temperature of the reaction taking place under adiabatic conditions.

Another common arrangement is the isothermal calorimeter (Figure 39). A sample undergoing a reaction can be forcibly maintained at a fixed temperature by cooling or heating it. Commonly, both an electric heater and a cooling device need to be provided. The latter may be a refrigerant loop or electrical cooling (Peltier effect) can be used. A rather sophisticated control circuit is necessary that can control the two devices. The reaction temperature always stays at T_1. The heat released is equal to the electric power consumed by the heater, minus any cooling power used.

For fundamental thermochemistry studies, the isoperibol (constant temperature bath) calorimeter is most commonly used (Figure 40). The bath liquid is generally water, and its temperature can be maintained by circulating it through a water chiller (not shown). Since finite heat transfer takes place between the specimen at T_1 and the water bath at T_2, a substantial calculational effort is needed to derive a corrected value of T_1 which represents adiabatic conditions. This type of arrangement is uncommon for the studying of self-heating materials' hazards.

In a similar vein, external conditions can vary widely if the heat flow from the specimen volume can be quantified and its temperature appropriately corrected. Devices based on this principle are known as heat flux meter calorimeters (Figure 41). The apparatus requires that the sample volume be surrounded by a material of accurately known thermal conductivity. A series of thermocouples are installed on the inner and the outer surfaces of this insulator layer and the heat losses computed using the Fourier Law. Once the heat losses are known, the sample temperature can be corrected to reflect adiabatic conditions.

For self-heating studies, determining the rate of reaction is essential. Thus, standard calorimeter devices which have been developed for measuring heats of reaction (total heat) must be extended to encompass a determination of rates, not just ultimate values. The most common devices which have been used in industrial practice are discussed below. DSC is also a calorimetric technique, but is discussed under

Thermal analysis techniques, below, since historically it evolved from earlier, non-calorimetric thermal analysis techniques and it is used as part of the general thermal-analysis tests toolkit. There are a number of scaled-up off-shoots of DSC developed solely for industrial safety studies and these are covered in the present Section.

The above discussion focused on device types and their differences. But it is also useful to consider the types of calorimetry data from a chemical point of view, irrespective of how they were obtained. These fall into three types:
(1) adiabatic
(2) isothermal
(3) not adiabatic and not isothermal.
The ultimate purpose of the isoperibol and the heat flux meter calorimeters is to produce adiabatic data, thus only adiabatic and isothermal data production has been discussed so far. Another type of data that is possible to collect is constant-rate-of-rise. A small sample may be heated in such a way that its temperature rises at a fixed rate. This principle is widely used in thermal analysis instruments.

ADIABATIC CALORIMETERS

An adiabatic calorimeter, by definition, is one where means have been taken to provide a volume from which no heat losses occur. A truly adiabatic condition, despite the nomenclature, is an impossibility, but relatively-low heat loss devices can be built. The first modern adiabatic calorimeter design to become widely used for self-heating studies was that of Raskin and Robertson[195] (Figure 42). Extensive data using this apparatus were reported by Gross and coworkers[196,197]. A later design by Güney and Hodges[198] involves an inner Dewar which contains the sample and a thermocouple. The inner Dewar is placed in an outer Dewar, with the space between being filled by a highly conductive oil. The space also contains a heater, a stirrer, and the reference junction for the specimen's thermocouple. The thermocouple is used to operate a temperature controller which controls the heater. A more recent form of guard-heater type of adiabatic calorimeter has been described by Kotoyori[199]. More modern devices used by the chemical manufacturing industry are individually discussed below.

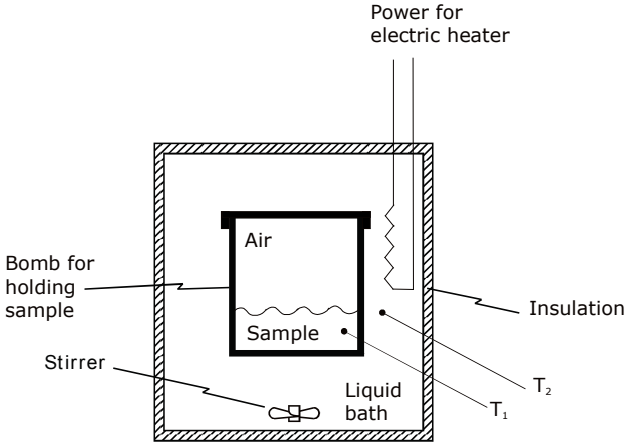

Figure 38 Adiabatic calorimeter (highly simplified)

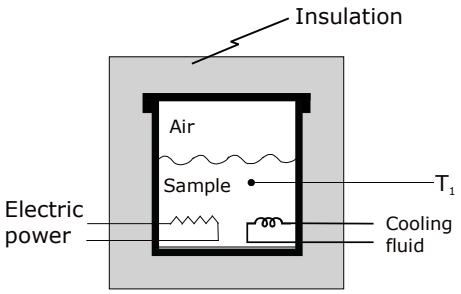

Figure 39 Isothermal calorimeter (highly simplified)

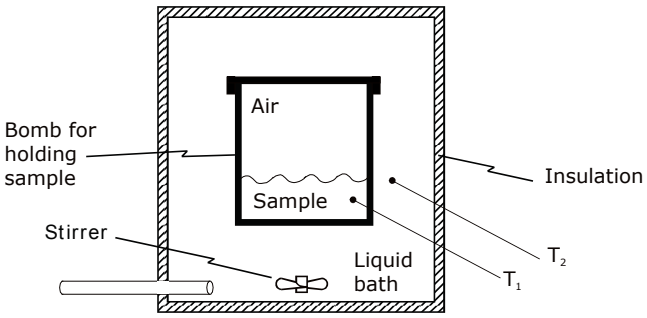

Figure 40 Isoperibol calorimeter (highly simplified)

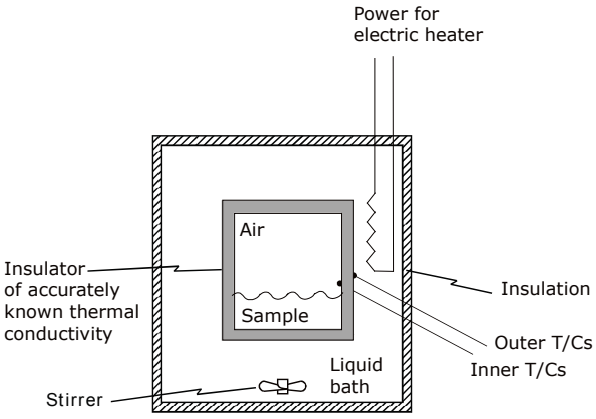

Figure 41 Heat flux meter calorimeter (highly simplified)

A proper analysis of an adiabatic calorimeter is quite complex, if thermodynamic errors are not to be committed. One immediate problem is that many industrial self-heating situations involve constant-pressure systems, and are not operated in closed-volume devices. The concept of an adiabatic system is easily applied only to closed systems. It can also be applied to a system which is leaking mass to the outside (due to thermal expansion), but in practice this is difficult, since accurate measurements of the convective outflow have to be made. Adequately accurate studies can be made in a closed, adiabatic calorimeter, if mass and heat balance terms are not simplified willy-nilly. Yin[200] gave a systematic derivation of the equations for an adiabatic calorimeter.

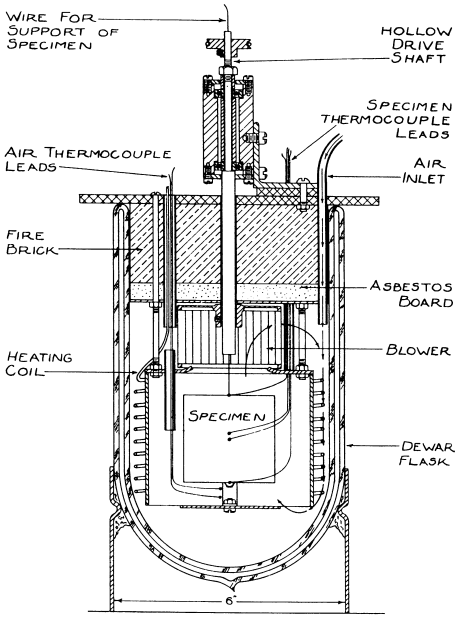

Figure 42 The adiabatic calorimeter of Robertson and Raskin

He also discusses the simplifying assumptions that are usefully made to render the problem tractable. Thus, it is often assumed that the heat capacity C_{vi} for any given chemical species i is independent of temperature and that change of the effective system heat capacity as the reaction takes place is zero:

$$\sum_i \nu_i C_{vi} = 0$$

where the summation is over all the species, both reactant and product. ν_i denotes the number of moles of substance i and is taken positive for products and negative for reactants. Note that if the number of moles in the system does not change as the reaction takes place, then automatically $\sum_i \nu_i \equiv 0$ and the above relation is satisfied. Many reactions are of this type, but others, of course, are not. In addition, it is assumed that only a single reaction takes place, that the reaction goes to completion, and that its reaction rate is:

$$\frac{dC_A}{dt} = k(T)\nu_A C_A^n$$

where concentration of the single reactant is C_A (mol m^{-3}); $k(T)$ = reaction rate constant (mol^{1-n} m$^{3(n-1)}$ s^{n-1}); ν_A = moles of reactant = moles of product; and n = the order of reaction (--). Then, a relatively simple equation is obtained for the rise in temperature of the system:

$$\frac{dT}{dt} = -\nu_A k(T)\left[\frac{T_f - T}{T_f - T_o}\right]^n \left(T_f - T_o\right) C_{Ao}^{n-1}$$

The ultimate temperature rise is:

$$T_f - T_o = \frac{\Delta U(T_o)\, C_{Ao}}{\nu_A \sum_i \left(C_{io} C_{vi}\right)}$$

where the subscript o denotes initial condition, thus, the summation over i includes all the components present at the start of the reaction, that is, both the reactants and the inerts. The inerts include any vessel in which the reactant is situated and, in Yin's formulation, its role is defined systematically, not as an arbitrary correction. The heat of reaction, $\Delta U(T_o)$ is obtained as:

$$-\Delta U(T_o) = \frac{\sum_i N_{if} C_{vi}}{\left(N_{Af} - N_{Ao}\right)/\nu_A}\left(T_f - T_o\right)$$

where N = number of moles; f denotes final (i.e. the state of the products); and i again is to be summed over reactants, products, and inerts. But it was already assumed that no reactants remain at the end of the reaction, the summation is only over the products and the inerts, and likewise $N_{Af} \equiv 0$ in the denominator.

In reality, a large fraction of studies in 'adiabatic' calorimeters are found in the literature where no thermodynamic rigor can be perceived and ill-defined systems are treated in a very casual way. Thus, one commonly finds a development of the following sort. It is assumed that the fraction of mass leaving an open system can simply be ignored and a heat balance performed on the portion that has not departed. In that case, the heat released by chemical reaction goes solely to raising the temperature of the sample and a heat balance gives:

$$C_p \frac{dT}{dt} = QAe^{-E/RT}$$

Since a vessel is present in the system, apart from the chemical reactants, it is then assumed that the mass of the vessel (commonly the inner liner of a Dewar) is also being raised to the same temperature. Thus,

$$\left(W_s C_{ps} + W_d C_{pd}\right)\frac{dT}{dt} = W_s QAe^{-E/RT}$$

where W_s = mass of specimen (kg), W_d = effective mass of Dewar that is being heated (kg), and the subscripts on C_p refer to specimen and Dewar. In reducing the data, $\ln(dT/dt)$ is plotted as a function of $1/T$. The slope of the line is $-E/R$, giving a value for E. The y-axis intercept is $\ln(QA/C_p)$ and from that a value of QA/C_p can be found. The data analysis procedure is only started when the specimen's temperature first equals that of the calorimeter. Substances which show autocatalytic reactions need a different treatment; as discussed by Grewer[72]. Empirically, autocatalytic behavior can be identified if, at the moment the specimen's temperature first reaches the calorimeter temperature, an exponential rise occurs, with no period of linearly-increasing temperature rise. Bowes[201] cautions that results of adiabatic calorimeter testing for specimens showing autocatalytic or parallel reactions can easily be misinterpreted, leading to unconservative predictions. He considers that isothermal methods should be used, instead, if there is any concern about this issue.

Another way that adiabatic calorimeter data are applied to practical problems is to plot the $\ln(t_{ad})$ on the y-axis and $1/T$

on the x-axis. If the reaction is not autocatalytic, the results will form a straight line with the slope $+E/R$. In many cases, the question to be answered is: Can this substance be kept safely for t time at T temperature? Since actual safe storage time will be greater than t_{ad}, simply extrapolating the results to the desired temperature and checking if the t_{ad} at that temperature is greater than the needed t can suffice.

ISOTHERMAL CALORIMETERS

Isothermal calorimeters, especially microcalorimeters, are a well-established tool of thermochemistry for studying Q, the heat of reaction. This does not suffice to pin down all of the needed problem variables, but a direct measurement can often be helpful. The measurement output of a microcalorimeter at any given temperature is a curve of 'specific power,' i.e., power/mass (W kg^{-1}), as a function of time. An instrument of modern design has been described by Nordon[202], who also reviewed some design history of earlier instruments. The method has only occasionally been applied to engineering studies of self-heating, see Tharmalingham[203] and Jones[204,205]. Jones suggested that microcalorimeter data can be used directly, as a routine go/no-go acceptance test, once the kinetic variables have been established for a particular chemical substance by other means. At any given temperature T_o, according to F-K theory, q, the specific power measured by the instrument is:

$$q = QAe^{-E/RT_o}$$

Thus, in his scheme, a value of q_c, the critical HRR per mass (W kg^{-1}) is first determined as:

$$q_c = \frac{\delta_c \lambda R T_o^2}{\rho E r^2}$$

where T_o is the critical ambient temperature for a given value of the radius, r. The evaluation process then simply involves measuring q in the microcalorimeter and determining whether or not $q < q_c$.

ARC AND APTAC TESTS

For the analysis of certain substances, it is important that the combustion products be retained in a constant-volume cavity. Thermal analysis equipment can use closed specimen cells, but these are typically not suited to explosive substances. Another limitation of DSC equipment was that, in the 1970s, the best DSC apparatuses had a resolution limited to about 20 W kg^{-1}; for certain reactions, however, it is necessary to probe lower values. The Accelerating Rate Calorimeter (ARC) was invented in 1978[206] by Townsend and Tou of Dow Chemical Co. to address these limitations. It was specifically developed for industrial screening, rather than fundamental research purposes, so the basic mode of operation was designed to allow rapid, unattended testing.

The ARC (Figure 43) comprises an oven in which is placed a spherical metal bomb. Unlike thermal analysis apparatuses, which are programmed only at one rate of rise, the ARC uses electronics which control the temperature in a 'heat-wait-search' mode (Figure 45). A starting temperature is programmed and the instrument heats up to this temperature, then holds the temperature. The reaction rate is monitored, and, if the rate is too small, the controller heats up to a higher temperature, and again holds that value. The reaction rate is monitored, and the process is repeated for as many steps as required. When the first temperature is found at which a pre-set minimum reaction rate occurs, the instrument then goes into adiabatic mode and tracks the HRR as a function of temperature from that 'final starting point.' Any 'adiabatic' apparatus based on a guard heater principle has a maximum rate at which the reaction can proceed so that control is not lost; for the ARC, it is 15ºC min^{-1}. Under poorly-selected test conditions, the adiabatic limit of the instrument may be exceeded; thus, the raw data must be examined to make sure that that the process has stayed within control. The standard bomb is a 25 mm sphere loaded with 5 – 10 g of sample, although variant bombs are available. A single test takes about 1 day to complete. The ARC test is only suitable for self-reactive substances; the specimen does not have access to air, and therefore it would not be a suitable test for self-heating substances where the exothermicity is caused by oxidation in air. Some of the advantages and limitations of the ARC method have been reviewed by Coates[207].

(Copyright Elsevier Science, used by permission)

The success of the ARC test motivated Young and Chippett[208] at Union Carbide Corp. to develop an improved apparatus termed the APTAC, Automatic Pressure Tracking Adiabatic Calorimeter (Figure 45). They saw that the need for a low thermal mass of the vessel and the ability to withstand high reaction pressures were not incompatible requirements, if the outside of the reaction vessel was pressurized. The differential pressure across the reaction vessel walls then becomes small and thick walls were not needed. The basic operating scheme is the same 'heat-wait-search' mode used in the ARC, although more sophisticated monitoring and control instrumentation is fitted. The APTAC is rated to stay in control up to 400ºC min^{-1}, which is a major improvement on the ARC.

(Courtesy TIAX)

The presentation of the data from the ARC that was developed by Townsend and Tou has been followed by most later users of the equipment, but unfortunately the nomenclature adopted is confusing. In heat transfer theory, the term 'thermal inertia' denotes the product: thermal conductivity × density × heat capacity. Townsend and Tou, however, defined *thermal inertia* as Φ:

$$\Phi = 1 + \frac{M_b C_{vb}}{M C_v}$$

where M = mass, C_v = heat capacity, the subscript b denotes values for the bomb, while the quantities without subscript refer to the sample. The heat capacity used is constant-volume, since the experiments are run in a fixed volume. Unless it is already known, the needed value of the sample heat capacity is obtained by using a DSC instrument. The quantity Φ, in fact, represents the 'inefficiency' of the calorimeter, or the total energy divided by the energy that goes into heating the specimen alone. Wilberforce[209] has more correctly termed it the *thermal dilution factor*. If the bomb had zero mass, then $\Phi \equiv 1$. The values of the measured temperature rate of rise dT/dt, or $\dot{T}$, are multiplied by Φ in order to obtain the true $\dot{T}$. In ARC terminology, the critical ambient temperature T_o is termed the *self-accelerating decomposition temperature*, T_{SADT}, while the critical stacking temperature, T_c, is termed the *temperature of no return*, T_{NR} (see Figure 46).

If Semenov theory is used (see Chapter 4), then the two temperatures are related according to:

$$T_{NR} = T_{SADT} + \frac{RT_{NR}^2}{E}$$

In an adiabatic system, the heat balance equation is:

$$\rho C_v \frac{dT}{dt} = Q\rho A e^{-E/RT}$$

Therefore,

$$\frac{dT}{dt} = \dot{T} = \frac{QAe^{-E/RT}}{C_v}$$

Now, the equation for the adiabatic induction period t_{ad} was earlier shown to be:

$$t_{ad} = \frac{C_v RT^2}{QAE} e^{+E/RT}$$

So substituting the value of $\dot{T}$ into this expression gives

$$t_{ad} = \frac{RT^2}{E}\frac{1}{\dot{T}}$$

In the ARC scheme, the experimentally-found quantity is the peak value of the rate of temperature increase, i.e., the peak $\dot{T}$. Zero-order Arrhenius kinetics would predict an ever-increasing rate of temperature rise until reactants are exhausted; at that point, reaction rate would immediately go to zero. The only reason that a peak is seen, followed by a diminished reaction rate, is that zero-order kinetics is not being obeyed. In ARC measurements, the *time to maximum rate*, TMR, or t_{MR}, is taken to be the same as t_{ad}. Clearly,

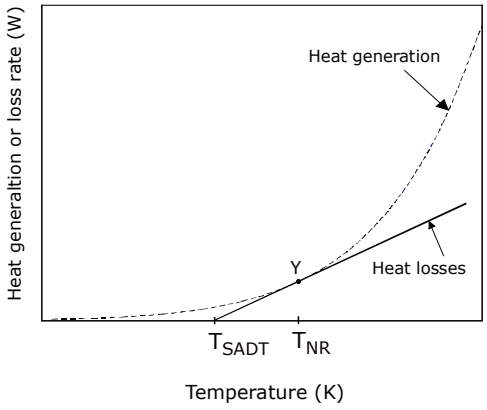

Figure 46 Nomenclature used in ARC testing

this is some form of approximation, since reactant depletion does not enter into the definition of t_{ad}, while t_{MR} could not exist, were it not for reactant exhaustion. Be that as it may, the experimental data are treated by plotting $T^2/\dot{T}$ on the x-axis and t_{MR} on the y-axis; the slope of the line gives R/E.

The energy of the reaction is determined as:

$$\Delta u = \phi \overline{C}_v \Delta T$$

where Δu = energy of reaction, per mass of reactant (J kg^{-1}), $\overline{C}_v$ = constant-volume heat capacity, mass-averaged for the sample and the bomb (J kg^{-1} K^{-1}), and ΔT = ultimate temperature rise (K). The resultant expression can be given in mole, instead of mass, units upon dividing by the molar mass. Reaction enthalpy Δh (J kg^{-1}) can be obtained as:

$$\Delta h = \Delta u + \frac{V \Delta P}{M}$$

where ΔP = pressure change within the bomb (Pa), V = volume of the bomb (m^3), and M = specimen mass (kg).

Since the order of the reaction n is not necessarily $\equiv$ 1, the general relation for reaction rate:

$$\frac{dc}{dt} = -kc^n$$

can be used. The kinetic constants are obtained from the ARC data by noting that the temperature rate of rise is expressible as:

$$\dot{T} \frac{(\Delta T)^{n-1}}{(T_f - T)^n} = A c_o^{n-1} e^{-E/RT}$$

where T_f = the ultimate value of T. By taking logarithms it can be seen that:

$$\ln\left[\dot{T} \frac{(\Delta T)^{n-1}}{(T_f - T)^n}\right] = \ln\left(A c_o^{n-1}\right) - \frac{E}{RT}$$

Thus, by plotting $1/T$ on the x-axis, and the left hand side of the above equation on the y-axis, a line of constant slope $-E/R$ will be found, if the value of n chosen was the correct one. The procedure thus entails trial-and-error plots using various values of n, with n = 1 being a reasonable starting place. When a straight line is found, the value of E is obtained from the slope of the line. The y-axis intercept is $\ln\left(A c_o^{n-1}\right)$ and, from that, the value of A can then be obtained. A substantially different data reduction technique was presented by Huff[210], where kinetic constants are not obtained, but scale-up to the real-scale problem is directly computed.

The ARC technique is not appropriate if a reaction is multistage or autocatalytic, and incorrect conclusions may be drawn from testing such materials[49]. Explosives expert Raymond Rogers[211] strongly cautioned that "the ARC has serious limitations and gives spurious results" when applied to solid explosives or propellants.

Even though it is not one of the UN tests, the ARC has received a lot of industrial use as a simple, quick tool for estimating the SADT that is required under the UN regulations. The original ARC apparatus had a sensitivity of 0.5 – 1.0 W kg^{-1}, and this was not adequate to estimate SADT values without extrapolation. Even with extrapolation, it has been found that SADT values are close to those of the official tests *on the average*, but with substantial plus and minus deviations. Thus, newer apparatuses having a sensitivity of 0.1 – 0.25 W kg^{-1} are considered to be necessary for acceptable predictions[213]. By contrast, it is estimated that the sensitivity of a typical DSC current-day apparatus is around 5 W kg^{-1}. Thus, if for screening purposes, the temperature of 'onset of reaction' is reported, values determined with the ARC are typically 50 – 100ºC lower than a comparable measurement with DSC. However, it must be re-iterated that the thermal stability problem contains three main variables: size, temperature, and time; focusing in on one of them to the exclusion of the other two cannot give a sound procedure. Industrial safety philosophies exist which deem it sufficient to use some convenient apparatus for obtaining an 'onset of reaction temperature,' then apply the results to industrial processes without considering size/time issues, but merely obtaining a 'safe working temperature' by decreasing the 'exothermic onset temperature' by some rule-of-thumb value such as 100ºC. Needless to say, the realism of this kind of approach is not reassuring[212].

A general technique for estimating the SADT from results in two different apparatuses having distinctly different heat loss characteristics has been presented by Whitmore and Wilberforce[213] who proposed a technique which involves using two apparatuses such as DTA, ARC, TAM, etc. Each apparatus is characterized by its own value of Φ, taken as Φ_1 and Φ_2. The heat capacity C of the substance can be computed in either apparatus. Also, in each apparatus the self-heat rate $\dot{T}$ (K s^{-1}) is experimentally determined at the temperature T of the onset of exothermicity. The specific power P (W kg^{-1}) is computed for both apparatuses according to:

$$P = \dot{T}\Phi C$$

An apparent activation energy E is computed as:

$$E = \frac{RT_1T_2}{T_1 - T_2}\ln\left(\frac{P_1}{P_2}\right)$$

The times to maximum rate at each T are computed as:

$$t_{MR} = \frac{RTC}{PE}$$

The values of t_{MR} are then plotted against $1/T$. The time constant of the package $t_{1/2}$ is then located along the t axis and from this a value of T pertinent to the desired package is found. This is the estimated SADT. The authors state that even though the method implicitly conforms to Semenov theory rather than Frank-Kamenetskii theory, it has been found to be accurate for solids, not just liquids.

OTHER INDUSTRIAL REACTION CALORIMETERS

Already in 1949 a reaction calorimeter was developed at VTT[214]. This apparatus was used to determine the heat released when air is bubbled through 20 g of substance held at 100ºC for 1 h. It was, effectively, an improvement over a 1905 test by Proctor and Holmes[215]. Using this device, it was found that the worst product, a linseed-oil based varnish, showed a heat of reaction of 250 kJ kg^{-1}, with various other paints and varnishes showing lower values. The method did not yield usable results for cellulosic products, since exotherms could not be detected at 100ºC.

Despite the long history of reaction calorimeters, the devices in current industrial use are all relatively recent inventions. Devices of some popularity within the chemical manufacturing industry include the Ciba-Geigy/Mettler reaction calorimeter; the PHI-TEC adiabatic calorimeter; isothermal microcalorimeters (heat flux calorimeters) such as the Setaram C80 and MS80, the Hart heat flux calorimeter, or the Thermal Activity Monitor (TAM) by ThermoMetric AB; the reflux heat flow calorimeter[216]; and the Fauske/Fike VSP (Vent Sizing Package). The reflux heat flow calorimeter is designed to study reactions near their boiling point, while the VSP is an adiabatic calorimeter which is intended to study liquids with a high potential of explosion. An advantage of some of these devices is their very high sensitivity. For example, the Hart heat flux calorimeter can detect a temperature rise of about 10^{-6} ºC min^{-1}, while an ARC may detect 0.01ºC min^{-1}, and a standard DSC no better than 0.1ºC min^{-1}. Sun et al.[217] demonstrated that quite misleading data can be reported if the sensitivity of the instrument is not sufficient for the substance being studied. Their study is especially interesting since it was based on a substance which led to an industrial spontaneous combustion accident. A highly sensitive instrument might be thought necessary when huge quantities are assembled of a substance that has only minimal self-heating tendencies. But the amount in the accident was moderate—a 220 L drum—yet the ARC method gave results very much different from the more sensitive C80 apparatus.

Many reaction calorimeters are operated in a similar stepwise manner as is the ARC. A temperature is selected and held for a few hours until a steady heat flow (mW) reading is obtained. A higher temperature is then selected, and the process is repeated. From the stepwise curve, a table of temperature vs. heat flow can then be created. Once this is done, Yu and Hasegawa[218] suggest that reaction calorimeter data be analyzed by allowing the reaction to have a to-be-determined order n:

$$\dot{q} = QAW^n \exp(-E/RT)$$

where $\dot{q}$ = heat flow (W), Q = heat of reaction (J kg^{-1}), A = pre-exponential factor, W = mass (kg), E = activation energy (kJ mol^{-1}), and T = temperature (K). If n =1, then the units of A are s^{-1}. Taking logarithms of both sides and restricting consideration to the initial stage of the reaction, when the mass W is still close to the original mass W_o (i.e., ignoring depletion of reactants):

$$\ln(\dot{q}) \approx \ln(QA) + n\ln(W_o) - E/RT$$

Thus, by plotting $\ln(\dot{q})$ on the y-axis versus $1/T$ on the x-axis, the value of E can be obtained from the slope, which is $-E/R$. Tests are then run at a single temperature, but for different mass loadings W_o. By plotting this second batch of results as $\ln(\dot{q})$ on the y-axis versus $\ln(W_o)$ on the x-axis, the slope obtained is n, the order of the reaction. Furthermore, if the y-axis intercept on this second graph is denoted as Y_i, then QA is obtained as:

$$QA = \exp\left(Y_i + \frac{E}{RT}\right)$$

These results are then applied to determining T_{NR} and T_{SADT} for the package size under consideration. Using Semenov theory, the value of T_{NR} is obtained by a trial-and-error solution of:

$$\frac{E}{RT_{NR}} - 2\ln\left(\frac{1}{T_{NR}}\right) + \ln\left(\frac{h_c SR}{QAW_o^n E}\right) = 0$$

where h_c = convective heat transfer coefficient (W m^{-2} K^{-1}), and S = surface area of package (m^2). The surface area will be known, while the convective heat transfer coefficient has to be measured or estimated. Finally, the value of T_{SADT} is determined from:

$$T_{SADT} = T_{NR} - \frac{RT_{NR}^2}{E}$$

Yu and Hasegawa point out that reactant depletion can indeed be ignored if the instrument is properly operated at sub-critical temperatures low enough that the mass lost during the test is less than 1%.

THERMAL ANALYSIS METHODS

Thermal analysis methods are, by definition, any of a variety of techniques where small amounts of substance are subjected to a specific temperature or temperature regime and their properties measured. The techniques originated in the 19th century, but only became popular after World War II, being used most extensively in the polymer industry. Some

thermal analysis methods are intended to be used only in qualitative, indicative ways. But other thermal analysis methods are intended to determine the relevant reaction chemistry variables E, A, Q, and possibly other variables (depending on what the detail level of the solution being sought is). Because the amount of specimen used and sensitivity of the different instruments are widely disparate, this effectively means that the operating range in which a specimen will be studied will perforce differ for the different instrument types. The unfortunate consequence of this is that, with many substances, the values reported for E, A, and Q depend on the instrument that was used. Jones[219] reported results on peat where it was illustrated how going from an instrument using large samples to a microcalorimeter decreases the apparent value of E. Some thermal analysis methods are calorimetric, but for convenience, discussion of all the methods is grouped together in this section.

For any reduced-scale test method, validation must be available if credence is to be placed in the method's ability to predict the real-scale situation. With thermal analysis methods, a few reports for a few substances exist in the literature comparing the results to other types of tests. But, in general, it must be considered that—for any of the thermal analysis methods—validation is unavailable and may be impossible. The methods are highly sensitive to experimental technique, to data-reduction procedural details, and to the assumptions of reaction chemistry. Larger-scale methods such as oven-basket testing are often somewhat tolerant towards violations of their underlying assumptions, e.g., the unanticipated presence of autocatalytic reactions. But with the micro-scale thermal analysis methods, any experimental work that uncovers something other than a single, simple, Arrhenius-form reaction leads to a situation that not even a framework exists for extrapolating results to the real-scale environment. And unfortunately, few substances of self-heating interest exist where thermal analysis results *do not* show such complications. Thus, the recommendation has to be that these methods are suited only for preliminary screening purposes; to obtain credible quantitative predictions of real-scale behavior, larger-scale tests must be run.

DTA, DSC, AND RELATED TECHNIQUES

It is possible to obtain the necessary variables (E, A, Q, and C, although not λ, if the latter is also needed) from thermal analysis techniques. Thermal analysis apparatuses of interest here are ones designed for monitoring the production of heat, or the loss of mass, of a tiny sample. The techniques include TGA (thermogravimetric analysis), DTA (differential thermal analysis), and DSC (differential scanning calorimetry). All use milligram samples (ca. 5 mg) of substance and expose it to heating conditions where the entire sample is essentially at a single temperature. Because of the small amount of sample tested, the accuracy of measurements are limited. Furthermore, while DSC is a calorimetric technique, it is not a calorimetric technique which has been optimized for producing results of the highest precision. Thus, thermal analysis techniques are more likely to be used for rough estimating purposes, rather than as best-possible sources of data.

TGA is of limited applicability to the self-heating problem; since heat is not being measured, only E and A, but not Q or C can be deduced. Using DTA or DSC, all four variables can be determined. DTA normally requires that a reference material be used which has nearly-identical heat capacity to the test specimen. This is relatively easy to arrange for some liquids, but difficult for most solids. DSC testing is the most versatile and has the fewest limitations, thus this is the preferred thermal analysis technique. The only drawback is that the equipment may be more costly.

Obtaining reasonably reliable self-heating information from thermal analysis techniques usually requires a degree of chemical expertise and a substantial analysis effort. Thus, if other screening techniques are viable (e.g., if sufficient sample exists for Dewar tests), these may be preferred as a more direct source of guidance. Bowes[10] provides a good example of using thermal analysis to obtain self-heating data on the explosive dioxyethylnitramine dinitrate (DINA). When thermal analysis results are obtained on a sample, they may show (1) a single, definite peak; or (2) multiple peaks or other complicated features. In the former case, results may be directly applied as input data to F-K or Semenov theories. In the latter case, the appropriate course of action is either to begin an extensive investigation of the material's chemical nature, or else to turn to techniques which require less interpretation: optimally, full-scale testing, if not, then FRS-style oven-basket testing. Kubler[220] noted that results obtained from any thermal analysis techniques that use only small quantities of sample may be intrinsically misleading for certain categories of substances. With a very small sample, gases released during pyrolysis escape freely from the test cell, but for some substances the initial reaction step of generating the volatiles is endothermic, while subsequent reactions among the gaseous products, or between the gaseous products and the residual solid, are exothermic. This error would not occur with apparatus designs where heating takes place in a closed cell, but the latter arrangement is common only in laboratories studying explosive substances.

When running thermal analysis tests, most users will follow one of the ASTM standards discussed below. Apart from these standards, a few other analysis techniques exist. For TGA data, Flynn and Wall[221] conducted an extensive review of data reduction techniques and one of their methods has been adopted in ISO 11358-2[222]. For DTA data, the data reduction technique of Borchardt and Daniels[223], later elaborated by Reed et al.[224], is normally used.

Various researchers have sought non-isothermal methods for determining the kinetic parameters of a reaction without

any assumptions about the reaction order or the form of the rate law beforehand. These attempts at 'model-free kinetics' usually rely on *differential* methods of analyzing data obtained from constant heating rate experiments, e.g., change in peak reaction rate temperature with heating rate. The drawback to the differential approach is the assumption that the peak reaction rate temperature corresponds to a particular extent of conversion*, typically ½. *Integral* methods obviate this need by allowing the extent of conversion to be determined experimentally from the partial areas of the reaction rate versus time (temperature) curve. Although more general and accurate, integral methods have been less popular because an exact, closed-form (analytic) solution of the Arrhenius integral does not exist, necessitating the use of cumbersome series approximations. Lyon[225] proposed an integral method which gives both E and A using the following procedure. It starts with a simple new approximation for the Arrhenius integral:

$$\int_{T_o}^{T} e^{-E/RT'} dT' \approx \frac{RT^2}{E+2RT} e^{-E/RT}$$

In his approximation, the lower limit is ignored since, in practical cases, at the starting (room) temperature of T_o, $E/RT \ll E/RT_o$. Compared to the numerical solution, he shows that the error is less than 1% when $E/RT > 10$. Practical values of E/RT might span from 5 to 100, and even for $E/RT = 5$, errors are less than 4%. Using this approximation, Lyon obtains

$$E(\alpha) = -R\left[\frac{d\ln\beta}{d1/T(\alpha)} + 2T(\alpha)\right]$$

where β (K s^{-1}) is the heating rate, and α is the conversion fraction. The method then depends on: (1) numerically integrating and normalizing the reaction rate data obtained at different heating rates to obtain α as a function of temperature; (2) determining several 'iso-conversion' (i.e., constant α) temperatures, $T(\alpha)$, at each heating rate β; (3) plotting the $(T(\alpha), \beta)$ data pairs for each α as $1/T(\alpha)$ on the x-axis and ln β on the y-axis. The slope of the curve, $d\ln\beta / d1/T(\alpha)$, at each $T(\alpha)$ is incremented by $2T(\alpha)$ and the total multiplied by the gas constant R to obtain the global activation energy for the reaction at a particular conversion $E(\alpha)$. The incipient temperature at complete conversion $T(\alpha = 1) \equiv T_\infty$, is determined for a series of heating rates β from the numerically integrated and normalized reaction rate data. In practice, T_∞ is the temperature at which the partial area under the reaction rate versus temperature (time) curve just equals the total area. The (β, T_∞) data pairs so obtained are plotted according to:

$$\ln\left(\frac{\beta}{T_\infty}\right) = \ln A - \left\{\ln\left(2 + E/RT_\infty\right) + \left(E/RT_\infty\right)\right\}$$

which is a linear equation of the form $y = a - bx$, with $y = \ln(\beta/T_\infty)$ and $x = \ln(2 + E/RT_\infty) + E/RT_\infty$. The global activation energy E is used as a fitting parameter to obtain unit slope (slope $b = 1$) and the pre-exponential factor is obtained directly as the intercept, $a = \ln A$.

DSC equipment can be operated in a temperature-scanning mode or in isothermal mode. Rogers[211] recommends that only the isothermal mode be used for explosives and similar unstable substances. If a DSC is operated in an isothermal mode, Rogers[226] showed that plotting ln (b) versus time will give a slope which is equal to $-A$, where b = chart deflection (arbitrary) and A = pre-exponential factor (s^{-1}).

Analysis becomes complicated when a liquid reacts to produce a gas and the depletion of the reactant cannot be ignored, since the masses and enthalpies of two different phases must be tracked. A technique has been developed[227] for producing kinetic data for reactions of this kind.

Users without a sufficient background in the subject matter sometimes feel that thermal runaway is precluded if thermal analysis techniques indicate that there is no detectable exotherm in the temperature region in question. Uehara et al.[228] provide a vivid example of the inappropriateness of this conclusion. In examining calcium hypochlorite, they found the first detectable sign of exothermic activity at 180ºC. Yet tests of a rather small (r = 191 mm) cylinder showed that thermal runaway occurred at 75ºC, some 105 degrees lower. The reason is because a DSC, being a device limited to milligram samples of material, cannot be made sensitive enough to detect the needed low values of reaction rate. To overcome the sensitivity limitation, apparatuses such as the ARC (see above) have been developed.

SIMPLE SCREENING TEST BASED ON DSC

In the most crude sense, DSC tests are sometimes used to simply identify whether exothermic peaks are located sufficiently above the working-temperature range of some chemical process or not. If the DSC peaks are located well above the working range, such reactions would be considered non-hazardous. This is not a robust screening strategy, however, since the indicated temperature at which exothermic peaks are found is not an absolute measurement, but is dependent on apparatus conditions, such as specimen size and heating rate. Furthermore, when comparative studies have been done it was commonly found that the exothermicity onset temperatures reported by DSC are not conservative. Thus, for initial screening of reactive liquids the current preference is for the running of ARC tests, instead.

While simple 'peak picking' using DSC is not a recommended screening test, an easy-to-use screening method has been proposed which is more usefully indicative. Hellmiss and Schwanebeck[229] recommend running a single DSC test in an air atmosphere. The heat of reaction Q_r is determined from the DSC curve (Figure 47) as follows:

$$Q_r = \frac{F}{m \cdot dT/dt}$$

* In reaction kinetics, 'conversion' means conversion of reactants into products, thus a conversion fraction of 0.5 means that 50% of the reactants have been consumed.

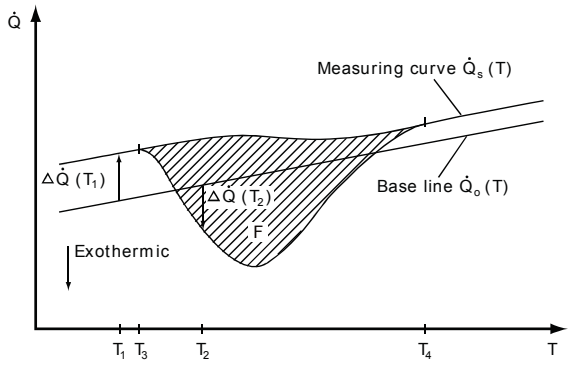

Figure 47 The parameters measured from a DSC curve
(Copyright ASTM International, used by permission)

where F = area under the curve (J K s^{-1}), m = specimen mass (g), and dT/dt = rate of heating (K s^{-1}). Note that for exothermic reactions, Q_r is a negative number. Endothermic reactions, i.e., those which show a positive deflection above the baseline, of course do not exhibit a hazard. If only endothermic peaks are found, no further evaluation of the self-heating safety need be done. The heat capacity C_p is determined as:

$$C_p = \frac{\dot{Q}_s(T_1) - \dot{Q}_o(T_1)}{m \cdot dT/dt}$$

where the quantity in the numerator (J s^{-1}) denotes the offset between the baseline $\dot{Q}_o$ generated with empty specimen and reference holders, and the baseline $\dot{Q}_s$ exhibited by the specimen.

The maximum temperature that could occur for an adiabatic self-heating specimen (that is, with zero heat losses) is:

$$T = T_o - \frac{Q_r}{C_p}$$

where T_o is the ambient temperature at which the substance will be stored. The principle of the screening method is then very simple. If the T computed above is small, say below 200ºC, then the material will not self-heat to ignition in a practical application, since losses will be present in reality and the true temperature will be lower. On the other hand, if the T computed is many hundreds of ºC, then the hazard is real and more detailed tests should be done to determine how large a pile can safely be stored.

QUANTITATIVE ASTM PROCEDURES

ASTM contains two types of recommendations for the use of thermal analysis data in evaluating self-heating substances. The first approach is a quantitative one, leading to simple predictions of the behavior of a real-scale substance. The standards involved for doing this are discussed in the present Section. In addition, ASTM also offers several methods for very rough screening, where no attempt is made to relate the results to the amount of the substance present (reminder: the amount of substance present is the single most important variable governing the self-heating potential). These very rough methods are discussed separately, below.

ASTM E 698

For quantitative estimation, ASTM provides the user with brief and basic experimental procedures for conducting thermal analysis tests using DTA or DSC equipment in ASTM E 698[230]. The standard recommends that hermetically-sealed containers or ampoules be used and that various heating rates β between 1 and 10ºC min^{-1} be used. The data reduction method of Duswalt[231] is recommended to obtain the activation energy and pre-exponential constant. The use of heating-rate corrections and non-linearity corrections is also explained. Doyle's method is described as an alternate. The ASTM standard presumes first-order kinetics and does not delve into a determination of the order of the reaction. The activation energy E is determined by plotting ln(β) on the y-axis and $1/T_p$ on the x-axis, where T_p = peak temperature (K). The slope of the line is $-1.08E/R$ and this gives the initial estimate of E. The approximation involves a numerical error of around 3%, and this can be reduced by performing a series of corrections to this initial value, based on the ratio E/RT. Knowing E/RT, where T is the value midway through the data set, a correction factor D is provided in a table. The next estimate of E is then $E = -\frac{R}{D}\frac{d(\ln\beta)}{d(1/T)}$. The method is predicated on the observation that the conversion fraction is constant at the peak of the reaction. A value for A is obtained from:

$$A = \frac{\beta E}{RT_p^2}^{+E/RT_p}$$

The test method also includes an additional procedure for cross-checking the values obtained.

ASTM E 793

Method E 698 does not include calculation of the heat of reaction, Q. Instead, ASTM provides a separate method for this, ASTM E 793[232]. It is suggested that a heating rate of 10ºC min^{-1} be used. The value is obtained simply by integrating the peak area and comparing the results to a reference substance.

ASTM E 1641

Within ASTM standards, there exists an alternative method for determining the values of E and A. ASTM E 1641[233] is based on the use of a thermogravimetric analyzer. However, since heats of reaction cannot be obtained from a TGA apparatus, most users will presumably find it more convenient to obtain both sets of data from a single apparatus. In the ASTM E 1641 method, E is determined essentially identically as in ASTM E 698. The value of A is found using Doyle's method[234], according to which:

$$A = \beta \frac{R}{E} \ln(1-\alpha) p(E/RT)$$

where $p(E/RT)$ is a tabulated function.

ASTM E 1231

The standard ASTM E 1231[235] is ASTM's procedure for using thermal analysis data as input into the F-K theory. It assumes that the user has obtained values of E and A from ASTM E 698, Q from ASTM E 793, and the thermal conductivity λ from any of a number of possible measurement techniques. Based on these input data, the critical size is computed by the standard F-K equation, without use of any corrections. The time to runaway conditions is estimated as being identically equal to the adiabatic induction period:

$$t_{ad} = \frac{C}{AQ} \frac{RT_o^2}{E} \exp\left(\frac{E}{RT_o}\right)$$

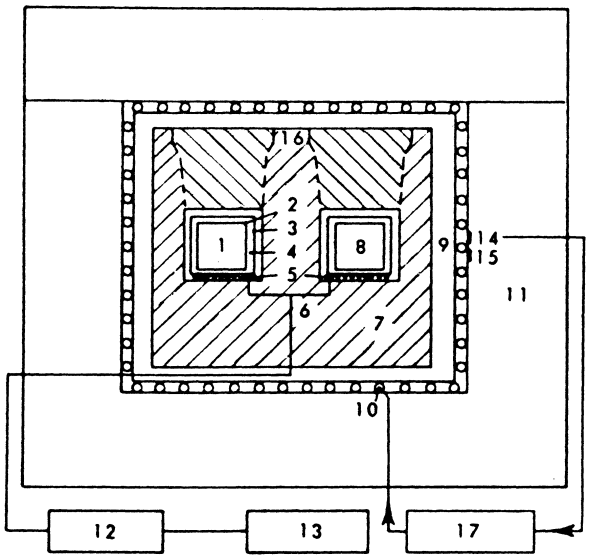
A value of the 'adiabatic decomposition temperature rise' T_{ad} is also computed as:

$$T_{ad} = \frac{Q}{C}$$

This is simply the temperature which a specimen would attain if all of the heat of reaction went into raising the specimen's temperature. This computation, of course, contradicts the assumptions of Frank-Kamenetskii's theory, since it presupposes that the substance is all at a single temperature means assuming that $\lambda \rightarrow \infty$.

QUALITATIVE ASTM PROCEDURES

A number of ASTM tests are intended as screening procedures. While the data are reported in quantitative units, no account is taken of the amount of self-heating substance that is actually present in the real-life application. Thus, the numbers can only, at best, have a qualitative significance.



ASTM E 537[236] is a brief standard which instructs the user of DSC equipment how to calibrate the equipment, conduct a test, and to report the values of the 'onset temperature,' the 'extrapolated onset temperature,' and the peak temperature for the substance. These data are not analyzed further to make predictions for real-scale substances.

ASTM E 487[237] is a vague thermal analysis procedure which instructs the user to procure an undefined amount of substance (but preferably less than 50 mg), to place it in an undefined heating apparatus equilibrated to a desired temperature, and to observe it for 2 h. If, for a given temperature, exothermic activity is observed during this period, but is not observed at a temperature of 10ºC less, then the specified temperature is reported as being the 'constant-temperature stability (CTS) value.

ASTM D 2883[238] method is a screening procedure whereby a liquid or solid specimen is placed in glass ampoule which is located in a test oven. Various amounts of substance may be introduced, and the results depend on the amount of substance that was used. Relative temperature rises are measured and a procedure is offered to extrapolate the results to 'incipient' temperature values. While based on a test oven and not a thermal analysis apparatus, the technique is very similar to screening methods based on DTA tests.

UN TEST H3—ISOTHERMAL STORAGE TEST

The apparatus was developed in the Netherlands at TNO and can be viewed as a larger-scale DSC apparatus and comprises an aluminum block surrounded by a heater and thermal insulation (Figure 48)[194]. A sample and reference cup, each of 70 cm^3 capacity and holding up to 20 g of sample, are embedded in the block. Peltier-effect heat flow meters are located between the bases of the cups and the

(Copyright Elsevier Science, used by permission)

aluminum block. The device is calibrated and used similarly to a DSC instrument. A test is generally 36 h long. Tests are conducted at multiple temperatures and the result is a plot of Q_T versus T. The calculation of the SADT is done similarly to UN Test H2. The sensitivity of the apparatus is about 1 mW kg^{-1}. Example of results from the testing of TNT[239] is shown in Figure 49.

Apart from the UN instructions, Van Geel[240] developed an analysis method for computing the safe storage radius for materials based on results of the isothermal storage test. The substance is to be tested in the apparatus at a temperature 10ºC higher than is the intended storage temperature. The basic input variable is the peak value of the heat generation rate (W kg^{-1}). Van Geel provides an example case where nitrocellulose powder was studied, but the results were rather anomalous and, in any case, he did not provide any validation data to back up his claim that his method will work in circumstances where the F-K theory fails.

EMPIRICAL OR QUALITATIVE TESTS

MACKEY TEST AND RELATED TESTS

Ordway test

In the late 19th century, insurance companies were seeking a reliable method whereby they could categorize oils by their self-heating propensities. Mills using the more hazardous oils would be assigned higher insurance rates. Much of the problem was due to oxidizable double C=C bonds; thus the standard chemistry technique of iodine number (see Chapter 14) was sometimes applied in the hopes that it would correlate to self-heating propensity. Iodine number results, however, were only partially indicative of the problem, thus efforts were made to develop a performance-based test, i.e., one which would actually examine self-heating. The earliest test described in any detail was that of Prof. Ordway of MIT, invented in 1884[241]. He configured a 100 mm diameter horizontally-oriented sheet-steel cylinder in which two balls of cotton were placed 300 mm apart. One 50 g ball was saturated in 50 g of test oil, while the other was an unoiled control. The cylinder was placed inside a larger, 150 mm wrought-iron cylinder (Figure 50), and the latter was heated at the midpoint by a Bunsen burner. Three thermometers were installed in the apparatus, and the procedure called for controlling the flame so that the center thermometer reached 125ºC, while the thermometer at the control sample attained 100ºC. It does not appear that specific failure criteria were laid down for the test.

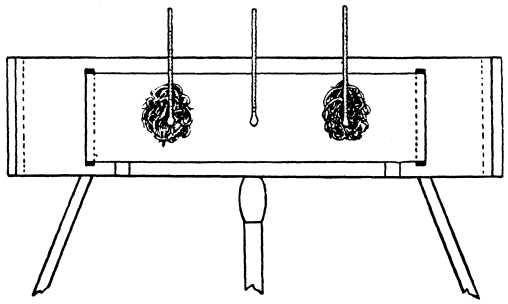

Figure 50 Ordway's test of 1884

Mackey test

Mackey's apparatus of 1895[242] was an improvement, since a definite shape was established for the sample, and a more reproducible heating arrangement evolved. He used 7 g of cotton wool, soaked with 14 g of the oil in question. This was wrapped into a cylinder shape using a piece of wire gauze 125 mm square. The upright cylinder was placed in an oven the temperature of which was held at 100ºC by means of a water jacket. No special provisions for air flow, were made, which entered in through gaps in the oven. A thermometer was used to record the specimen temperature, with an experiment lasting more the 5 h, unless active flaming resulted earlier. From these initial results, Mackey recommended that observing for only 1.5 or 2 h was sufficient to identify problematic oils. In the discussion on the paper, a number of comments were made to the effect that the test apparatus was not well controlled. A year later, Mackey improved his apparatus. The second version[243] of Mackey's 'Cloth-Oil Tester' (Figure 51) is essentially a percolator, holding a 150 mm long gauze cylinder, 37 mm in diameter. The gauze cylinder is filled with 7 g of cotton wool, soaked with 14 g of the test oil. A flow of air by natural convection is created by placing a low inlet and tall outlet into the cavity area. The vessel is placed on a ring stand and heated with a Bunsen burner. If the specimen temperature does not exceed 100ºC during a 1 h exposure period, a passing result is reported. Since the specimen is surrounded by a water jacket held at 100ºC, even with no exothermicity, a specimen will equilibrate to a temperature of only slightly under 100ºC. In Mackey's data, olive oil, which is to be considered a passing substance, attains 97 – 98ºC at 1 h, but it reaches a maximum temperature of 228 – 241ºC in 3.5 – 4.5 h, which is actually higher than some products which fail

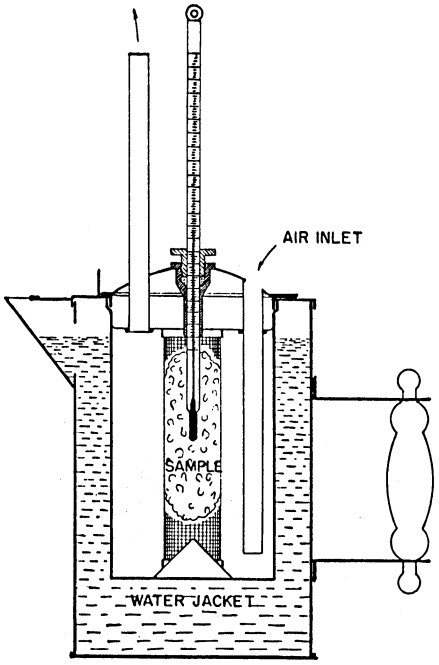

Figure 51 The Mackey apparatus for testing of self-heating propensity of materials

the test. Additional data indicated that the method, using Mackey's criteria, did not have any reasonable margin separating failing from passing specimens. In a much later paper[244], Mackey recommended ranking substances according to the time it takes to reach 200ºC, but it does not appear that this time-to-effect criterion was adopted by users of the test.

Gill compared results from the Ordway apparatus and the two versions of Mackey's[245]. He concluded that Mackey's old version was the most reliable. His data for the second version show that oils with widely varying iodine numbers were exhibiting very similar temperature rises. Bowes[246] has pointed out that, because of the time limit, misleading results can be obtained with oils which have an antioxidant or which are diluted with another liquid. In these cases, there can be a prolonged period during which temperatures do not rise much, but after this period is over, serious self-heating can still be possible.

A radically modified Mackey test was proposed by Factory Mutual in 1927[247], but did not win acceptance. Another modification to the Mackey test was proposed in 1934 by J. B. Firth, who fitted a steam-jacketed chimney and reduced the specimen insertion aperture to 38 mm[248]. In this version the specimen roll occupies the middle 65 mm of a 100 mm long stainless steel gauze cylinder. With oil-covered cotton, visible darkening of the specimen is generally noted at around 150ºC, and charring at around 240 – 260ºC. In 1953 UL described the use of a scaled-up Mackey tester which used a specimen size of 305 mm diameter and 584 mm height[249]. Yet another modification of the Mackey test was standardized as ASTM D 3523[250] in 1976. The reason why such a crude test was put forth so late is unclear. In any case, the ASTM version is a 'Siamese percolator,' with two vessels in one water bath. Thus, it appears conceptually to be a cross between the Ordway and the Mackey schemes. No criteria have been proposed in connection with the test results, which simply comprise the temperature difference of the two containers at the 4 h mark.

ASTM E 771 test

The ASTM E 771 test[251] was specifically intended for examining the self-heating of liquids impregnating inert fibers and can be viewed as an offshoot of the Mackey test. A heated oil bath is used, in which is placed a sample well made of stainless steel pipe. Some 10 mL or more of test liquid is soaked into 5 – 10 g of inert fibers, which is then shaped into a cylindrical shape and placed in a 63 mm diameter, 153 mm tall iron-mesh cylinder. An air flow of 0.8 L min^{-1} is forced through the sample well. The test is conducted for 24 h and the lowest bath temperature at which a 5ºC rise occurs is recorded as the spontaneous heating temperature. The test method was withdrawn in 2001.

ASTM E 476

The thermal stability bomb, ASTM E 476[252] is a small, stainless steel pressure vessel wherein an 0.3 g sample is placed. The bomb is then put into a Wood's metal bath capable of being raised up to 500ºC, and the bath is heated at 8 – 10ºC min^{-1}. The test is stopped when either the pressure-relief diaphragm bursts or a desired temperature is reached. A 'threshold temperature' is reported as the extrapolation to baseline of the runaway exotherm peak.

UN TEST O1 FOR OXIDIZING SOLIDS

This test is a combination ignition and burning rate test. The test is not one that truly examines hypergolic behavior, since an external ignition source is presented. The substance is tested by being mixed with dry cellulose fibers, poured into a conical pile, and presented with an igniter in the form of a 150 W Nichrome wire heater applied for 3 min. Two ratios of oxidizer : cellulose are tested, 4:1 and 1:1, by mass. Reference tests of potassium bromate + cellulose fibers are run in three different oxidizer/fuel ratios. Assignment of the substance into 'Not Division 5.1,' or into Division 5.1 Packing Group I, II, or III is based on comparison of burning time results with those for the reference mixtures. Koseki et al.[253] reported on a number of difficulties in using this test, most important of which is a great sensitivity both to the type of cellulose fibers used and the moisture content.

UN TEST O2 FOR OXIDIZING LIQUIDS

This test method is intended to test for liquids with hypergolic reactivity and also for liquids that promote very rapid burning. The test apparatus comprises a small pressure vessel wherein a mixture of 2.5 g of the test liquid and 2.5 g of cellulose fibers is placed. If the mixture self-ignites during mixing or filling, then it is classified into Division 5.1 Packaging Group I. If it does not, then the test is continued: the mixture is packed into the vessel, a Nichrome heater applies heat for 60 s, and pressure is monitored. Three different reference standards are run and assignment of the substance into 'Not Division 5.1,' or into Division 5.1 Packing Group I, II, or III is based on comparison of the time/pressure results with those for the reference mixtures.

UN TEST S1—TROUGH TEST FOR FERTILIZERS CONTAINING NITRATES

The test method uses a 150 × 500 × 150 mm deep stainless-steel mesh tray which is filled with the fertilizer to be tested. One end of the tray holds a steel plate which is heated either by two Bunsen burners or by an electric plate heater. The test is intended to measure self-sustained exothermic decomposition, but the small amount of unconfined substance never leads to an explosion in the apparatus. The substance is heated for up to 2 h, until a decomposition front is determined to be well established. Heating is then stopped and the specimen is monitored to see if the decomposition front reaches the far end of the device. If it does, then a failing result is recorded. The test does not normally require instrumentation, but Kiiski[254] installed thermocouples at various locations along the trough and obtained typical results shown in Figure 52. Temperature rate-of-rise is shown in Figure 53, with ignition corresponding to the time at which the rate of rise begins to increase again (265ºC). The method is further discussed in Chapter 14 under *Fertilizers*.

BUREAU OF MINES DUST LAYER IGNITION TEMPERATURE TEST

The BM test[255] was developed in the early 1940s, predating the concepts of modern self-heating theory. A 12.7 mm layer of dust is placed in a 25 mm dia. wire-mesh basket and suspended in the middle of the Godbert-Greenwald furnace (described in Chapter 5). A thermocouple is placed in the middle of the specimen and ignition is deemed to occur if a point of inflection (in the rising-temperature direction) is found on the temperature trace. The Bureau of Mines collected and reported a very large amount of data using this procedure, especially on agricultural dusts, but its results do not find a role in current evaluation strategies for self-heating hazards. In standard testing, the dust size was specified by passing it through a 200-mesh sieve, i.e., particle size of < 75 μm.

OXYGEN CONSUMPTION CALORIMETRY

A number of studies have been reported where the oxidation of a substance was studied directly by using a means of measuring the oxygen consumed. An early example is the 1949 method developed by the Technical Research Center of Finland (VTT)[214]. In this test, a flask containing the test substance was placed in a heated oil bath and the drop of oxygen pressure over time was monitored. From the results, the oxygen consumption (volume of oxygen consumed, per gram of specimen, per unit time) was computed. The authors showed that mineral oils exhibited no oxygen consumption, but some vegetable-origin liquids showed large consumption. Two measuring temperatures, 50 and 100ºC, were used. A later variant has been described by Carras[78]. Oxygen consumption calorimetry is an easy, standard procedure[256] when it comes to fast oxidation, e.g., substances

actually burning. However, measuring the tiny amounts of oxygen consumed during slow self-heating is a much more difficult task. Because of this, no standardized test method of this type has been developed.

Highlights and summary of practical guidance

In this Chapter we treat a wide variety of solids and a smaller number of liquids which have a propensity for reacting very rapidly. Substances specifically designed to release energy very rapidly are, of course, known as *explosives*. *Pyrotechnics* are substances which are used to create sound, light, smoke or limited force, but do not normally detonate. *Propellants* are used for various propulsion purposes, including armaments and rockets. These three classes of substances are sometimes collectively referred to as *energetic materials*. *Unstable* and *reactive substances* are normally understood to be substances which are not intended to explode, but which can react or decompose in an explosive manner under accidental conditions. There is no fundamental difference in chemistry between the behavior of explosives and of unstable substances; instead, they are differentiated simply according to whether or not there is a purposive use for explosion from the substance.

The unifying theme of these materials is that they do not require oxygen from the air as their primary reaction partner (although they may undergo secondary reactions that involve oxygen from the air). The reaction rates of reactions where gaseous oxygen must arrive at the flame front from the air are limited by the intrinsically slow process of diffusion through a gaseous medium. Since the process is slow, the heat release rate cannot be large. This is why burning of 'common solids' proceeds at a modest rate, compared to explosives or unstable substances. Many explosives or unstable substances, however, do undergo later, secondary reactions with oxygen from the air; the concept of *oxygen balance* is a first-order estimate of this propensity.

Unlike with 'common solids,' the distinction between autoignition and piloted ignition is not meaningful for explosives and unstable substances. The exothermic reaction responsible for explosion or flaming occurs within the solid or liquid, and the presence of a pilot in the gas phase outside it would not affect matters, except as a slight supplemental heating.

To the non-chemist, it may be confusing to find out that some hazardous compounds are referred to as 'endothermic.' The meaning of this designation is that energy would have to be externally supplied in order to assemble them from the constituent elements, as indicated by a positive heat of formation. From the point of view of simple thermodynamics, it might be thought that these compounds should immediately fly apart, i.e., be so unstable as to not exist as a substance that can be produced and warehoused. In practice, not all endothermic compounds are grossly unstable, since the kinetics of the decomposition process must also be taken into account and, if it takes a very long time for the decomposition to take place, the compound may be functionally stable. Nonetheless, relative hazard for unstable compounds is often estimated on the basis of the energy

of decomposition, which quantifies the degree of endothermicity.

Theoretical methods are probably of less use to the hazard specialist in connection with explosives, than with any other class of ignitable substances. A preliminary estimation of reaction hazards is often made with the ASTM CHETAH program[1], which is computer code widely used as first-recourse tool to estimate instability or reactivity of chemical compounds. Highly advanced theoretical computation methods, based on molecular dynamics, have been developed by explosives researchers, but these would be exceptionally difficult to use by the non-specialist. And even with the availability of advanced theories, most hazard assessment of explosives is done on a purely empirical basis. Thus, testing is the cornerstone of hazard assessment and the more widely used test methods are reviewed at the end of this Chapter. Unfortunately, even here things are difficult, since there is little standardization and each research group working in the area generally prefers to invent its own test methods. Furthermore, there is an intrinsic need for a diverse collection of test methods since explosives can be ignited or initiated in various ways, ranging from self-heating to electric spark discharge, and there is generally no correlation between a material's sensitivity to two different types of ignition stimuli.

Commercial uses of explosives are generally driven primarily by economics or availability. This is the reason why, for instance, ANFO has been predominantly used in blasting operations in recent decades as opposed to, say, liquid oxygen explosives, which could also do the job, but not economically. Among the armed forces, over the last two decades, there has been a move to switch over, as much as possible, to 'insensitive munitions.' These utilize energetic compounds that still achieve their intended military purpose, but are not easily exploded by accidental energy sources, such as external shock or heating from a fire.

Unstable substances

Some substances may easily or spontaneously react with certain other substances. Such *reactive* substances are considered in the next Section. Other substances, sometimes called *self-reactive*, are hazardous not necessarily because they can easily react with other substances, but because the molecule itself can 'fly apart.' Common porous solids such as hay or wood fiberboard can be 'unstable' insofar as they are capable of self-heating to ignition. But this form of instability does not lead to an energetic event and substances showing such behavior will not be identified as 'unstable substances.' The self-heating of energetic substances is an important topic, however, and the work in Chapter 9 also lays the basis to understanding some of this behavior. Thus, references will be made in this Chapter to the theory developed in Chapter 9. Also, for convenience all test methods pertinent to self-heating properties have been compiled in Chapter 9, irrespective of whether they are used for energetic materials or materials that self-heat relatively slowly by reacting with the oxygen from the air. Test methods specifically for explosives are presented at the end of this Chapter; these same methods can be applied to the testing of compounds that are not purposive explosives, if their potentially explosive behavior is to be studied. In testing for detonability of unstable substances, it must be kept in mind that there exists a minimum size, below which detonation will not occur. The size is lowered if confinement is provided, but still a minimum exists. Thus, very-small-scale test methods will not be suitable for determining this tendency.

Table 1 Structural features of compounds associated with unstable behavior

Feature	Examples
unsaturated carbon bonds	acetylenes, acetylides, dienes
contiguous nitrogen atoms	hydrazines, azo compounds, diazonium salts, azides
N–O	nitrosos, nitros, nitrates, N-oxides, oximes, 1,2-oxazoles
N–halo	chloramines, fluoramines
O–halo	chlorates, perchlorates, iodosyls
C–metal, N–metal	Grignards, organo-lithium compounds
P–O	phosphates, phosphites
S=O	sulfonyl halides, sulfonyl cyanides
strained rings	epoxides, aziridines
polymerizable groups	compounds with unsaturated groups
mutually reactive groups	amino nitriles, organic salts of oxidizing acids

The UN[2] considers substances containing the following functional groups to be potentially unstable:

(a) aliphatic azo compounds (–C–N=N–C–)
(b) organic azides (–C–N≡N≡N)
(c) diazonium salts ($–CN_2^+Z^-$, where Z^- is a negative-valence group)
(d) N-nitroso compounds (–N–N=O)
(e) aromatic sulfohydrazides ($–SO_2–NH–NH_2$)
(f) organic peroxides (–O–O–); these unstable substances are classified by UN into a category of their own.

Other functional groups identified as potentially unstable include[3,4,5]:

(g) nitro ($–NO_2$). This is generally considered to be the most important group of unstable or explosive compounds[3].
(h) nitrate esters ($–ONO_2$)
(i) nitroso (–NO)
(j) azo and diazo (–N=N–)
(k) azido ($–N_3$)
(l) fulminates (–OCN)
(m) cyano (–C≡N); isocyano
(n) hydrazines (–HN–NH–)
(o) ethynyl (–C≡CH)
(p) alkynes (–C≡C–)
(q) hydroperoxy (–O–OH)

(r) ozonides (–O–O–O–)
(s) chlorates ($–OClO_2$) and perchlorates ($–OClO_3$)
(t) halogenated amines (–NX; $–NX_2$; $–NX_3$)
(u) polymerizable compounds, including certain substituted olefins, epoxides, aziridines, and diketene.
(v) certain organic heavy metal compounds.

A more general list[6] of structural features of compounds potentially unstable has been offered (Table 1).

HEAT OF FORMATION

One way of estimating the stability of compounds is to consider their heats of formation. The heat of formation is the enthalpy which is required to be added in order to form a compound out of its elements. Thus a substance with a high positive value of Δh_f is one which is difficult to 'unite' into a compound and, therefore, one which may have a tendency to spontaneously decompose into its elements or into some larger fragments. Conversely, a substance with a high negative value of Δh_f is one which gives off a lot of heat when formed from its parent elements. Thus, it requires the addition of substantial heat into the system from the outside for such a compound to decompose. Table 2 illustrates this for some common substances. The values shown are all for the vapor state. Compounds showing positive Δh_f values are called *endothermic compounds*.

Molecules of methane, propane, and butane are all known to be stable against disintegrating into pieces. They show heat of formation values well below zero. Acetylene, carbon disulfide, and ethylene are known to be unstable compounds which can decompose under certain conditions. These all have highly positive Δh_f values. Propylene shares some traits with ethylene, but is not as unstable. This is reflected in the fact that its Δh_f value, while positive, is lower than that of ethylene.

Table 2 The heats of formation for some common substances at 298 K

Compound	Prone to decompose spontaneously	Lowest pressure for decomposition (atm)	Δh_f (kJ mol^{-1})
vinylacetylene (C_4H_4)	yes	≈1.0	304.6
acetylene (C_2H_2)	yes	≈1.0	226.7
monochloroacetylene	yes	0.079	214
propadiene (C_3H_4)	yes	2.22	192
methylacetylene (C_3H_4)	yes	3.95	185
propargyl bromide (C_3H_3Br)	yes	0.002	≈170
ozone (O_3)	yes		142.7
carbon disulfide (CS_2)			117.1
hydrazine (N_2H_4)	yes	0.016	95.4
ethylene (C_2H_4)	yes		52.3
propylene (C_3H_6)			20.4
ethylene oxide (C_2H_4O)	yes	0.069	-52.7
methane (CH_4)	no	--	-74.8
propane (C_3H_8)	no	--	-103.9
n-butane (C_4H_{10})	no	--	-126.2
ethyl nitrate ($C_2H_5NO_3$)	yes	< 0.033	-154

For the substances which are prone to decomposition, the lowest pressure under which spontaneous decomposition may occur at 0% oxygen and room temperature conditions is also listed[7]. In all practical cases, details of the test conditions are very important and a tabulation such as this should only be used for preliminary screening. In any case, there is not seen to be a quantitative relation between Δh_f and the pressure sensitivity of the substances.

HEAT OF DECOMPOSITION

Heats of formation are readily found in chemical reference handbooks, since that is one of the most fundamental thermochemical properties of a substance. Minus-one times the heat of formation is the heat which would be evolved, under constant pressure, if the molecule were to fly apart into the constitutive elements. This is exactly what happens with hydrogen peroxide, for example:

$$H_2O_2 \rightarrow H_2 + O_2$$

More complex molecules rarely disintegrate into their elements, and may produce many reaction products. Thus, a more realistic measure is often sought. The heat of decomposition is what describes the heat which is evolved for actual reaction products. Furthermore, unstable chemicals are more likely to be held in a constant-volume environment rather than constant pressure, thus, the 'heat' is preferably an energy rather than an enthalpy. Determining heats of decomposition requires more than simple thermochemistry, since one must know the identity of the pieces into which the molecule will decompose. If this identity is known, then the heat of reaction, for producing the known reaction products, is readily calculable. Otherwise, values must be obtained from testing. For highly energetic materials, the oxygen-bomb apparatus is used, but without adding oxygen. Decomposition is initiated by firing the igniter wire. Compounds that are only moderately unstable will not decompose in this manner, thus data on them must be obtained by less direct means. Often this involves using DSC or other tests discussed in Chapter 9. For explosives, the negative of the heat of decomposition is usually termed the *heat of explosion*.

Table 3 lists some example values for decomposition energy compiled by Grewer[8]. Highly unstable substances show ΔE_d values ranging as high as –6070 kJ kg^{-1}. Roughly, it is suggested that substances having ΔE_d values below –3000 kJ kg^{-1} are very highly hazardous and should be evaluated as to possibly being prone to detonating. Substances with $-3000 < \Delta E_d < -500$ are in a lesser category of hazard, while substances with $\Delta E_d > -500$ kJ kg^{-1} are not likely to undergo violent decomposition (but may be subject to mild

self-heating). Grewer also provides some detailed experimental data which illustrate that changing the test apparatus or conditions under which ΔE_d is determined can lead to variations of more than 2× in the results. Grewer's[8] and Bretherick's[9] monographs should be consulted for detailed discussions of the decomposition chemistry of various unstable substances.

Table 3 Decomposition energy of some substances

Substance	Formula	$-\Delta E_d$	
		(kJ mol^{-1})	(kJ kg^{-1})
diazodinitrophenol	$C_6H_2N_4O_5$	1275	6070
picric acid	$C_6H_3N_3O_7$	1010	4400
2,4,6-trinitrotoluene	$C_7H_5N_3O_6$	998	4395
trinitrobenzoic acid	$C_7H_3N_3O_8$	1073	4170
1,3-dinitrobenzene	$C_6H_4N_2O_4$	590	3510
trinitromethane	CN_4O_8	502	3325
3-nitroaniline	$C_6H_6N_2O_2$	350	2530
lead azide	PbN_6	449	1540
mercury fulminate	$C_2HgN_2O_2$	423	1490
benzoyl peroxide	$C_{14}H_{10}O_4$	340	1400
ammonium perchlorate	NH_4ClO_4	172	1465
tert-butyl peroxybenzoate	$C_{11}H_{14}O_3$	260	1340
propylene oxide	C_3H_6O	65	1120
styrene	C_8H_8	58	560
cornstarch	--	NA	460
1,2-diphenylhydrazine	$C_{12}H_{12}N_2$	81	440
sucrose	$C_{12}H_{22}O_{11}$	140	410
glucose	$C_6H_{12}O_6$	73	405
cellulose	--	NA	330
phosphonic acid	H_3O_3P	8	100

The UN defines[2] unstable substances as substances having a decomposition energy < –300 kJ kg^{-1} and a self-accelerating decomposition temperature (SADT) < 75ºC for a 50 kg package. According to Grewer's results, this is an exceedingly conservative stance; presumably only common sense or SADT testing keeps substances such as cellulose or glucose from being classified as unstable. Substances may also be unstable because of the opposite effect to flying away: *spontaneous polymerization*.

SELF-HEATING OF LIQUIDS

Many liquids are subject to self-heating, although this problem is most commonly encountered only in chemical manufacturing or storage facilities. Self-heating of liquids can occur under two opposite conditions: stirred, or stagnant. Stirred conditions will often be found in chemical plants, where reactor vessels are normally stirred. Stagnant conditions will generally prevail when liquids are warehoused. The possibility of being stirred is unique to liquids and gases—solids, by definition, cannot be stirred. Granular materials could, in principle, be stirred, but environments in which they self-heat in practice are usually at rest. Whether or not a container is stirred has major implications for the analysis of the problem. The purpose of stirring is to make uniform the temperature and concentration within a vessel. Thus, a stirred container problem will be analyzed theoretically as being at a uniform temperature. A stagnant volume of liquid, on the other hand, can show temperature gradients. The case here will be more similar, but not identical, to the case of solid material. Convective flows will occur in a volume of liquid which has significant temperature differences (if the layering is not stable). Such self-stirring does not occur in solids.

Self-heating of liquids is a main cause why chemical plants blow up (with or without an additional flaming fire), thus understanding how such ignitions occur is important. In many cases, only a single reactant is involved, that is, it is a *unary* reaction. The nature of the reaction can be:

- decomposition—a molecule splits up into two or more fragments
- polymerization—molecules join up into longer chains; this is normally an exothermic process
- isomerization—a molecule rearranges its functional groups

More complicated reactions in liquid systems can of course also occur that lead to disastrous self-heating. If a chemical plant reactor failure occurs, it may be followed by additional reactions, e.g., the substance may further burn in air, once ejected from the vessel.

Because the density of a gas is about 1000 times less than that of a liquid, a decomposition reaction causing gasification of a liquid can create pressures on the order of 1000 atm. Some compounds can achieve a flame temperature on the order of 3000 K. From the latter heating effect, another factor of 10 increase in pressure can result, leading to expectations of *ca*. 10,000 atm pressures in the worst case.

The chemistry of many potentially hazardous chemical plant self-heating situations is difficult to unravel because the actual decomposition products are unknown. In many cases, even after extensive investigation post-explosion, only a surmise of the actual chemical mechanism can be made. This means that detailed features such as the heat of reaction cannot be computed quantitatively, since knowledge of reaction products is required for such computations. Also, unless the heat of decomposition is large, the decomposition products are likely *not* to be the equilibrium products. An analogy to this situation can be seen from normal open-air burning: low HRR substances generally burn 'dirty' and do not simply produce CO_2 and H_2O.

Decomposition reactions in liquids can be grouped into three types:

(1) homogeneous reactions which can be considered a thermal explosion
(2) deflagrations (a steadily-moving combustion wave)
(3) detonations (a combustion wave propagated by means of a shock wave).

Fortunately, the fraction of substances prone to showing liquid-state deflagrations is small, and the fraction capable of detonations is smaller yet. Explosions of substances with a high heat of decomposition may start as a thermal explosion then change to a deflagration.

The two main theories of self-heating are those due to Semenov and Frank-Kamenetskii, with the latter having been much expanded by Thomas. Semenov's theory assumes that the substance has no thermal gradients within it. This would generally be a very poor assumption for porous solids, which is the reason that the theoretical development in Chapter 9 did not focus on Semenov's theory. But in the chemical engineering arena, reactions often take place in stirred vessels. The chemical engineering application has the difference that, in many cases, the material is not simply held and stirred, but rather flows in and out of a stirred reactor vessel. These are known as continuously-stirred tank reactor (CSTR) problems and self-heating can be analyzed according to Semenov's basic theory, since neither temperature nor concentration gradients are assumed to exist inside the vessel.

The *time* element is often much different in chemical plant liquid reactions, as compared to storage problems of solids. A reaction is normally completed in a matter of several hours, at which point the substance is cooled and taken out of the reactor. Thus, safety investigations often select a 24 h period as the maximum storage time for which the self-heating potential is to be examined. For solid materials, storage times of weeks or months are common, and the extended-period storage problem (ambient temperature starting conditions) is more commonly encountered than the hot work problem (high initial temperature). In the case of reactive liquids, the starting temperature is commonly in the 100 – 200ºC range.

Many unstable liquids (and explosives) can deflagrate or detonate directly in the liquid phase, without first generating a flammable gas. The combustion which takes place after the ignition is notably different in liquids than in solids, and it is not covered by general combustion textbooks. Probably the best introduction to the science is given by Verhoeff[10]. Unstable liquids may also first vaporize, then decompose. The latter occurs if the decomposition temperature T_d is higher than the boiling point T_b. Verhoeff suggests that a functional definition of T_d is the temperature at which the self-heating liquid first attains a heat release rate of 100 W kg^{-1}.

Less well studied are *heterogeneous explosions* involving liquids that are oxidative, rather than decompositional in nature. When some organic liquids are presented with a gaseous oxidizer, especially at high-pressures, surface explosions, bubble explosions, foam explosions, and aerosol explosions can be possible. These reactions are not constrained by the same flammability limits pertinent to normal gas-phase explosions of the vapors. Hieronymus et al.[11] have presented some illustrative examples, but a systematic overview has not yet been attempted. A similar problem is heterogeneous reaction between two liquids that form different phases. A theory for this problem of *liquid-liquid reaction* has been described by Fujimoto[12].

Our approach in this book concerning condensed-phase substances burning directly in the condensed phase will be slightly different than for substances burning in the gas phase. For the latter, it is appropriate to develop some elementary background of the post-ignition aspects of combustion (Chapter 3). But for liquids and solids we will explore solely the ignition event and leave to specialist texts to develop principles and theories describing post-ignition conditions. Even so, our scope will necessarily be restricted, since theoretical concepts that have wide applicability to a variety of substances are scarce. Typically, research on unstable liquids has been focused solely on a particular substance and the ability to generalize that knowledge may be limited.

THEORY

The earliest theory of self-heating is the one due to Semenov, wherein he assumed that there is resistance to the flow of heat at the edges of the body (i.e., a convective cooling coefficient), but that there are no thermal gradients within the body. A condition of no thermal gradients within the body can come about in two ways: (1) if the substance has a high thermal conductivity, or (2) if the substance is mechanically stirred or agitated. Many unstable substances are liquids which have high thermal conductivities, and reaction vessels for liquids are also often stirred. Thus, the Semenov model can be quite useful for chemical reactor vessels. In the Semenov theory, zeroth-order kinetics is assumed and heat generation within the body is then:

$$\rho VQAe^{-E/RT} + G$$

where we have included an optional heat generation term G (W) due to mechanical agitation or electrical heating. Mechanical agitation is common in reaction vessels for liquids, and the heat contribution from this source has been sufficient to account for some industrial accidents[13]. The convective heat losses are represented as:

$$h_c S\left(T - T_o\right)$$

where S (m^2) is the exposed surface area. Equating the two expressions gives:

$$\rho VQAe^{-E/RT} + G = h_c S\left(T - T_o\right)$$

Also at the critical temperature, which we will define as T_c, the *slopes* are identical (Figure 3 in Chapter 9), thus:

$$\frac{d}{dT}\left(\rho VQAe^{-E/RT} + G\right) = \frac{d}{dT}\left(h_c S\left[T - T_o\right]\right)$$

or

$$\rho VQA\frac{E}{RT_c^2}e^{-E/RT_c} = h_c S$$

and after combining with the previous equality, a solution can be obtained for T_c:

$$T_c = \frac{E}{2R}\left(1 - \sqrt{1 - \frac{4GR}{h_c SE} - \frac{4RT_o}{E}}\right)$$

If there is no internal generation of power, then the classical solution is:

$$T_c = \frac{E}{2R}\left(1 - \sqrt{1 - \frac{4RT_o}{E}}\right)$$

Thus, the power generation term raises the effective ambient temperature from T_o to $T_o + G/h_c S$. An extension of the Semenov theory has been developed[14] for treating industrial dryers and fluidized bed processes, where enthalpy is introduced directly into the system via an air stream.

For many applications, the classical solution to the Semenov theory is further approximated by the use of the power series expansion:

$$\sqrt{1 - \frac{4RT_o}{T}} = 1 - \frac{2RT_o}{E} - \frac{2R^2T_o^2}{E^2} + \ldots$$

and keeping only the two leading terms gives:

$$T_c \approx T_o + \frac{RT_o^2}{E}$$

This approximation is valid if E is sufficiently large, specifically if $2RT_o/E << 1$. Since E may be 100 kJ mol^{-1} and $T_o \approx$ 300 K, then 0.02 is indeed much less than 1.

Bowes[15] suggests that, in parallel to the δ parameter based on Frank-Kamenetskii/Thomas theory that was developed in the previous Chapter, practical analysis of stirred liquids should be based on the Semenov number ψ:

$$\psi = \frac{E}{RT_o^2}\frac{QAV\rho}{hS}e^{-E/RT_o}$$

The critical value of ψ, denoted as ψ_c, is found to be $1/e$. Now, the heat transfer coefficient is found to depend on the radius roughly as:

$$h \approx k_1 r^{-1/2}$$

where k_1 is a constant. For regular geometric shapes such as sphere, cylinder, etc., $V/S = k_2 r$, where k_2 is another constant. Then,

$$\psi = \frac{E}{RT_o^2}\frac{k_2}{k_1}r^{1.5}QA\rho e^{-E/RT_o}$$

and $$\psi_c = \frac{1}{e} = \frac{E}{RT_o^2}\frac{k_2}{k_1}r^{1.5}QA\rho e^{-E/RT_o}$$

In a manner similar as developed in Chapter 9, a data analysis strategy can be developed by multiplying out and taking the natural logarithms of both sides of this equation:

$$\ln\left(\frac{T_o^2}{er^{1.5}}\right) = P - \frac{E}{RT_o}$$

where $$P = \ln\left(\frac{E}{R}\rho QA\frac{k_1}{k_2}\right)$$

Thus, if $1/T_o$ is plotted on the x-axis and $\ln\left(\frac{T_o^2}{er^{1.5}}\right)$ on the y-axis, the slope will be $-E/R$ and the y-axis intercept will be P. Once a sufficient number of data points are obtained to allow a straight line to be fitted, the resultant straight line can be used to estimate the critical size for other values of initial temperature T_o.

While standard theories of self-heating—whether Semenov's or the F-K theory discussed in Chapter 9—can often be applied to analyzing unstable substances, there can arise numerous complications. If the substance undergoes a significant volume change in reacting, for example, when the reaction product is a gas, the formulation has to be modified. A method has been described for treating such substances[16], but it does not appear to be readily usable. Heat transfer conditions can often be adequately estimated for porous-substance self-heating problems. But for unstable substances, changes of phase can introduce mixing which affects heat transfer in a way that is difficult to characterize, since the system is continuously self-modifying.

A unique feature of self-heating in liquids that is not found in solids is *convective flows* of the reactant. If the volume of liquid has only small temperature differences, then convective flows are absent. But if the temperature differences become greater than a certain amount, then convective flows may begin. Conduction plays only a small role in the self-heating of liquids, but convection is effective in diffusing away localized packets of heated material. Thus, Verhoeff[10] found that with some unstable liquids, the system is stabilized by a stirrer's introduction of convective flows, rather than being adversely affected by the added energy.

Verhoeff considers that an explosion of a liquid proceeds in the following stages[10]:

1. *Thermal runaway*. Time scale: 1 – 10^4 s. During this stage the liquid is at a uniform temperature, but the temperature is rising.
2. *Initiation*. Time scale: 0.1 – 10 s. During this state the liquid forms a hot spot. Verhoeff considers that non-uniformities of 2 ⌗C are an empirical sign of the start of initiation.
3. *Explosion*. Time scale: 10^{-3} – 1 s. A propagating reaction zone moves through the mass of the liquid. This is a condensed-phase deflagration, but detonations, while rare, are also possible, especially if the liquid is aerated.

The above presentation focused on a fixed control volume. But liquids in a continuous-flow reactor are also able to reach thermal runaway. These systems exhibit some special peculiarities, one of which is a propensity to undergo temperature/concentration cycling[17]. Merzhanov[18] has developed extensive theories for treating flow-through systems.

EXPERIMENTAL STUDIES

For studying the self-heating of liquids, similar equipment to those used for granular solids cannot be used, since pressure rises can be high and the equipment would be destroyed. Thus, autoclaves are used which can withstand the necessary pressures of up to 150 MPa[10]. Because of the design necessary to withstand high pressures, the thermal conditions within the experimental apparatus end up being less straightforward than in test methods such as oven-basket tests. Consequently, data analysis and interpretation becomes more complex.

A complication of self-heating liquids is that often the chemical reactions cannot be described by a single set of Arrhenius constants, but will change over time. This behavior can be correlated to a conversion fraction variable x which is defined as:

$$x = \frac{\text{reactant mass consumed}}{\text{initial reactant mass}}$$

and is thus 0 at the beginning and 1.0 when the reactant is fully reacted. Verhoeff[10] showed that for the organic peroxide *tert*-butylperoxybenzoate (TBPB), the reaction is autocatalytic up to $x \approx 0.05$, and is approximately first-order for $0.05 < x < 0.98$. He also showed that both the test apparatus used and the numerical technique employed to reduce the kinetics data can have a major effect on the values reported.

For liquids contained in a pressure vessel, *pressure* affects the course of an explosion. Much of the chemistry of the reaction has to take pressure in account, both the initial pressure conditions and the influence of confinement on the pressure rise. If the reaction is autocatalytic and involves generation of gaseous products, then a decrease in pressure leads to a decrease in reaction rate, because the catalytic feedback chain is impaired due to removal of products. In open systems, *evaporation* of reactant may occur. This affects the energy balance of the system and, clearly, criticality, if it occurs, will not occur if it requires a temperature greater than the boiling point of the substance.

Apart from self-heating, unstable liquids can also explode by *forced ignition*, i.e., with the presence of a localized source of heat. While this form of ignition may be less common in industrial accidents it has received some experimental study; for example, Verhoeff[10] examined the effects of a Nichrome heating wire on TBPB.

SELF-HEATING OF SOLIDS

Solids undergoing unary reactions (unstable solids and explosives) are often treated by some version of Arrhenius kinetics that was originally developed for gases, deriving values of E and A as constants supposedly characteristic of the reaction. Gomes[19] has pointed out that values derived in this way may be artifacts of the experiment and little else. A justification for developing rate constants does exist if a reaction mechanism can be elucidated, but this is often not known.

A decomposition reaction in a granular solid may lead to a shock wave being produced if gases that are produced are channeled through small openings among the particles, since acceleration of velocity can occur.

Runaway exothermic reactions

A major fraction of industrial explosions occur not because manufactured products are handled which are unstable. Rather, they occur during production—an exothermic reaction is needed in order to produce a certain substance. An exothermic reaction is perfectly acceptable, if a combination of heat removal (e.g., a water-cooled reaction vessel jacket) and controlled rate of substance introduction keeps the reaction at a stable temperature. In the case of explosions, some procedural error, contamination (e.g., a reaction turns out to be very sensitive to moisture as a contaminant), equipment failure (e.g., cooling water, electricity for stirring), or miscalculation, leads to a condition where heat removal can no longer keep up with heat generation, and a runaway condition ensues. Industrial reactions can be quite difficult to quantitatively model, especially if many steps or manual steps are involved. Many explosions have occurred because a process was stable in bench-scale design, but scale-up to production quantities proved to remove needed safety margins. The thermal aspects of these explosions follow the same principles as do single-substance decomposition reactions. In practice, the application can be very difficult when more than one substance must be considered. There have been a series of proceedings on this topic hosted by AIChE[20]. Also, a European symposium[21] was held on this topic, and a textbook has been published by Grewer[8].

Before detailed thermochemical calculations are undertaken, it is often useful to know whether the reactions have a high potential for exothermicity. A number of estimating rules have been proposed for assessing the risk, with the Dutch scheme[22] being given in Table 4.

Table 4 Dutch scheme for classifying the hazard of exothermic reactions

Hazard rating factor	Type of reaction	Examples
0.30	mild exothermic reactions	hydrogenation, hydrolysis, alkylation, isomerization, sulfonation, neutralization
0.50	moderate exothermic reactions	esterification, oxidation, polymerization, condensation
1.00	critical-to-control exothermic reactions	halogenation
1.25	particularly sensitive exothermic reactions	nitration

Reactive substances

Reactive substances are understood to be ones which react violently or 'immediately' upon mixing. These are sometimes divided into pyrophoric, water-reactive, and hypergolic categories. *Pyrophoric substances* are defined by the Department of Transportation[23] as liquids or solids that, even in small quantities and without an external ignition source, can ignite within 5 minutes after coming in contact with air. If the time for ignition is long, then the substance is *self-heating*, not pyrophoric. Some researchers do not restrict the definition to solids and liquids, but also includes gases, e.g., silane; however, such gases are more correctly referred to as being hypergolic. Also, in scientific usage, pyrophoric substances can include ones which react not with air, but with pure gaseous oxygen, or liquid oxidizers of various sorts. Chemical families where many members are pyrophoric include:

- alkali-metal carbides
- aluminum alkyl compounds
- boranes
- alkyl-metal compounds
- aryl-metals compounds
- acetylenic compounds
- metal and non-metal hydrides
- metal sulfides
- hexamethylnitratodialuminate salts
- metal carbonyls
- organometallic compounds
- phosphines
- silanes

Urben[9] provides extensive listings along with literature references. Carson and Mumford[24] provide additional listings and example case histories. Two papers by Zehr comprise essentially an annotated bibliography of pyrophoric dusts through 1966; the first part is in German[25], while the second part is available in English[26]. While many metals are pyrophoric when in a finely divided, reactive state, the size required is usually very small, generally 0.1 – 1.0 μm. Uranium, uranium hydride, thorium, and plutonium are also pyrophoric when in the form of large pieces[27]. Pyrophoric metals are further considered in Chapter 8 and in Chapter 14.

Calcium permanganate and potassium permanganate are strong oxidizers, and pyrophoric reactions occur between these and glycerin, benzaldehyde, or dimethyl sulfoxide. Ignition can also occur when calcium permanganate contacts paper or cotton. The reactivity of the permanganates is further increased if concentrated sulfuric acid is added. Calcium hypochlorite ignites upon being mixed with a number of organic compounds and it is considered in some detail in Chapter 14.

Chemically different, but with similar hazard considerations are *water-reactive* materials. These include alkali metals and their hydrides, carbides, and amides. Some uranium compounds are both highly pyrophoric in air and water-reactive. Certain *mixtures* also react violently when wetted. These include magnesium powder with silver nitrate, aluminum powder with iodine, aluminum or magnesium with sodium peroxide, sodium hydroxide with ferrosilicon (which glows rather than exploding). The major works on water-reactive substances are the survey by Ripley[28] and the handbook by Gibson and Weber[29]. Water-reactive substances have some use in military and commercial applications, but accidental fires due to water-reactive substances have been very rare, so the cited works should be consulted for details on specific substances.

An exothermic reaction is said to be *hypergolic* if ignition occurs immediately upon contact between two substances. Such pairs of substances are common in the rocketry field, where a hypergolic reaction turns out to be a good way to provide a controllable propulsion source. The hypergolic nature makes it easy to quickly start up the process without a period of preheat. In other circumstances, such a combination of ingredients, if inadvertent, would be highly dangerous. Typical fuel portions of a hypergolic pair include hydrogen, ammonia, hydrazine, and various amines. The oxidizer portion can include hydrogen peroxide, fluorine, white fuming nitric acid, and nitrogen dioxide. Not all pairings have the hypergolic property. For instance, hydrogen will react with fluorine in a hypergolic manner but not with nitric acid. Conversely, ammonia will produce a hypergolic reaction with nitric acid, but not with hydrogen peroxide. Fletcher and Morrell[30] have reviewed research on the ignition of hypergolic rocket propellants. The physical aspects of the explosion that occurs when two hypergolic substances are combined have been studied in high-speed photography by Daimon et al.[31]

Apart from in the rocketry field, some hypergolic reactions find use in mundane applications. One such is a type of self-lighting welding torch which uses chlorine trifluoride and hydrogen. These gases ignite upon mixing, and yield HF and HCl as products. Fire bombs have also been made which depend on the hypergolic reaction between sulfuric acid and a sugar/potassium chlorate mixture.

Explosives

Explosives*, pyrotechnics, and propellants are substances which share some common traits: they are solids or liquids, not gases; and their main utility lies in the fact that they burn very fast. In the latter trait, they differ from liquid or solid combustibles of other types, which are substances that burn slowly, in comparison. The relative HRR differences are enormous. Where a solid combustible might show HRR values of 200 kW m^{-2} and a liquid 2000 kW m^{-2}, a detonating explosive may show 10,000,000 kW m^{-2}. Explosives are typically designed to detonate, while propellants and pyrotechnics must deflagrate rapidly, but not detonate. The pressures attained in a detonation are enormous, commonly

* More precisely, *condensed-phase explosives*.

being around 250,000 atm. Propellants comprise a wide variety of substances which are used for propelling rockets or ammunition. The main distinction between propellants and explosives is the time frame over which the energy is released. Whereas explosives may release their energy in a microsecond, a propellant, in order to deliver useful propulsion, may deliver it in a millisecond up to many seconds. Pyrotechnics are substances which react rapidly but are used for purposes other than shattering objects or propelling rockets or ammunition. The uses of pyrotechnics are for creating light, sound, gasses, motion, or smoke. The distinctions between these classes of substances are not always rigid. The term 'propellant' only came into use in the mid-20th century; earlier these substances were simply categorized as 'low explosives.' There is no substantive difference between propellants and pyrotechnics used for producing gas or motion.

Explosives do not necessarily always react by exploding; they may simply burn in a quiescent manner. This depends on the mode of ignition, as originally discovered by the British chemist Frederick Abel. In 1866 he documented that guncotton will simply burn if ignited by a flame, but will detonate if hit by a hammer with a heavy blow[32].

In this Section, we will first consider explosives and develop general principles for them. Many of these apply directly to pyrotechnics and rocket propellants, thus the following two sections are somewhat more brief in coverage. Some broad differences among combustibles are illustrated in Table 5. Note especially the low energy of explosion for TNT. This is the energy which can be delivered in an explosion, utilizing only the condensed-phase substances. The actual heat of combustion of TNT is 14.5 MJ kg^{-1}. To release this amount of heat requires that some of the carbon of TNT combine with gaseous oxygen from the atmosphere. Such further combustion can occur, but it is not part of the main explosion. Most pyrotechnic substances produce solids, rather than gases, as their primary reaction products. Thus, the volume of products is very small compared to ordinary combustibles or most explosives (some pyrotechnics used as airbag inflators, etc., are designed to produce substantial quantities of gaseous products). The examples in Table 5 make vividly clear that the hazard of explosives is not because there is a large amount of heat produced, but because the heat is produced very rapidly.

Table 5 A comparison of characteristics of some condensed-phase combustibles

Combustible	Formula	Gross Δh_c (MJ kg^{-1})	Volume of products, per mass of combustible (m^3 kg^{-1})
gasoline	$\approx CH_2$	46.9	3.20
wood	$\approx C_{24}H_{60}O_{28}$	19.5	1.52
TNT	$C_7H_5N_3O_6$	2.8[e]	0.740
photoflash mixture	$Ba(NO_3)_2$ + 13Al + $2KClO_4$	8.9	0.025
gunpowder	NA	2.0	NA

[e] energy of explosion

Most common liquids or solids burn by first evaporating or pyrolyzing to produce a flammable gas, then the gas combines with oxygen in a combustion reaction. These types of processes involve two steps, and both can be slow. (1) Evaporation or pyrolysis is limited by the time needed by heat to diffuse into the liquid or solid. (2) When the flammable vapor has been generated, it then still has to go through a slow process where fuel and oxygen molecules diffuse towards each other before the combustion reaction can occur. Explosives also acquire some of their energetic properties from the fact that heat transfer between the burned and the unburned substance is very high, since it occurs in the solid. By contrast, for pyrolyzing solids, the heat feedback from the burning gas back to the solid is inefficient. Thus, many of the unique properties of solid explosives and pyrotechnics come about because the basic reactions follow the form of:

solid A → solid B + gas (reaction #1)

or

solid C + solid D → solid E + gas (reaction #2)

in other words, either a single substance flies apart into fragments, or two types of molecules in intimate physical contact undergo a reaction. Explosives based on reaction #1 are referred to as *single-component explosives*, *molecular explosives*, *intramolecular explosives*, or *monomolecular explosives*. The reaction is one simply of decomposition. RDX (cyclo-1,3,5-trimethylene-2,4,6-trinitramine) is an example of a single-component explosive. Explosives based on reaction #2 are referred to *multi-component explosives*, or *intermolecular explosives*. Physically, the reactants in reaction #2 can be mixed and pressed powder, a particulate phase dispersed in a polymer matrix, a eutectic[33] formed by melting two substances together, etc. ANFO is an example of a multi-component explosive. Even though finely-ground powders and similar mixtures establish close contact between substances, nonetheless the possibility of reacting fast is greatest if a second substance is not needed at all, in other words, if a monomolecular reaction takes place. While there are exceptions and untypical substances, nonetheless many of the common explosives represent reaction #1, while pyrotechnics all correspond to reaction #2. This is because the speed of reaction should be maximized in an explosive, but if a pyrotechnic reacts too fast (i.e., detonates) it becomes a serious hazard rather than a technological tool. In some explosives, features of both reaction #1 and #2 exist—there exists more than one reactant, but at least one of those reactants itself acts as both a fuel and an oxidizer.

The role of the speed of the controlling processes that govern the rate of combustion can also be seen in reactions

between a fuel gas and air. If a fuel gas starts to leak into the air and is immediately ignited, it burns slowly, since diffusion of oxygen molecules to combine with the fuel molecules is necessary. But if a mixture of a fuel gas and oxygen is well stirred, then ignited, a forceful explosion will result.

TYPES OF EXPLOSIVES

Traditionally, explosives were subdivided as low explosives or high explosives according to the scheme below. In modern times, the substances that used to be termed low explosives are classed as propellants, although the traditional classification still sees some use. Flash powder has also been classed as a low explosive, but is currently classified as a pyrotechnic.

- *Low explosives* are fuel/oxidizer mixtures which burn when ignited but do not detonate. Low explosives must be confined for an explosion to be produced and tend to burn without explosion if unconfined.
- *High explosives* are capable of detonation under unconfined conditions.
  - *Primary explosives* are explosives that can detonate by means other than shock waves, for example, mechanical impact, heat or electric discharge. Primary explosives often serve as *initiators*. Examples: mercury fulminate, lead azide, lead styphnate, tetrazene.
  - *Secondary explosives* require a shock wave to detonate; the shock wave is typically supplied by a primary explosive. They tend to deflagrate, not detonate, when initiated by heat or sub-sonic shock. Examples: dynamite, nitroglycerin, PETN, RDX (cyclonite), TNT.

In explosions which do not reach the velocity of sound, i.e., in deflagrations, the damage is mostly from flying pieces of the container which was exploded. By contrast, in detonations the primary damage is from the blast wave itself, except for devices specifically designed to create shrapnel, such as bombs.

Explosives take the form of several *states of aggregation*:

- liquid
- slurry, gel or emulsion
- homogeneous solid
- granular solid

Liquid explosives are relatively rarely used, despite their long history of development. Nitroglycerin is an example of a liquid explosive, but as a pure substance it is not a practical explosive due to its instability. Instead, nitroglycerin is used as an ingredient in the manufacture of other explosives. *Sprengel explosives*, named after the German inventor Hermann Sprengel, are explosives where an oxidizer and a liquid fuel are mixed by the user just before use. At least one of the two components is a liquid. A wide variety of fuels and oxidants was explored by Sprengel. The oxidizer can include potassium chlorate, liquid NO_2, etc. The fuel can be CS_2, picric acid, petroleum, etc. While viable for commercial use, the actual use has been rare. LOX (liquid oxygen) explosives[34] are a still-used example of Sprengel explosives. A wide variety of substances can be used for its fuel component. During World War II, the Russians used the mixture KD in aerial bombs, which comprised 60% nitric acid and 40% dichloroethane[35].

Many explosive mixtures are neither liquid nor solid, but in a state of aggregation which is somewhat intermediate. These are commonly identified as slurries, gels, and emulsions. *Slurries or gels* often consist of ammonium nitrate, a fuel such as aluminum powder, and a thickening agent. The consistency is typically somewhat firmer than that of fresh concrete. The US military has explored a wide variety of liquid explosives, including sensitized nitromethane and hydrazine-based materials, with an eye toward developing gels that use the liquid explosive plus a gelling agent. These have been described[36], but have not come into significant use. *Emulsions* are typically water-in-oil emulsions which comprise a saturated nitrate solution and mineral oil. These are available as packaged cartridges but may also be site-mixed. Slurries, gels and emulsions also require entrained air to be sensitive enough for useful work; this is commonly accomplished by including air-filled microballoons. Additional sensitizing components are often added; these may be aluminum flake, methyl amine nitrate, isopropyl nitrate, hexamethylene triamine trinitrate, ethyl glycol mononitrate, PETN, or TNT.

Many explosives are homogeneous solids, e.g., nitrocellulose. The physical properties are also homogeneous when an explosive is prepared from two or more components as a solid colloidal solution, for example, nitrocellulose and nitroglycerin. *Plastic explosives* contain a polymer such as polybutadiene or polyurethane in which is dispersed a granular explosive (e.g., octogen, RDX). The plastic explosive can be formed into thin sheets or into other desired shapes. Plastic explosives became very successfully commercialized by the Czech firm VCHZ Synthesia (formerly, Semtin) in the form of Semtex. While various grades exist, Semtex generally consists of PETN and RDX in a plastic substrate (styrene-butadiene copolymer), along with dye, antioxidant, and plasticizer. Semtex became a favorite of terrorists due to its ease of concealment and the difficulty of detecting it by chemical sensing outside the package. Thus, a 1991 treaty, the Convention on the Marking of Plastic Explosives for the Purpose of Detection, to which US is a signatory, was enacted which requires that all plastic explosives be 'tagged' by adding an agent to the explosive which has sufficient vapor pressure and a unique signature allowing detection. Synthesia is currently using para-mononitrotoluene or dimethyl-dinitrobutane as taggants for its products. In military applications, C-4 is the most common; it comprises 91% RDX, 5.3% di-(2-ethylhexyl)sebacate, 2.1% polyisobutylene, and 1.6% motor oil. Various types of explosives are also prepared as *putties*, *extrusions*, *castings*, *rubber sheets*, etc.

Granular solids comprise a large category of commercial and military explosives. *Dynamite* was originally a trade name of the Nobel company and referred to powders impregnated with nitroglycerin. Later, gel forms of dynamite came into use. The term has become very broad in meaning, and one definition is[37]: an organic nitrate ester (e.g., NG) along with optional presence of oxidizing salts, carbonaceous filler, sulfur, NC, or microballoons. In US Army usage, a dynamite does not contain any nitroglycerin but, rather, is based on RDX and TNT. For commercial blasting purposes, dynamites have largely been supplanted by ammonium-nitrate based ANFO explosives (see Chapter 14).

Forensics experts often classify explosives according to their origin as:

- commercial explosives
- military explosives
- improvised (i.e., home-brew) explosives.

A bomb concocted from improvised explosives is designated as an IED, an *improvised explosive device*. Improvised explosives are often formulated because raw materials are more readily available for them then for making commercial or military explosives. Unfortunately, many of these are substances which are of poor stability, even in normal handling. In recent years, improvised explosives encountered by authorities included urea nitrate (used in the 1993 bombing of the World Trade Center), TATP (triacetone triperoxide), and HMTD (hexamethylenetriperoxidediamine).

CHEMISTRY OF EXPLOSIVES

The vast majority of explosives are based on molecules which contain nitrogen atoms. The most common functional groups include:

- nitro ($-NO_2$). Example: TNT (2,4,6-trinitrotoluene), $C_7H_5(NO_2)_3$
- nitroso ($-NO$). Example: hexanitrosobenzene, $C_6N_6O_6$
- nitrate ($-ONO_2$). Example: PETN, pentaerythritol-tetranitrate, $C_5H_8(ONO_2)_4$
- nitramine ($>NNO_2$). Example: RDX (cyclotrimethylene trinitramine), $C_3H_6N_3(NO_2)_3$
- azide ($-N_3$). Example: lead azide, $Pb(N_3)_2$

The combustion of pyrotechnics and solid or plastic explosives is sometimes viewed as being based on *solid-state reactions*. In chemistry in general, most reactions occur between liquids or gases, not between solids. The same is true of combustion. A piece of wood is able to ignite and burn because localized high temperatures break down the molecular structure of the solid and release low-molar mass gases. These gases combine with the oxygen in the air to exhibit flaming combustion. A second reaction in the combustion of wood occurs when the heated, charred solid material is directly attacked by oxygen—this exhibits glowing. In no case, however does wood show a reaction involving two solids. Explosives and pyrotechnics, in fact, constitute the only important examples where combustion may involve solid-solid reactions. Whether or not direct solid-solid reactions are important has been debated. McLain[38] considers that they are pivotal, while Hardt[39] feels that they are secondary, at best. In McLain's view, the reactions of solids cannot be viewed in terms of simplified idealizations which are possible with gases. For gases, use of ideal-gas relationships often provides accurate answers, at least if extremes of pressure or temperature are avoided. With solids, however, the defects of their crystal structure tend to govern much of their chemistry. A unique feature of solid-solid reactions is that they must be exothermic. According to the Second Law of Thermodynamics, the Gibbs Free Energy, ΔG, must be negative for a reaction to occur. But $\Delta G = \Delta H - T\Delta S$, where H = enthalpy, T = temperature, and S = entropy. If the reaction products are solids, then $\Delta S \approx 0$. Thus, to have a negative ΔG requires a negative ΔH, in other words, an exothermic reaction.

In Hardt's view, by the time the ignition temperature has been reached, for the majority of explosives or pyrotechnics, at least one component has already melted; thus, the actual reaction is solid-liquid. Furthermore, in his view, many explosive reactions are actually controlled by the diffusion of heat and not by chemical reaction rates. Thus, a number of explosives exist where the reaction rate is independent of temperature but dependent on the thermal conductivity. In actual fact, both types of behaviors must be recognized. In general, solid explosives can be organic, inorganic, or organometallic compounds. These will innately show different thermal and explosive behaviors, since organic materials usually melt before decomposing, while inorganic and organometallic explosives generally decompose before melting. This is why a melting point temperature for many explosives cannot be stated, and chemical handbooks instead state "decomposes." The basic difference stems from the covalent bonds in organic solids, versus ionic bonds in inorganic. The above grouping is very rough however, and some inorganic azides, for example, melt before exploding. There can be difference in the type of chemical bonds even within one chemical family. As an example, inorganic azides range widely in their sensitivity—lead azide is highly sensitive and has covalent bonds, sodium azide is insensitive and has ionic bonds.

Even metal-metal reactions sometimes turn out to be solid-liquid, rather than solid-solid. Hardt cites Pyrofuze as an example. Pyrofuze is made by cladding an aluminum wire with an outer layer of 95% palladium/5% ruthenium. When heated to a critical temperature, a rapid exothermic reaction takes place, but it requires initial melting. The rate of reaction is then limited by diffusion, not by chemical kinetics. *Solid-gas* reactions are also involved in some explosives, and the gas referred to here is not oxygen from the air, but, rather, a gas which is evolved from one of the solid components during early stages of decomposition.

In addition to unwanted detonations, the other hazard which can exist with explosives is *thermal decomposition*. The chemical reactions and reaction products are different for

the two cases. In a detonation, commonly most of the reactants become converted to their maximum oxidized state, such as CO_2 or water vapor. In decomposition, however, it is usual to find that molecule fragments are formed which are far from being fully oxidized. The decomposition reactions of explosives can be complicated, and may often include autocatalytic regimes. The decomposition of cellulose nitrate is discussed in some detail in Chapter 14.

OXYGEN BALANCE

For a condensed-phase explosive to be most effective, the needed oxygen must come from the condensed phase. It should not be necessary to use oxygen diffused from the air, since the diffusion process is much slower than is the process of reaction when molecules of fuel and oxidizer are in close physical contact. However, if an explosive contains too much of oxidizing components, then these cannot be reacted because there is not enough fuel. Thus, the concept of oxygen balance arises. It is defined as the amount of oxygen contained in the explosive, minus the amount needed for complete oxidation, expressed as mass percent of the initial explosive. An effective explosive will have an overall oxygen balance close to zero. Each of the components, however, may have a negative or positive contribution. For an explosive having the general composition $C_cH_hN_nO_o$, the oxidation can be expressed as:

$$C_cH_hN_nO_o \rightarrow n_cCO_2 + \frac{n_h}{2}H_2O + \frac{n_n}{2}N_2 + \left(\frac{n_o}{2} - n_c - \frac{h_c}{4}\right)O_2$$

If the amount of oxygen atoms is large in the explosive, then there is some oxygen left over in the form of O_2, and that amount is $\left(\frac{n_o}{2} - n_c - \frac{n_h}{4}\right)$. Conversely, if the amount in parentheses is negative, then it means that the reaction will seek out the deficit from atmospheric oxygen. Consequently, the oxygen balance OB (percent) is expressed as:

$$OB = 100 \times \frac{32}{M}\left(\frac{n_o}{2} - n_c - \frac{n_h}{4}\right)$$

where 32 is the molar mass of O_2 and M denotes the molar mass of the explosive. Substances which function as oxidizers have a positive OB, substances which are fuels that have a negative OB. As an example, TNT has the formula $C_7H_5N_3O_6$ and a molar mass of 227.1, so

$$C_7H_5N_3O_6 \rightarrow 7CO_2 + \frac{5}{2}H_2O + \frac{3}{2}N_2 + \left(\frac{6}{2} - 7 - \frac{5}{4}\right)O_2$$

then its oxygen balance is:

$$OB = 100 \times \frac{32}{227.1}\left(\frac{6}{2} - 7 - \frac{5}{4}\right) = -74\%$$

This number is highly negative and implies that, for the most efficient explosion, it should be paired with another component which has a positive oxygen balance. Figure 1 shows the relation between OB and the heat of explosion, as evaluated for 13 different propellants. It is evident that OB = 0 correlates to the highest heat of explosion and deviations to either side cause a reduction. The oxygen balance concept should not be used heedlessly as a measure of hazard across widely disparate chemical families[40], but is otherwise a highly useful 'first indicator.' The propellant at the cusp of the graph, by the way, is EGDN. It should be noted that while the definition given above is the most common, some authors have used different definitions. For example, Kamlet and Adolph[41] proposed that (a) carbon atoms should end up in CO, not in CO_2; (b) that the COO group (carboxyl) should be considered non-participating in the combustion reaction; and (c) that the equation be normalized by dividing through by 8. Thus, their definition of oxygen balance becomes:

$$OB_{Kamlet} = 100\left(2n_o - 2n_c - n_h - 2n_{coo}\right)$$

According to Kamlet, then, TNT would have OB_{Kamlet} = –3.08%.

If the oxygen balance is significantly negative, then a *fireball* should be expected to follow after the detonation wave is finished. If large amounts of black smoke are visible, this is likely to be because the oxygen balance was negative and carbon was left over unreacted. A positive oxygen balance does not mean that a fireball is precluded, since fuel can be made available by the blast wave itself if, for instance, a combustible material is pulverized and dispersed into the air.

For the oxygen balance concept to be meaningful, the oxygen contained in the solid-phase material must be readily available for reaction, not just be present. Thus, for multicomponent solid explosives it is important to make sure the powder is finely ground, where the grains of fuel and oxidizer are closely intermixed.

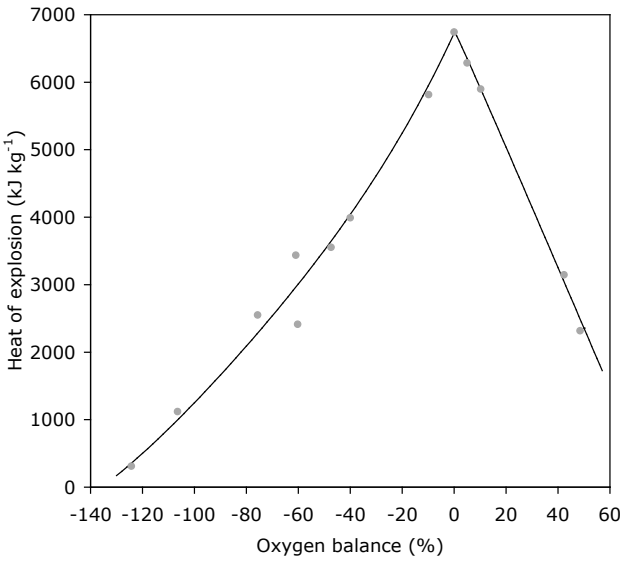

Figure 1 The relation between OB and heat of explosion for a number of propellants

INITIATION AND IGNITION

The beginning of a detonation in explosives is normally termed *initiation*, whereas the term *ignition* implies the start of combustion, but not necessarily of detonation. There can be many modes of initiation for explosives, with some examples being:

- self-heating
- flames or external heat flux
- friction, impact, shock, vibration
- electricity
- light energy, including photochemical excitation
- compression
- sympathetic explosion due to shock waves from an initiating explosion
- crystal growth.

Despite the variety of forms by which energy is delivered, most of these processes ultimately express their effect through thermal means. The actual mode of ignition is often not clear in accidents, and there may be more than one mode involved. For example, nearly a century ago, BM[42] documented three fatal explosions that each took place when wooden tools were driven into the top of a wood keg of black powder in an effort to remove the top. Wood-against-wood will not produce sparks and black powder would not be expected to explode from a small amount of compression, although perhaps a large amount of compression was sustained to particles trapped between two chimes.

In military usage, *sensitivity* is a measure of the amount of energy required for initiation[43]. This general concept has been very difficult to quantify in an acceptable manner, since the energy required for initiation not only depends on the mode by which it is supplied, but also depends on details of the test apparatus. For instance, even results from several types of drop-hammer tests for initiation by impact agree—at best—only qualitatively. It has been proposed that, within a particular chemical family, the sensitivity of an explosive can be related directly to its heat of reaction. Table 6 illustrates this for inorganic azides.

Table 6 Relative sensitivity of inorganic azides[53]

Sensitivity	Substance	$-\Delta h_r$ (kJ mol^{-1})
Most sensitive	$Pb(N_3)_2$	481
↓	TlN_3	234
↓	$Ca(N_3)_2$	46
Least sensitive	LiN_3	13
Non-explosive	KN_3	0
	$Ba(N_3)_2$	-21

SELF-HEATING, STABILITY IN STORAGE, AND EXPOSURE TO HEAT

Until the middle of the 19th century, the only available explosive was black powder, and it is quite stable against self-heating. Subsequently, nitrocellulose, nitroglycerin, and other nitrate ester explosives were invented. The RO–NO_2 bond in these is of limited stability, and numerous accidental explosions began to demonstrate this fact. A stabilizer is added to such explosives in order to increase their useful lifetime; it is a substance that interferes with the decomposition reaction in some manner. The stabilizer is typically sacrificial, and when it is largely used up, the explosive becomes unstable. Thus, the effective lifetime of stabilization is finite. For explosives in the nitrate ester family (nitrocellulose, nitroglycerin, etc.) testing can be done by monitoring for the production of NO_2, which is a decomposition product. This product will not be produced in significant quantity until the stabilizer is used up, after which point rapid production sets in and the explosive becomes unstable. If the explosive has become highly unstable, sufficient NO_2 may be produced so that reddish-brown fumes are actually visible. In laboratory studies, simply monitoring weight change is often sufficient. Figure 2 shows the decomposition of two nitrocellulose-based propellants[44] when tested at an elevated temperature of 90ºC. Propellant B becomes unstable at about 50 days, while Propellant A has a lifetime about half that.

The effective storage lifetime of the explosive can be estimated by determining the decay of the stabilizer's concentration with time. Volk[45] has shown how a plot can be created on the basis of a simple study using thin-layer chromatography (Figure 3). Since the plot is found to be linear using semi-log axes, extrapolation can readily be made to longer periods and lower temperatures.

Assuming that any necessary stabilizer has *not* been depleted, an explosive may still go into thermal runaway if its storage temperature/size relationship is unfavorable. The theory commonly used is the same 'thermal explosion theory' as was already presented in Chapter 9 for self-heating substances. In other words, the explosive is assumed to comprise a volume of substance which is homogeneous. Its chemistry can be represented by a single-step reaction, whose rate follows the Arrhenius form. Many different conditions are possible at the boundaries, same as in the self-heating problem: convective cooling; conduction; a fixed surface temperature; an imposed heat flux, etc. Looking at the details of actual ignition of explosives, it has been demonstrated[46] that initiation occurs at small hot spots rather than homogeneously throughout the body of the substance. However, generally successful correlations based on thermal explosion theory have been achieved ignoring the hot spot complication. A more serious problem is that a computationally useful form of the theory has to assume that the heat of reaction is a constant, whereas for some unstable explosives, this is not true. van Geel and Verhoeff[47] proposed that a test method similar to UN Test H3 (see Chapter 9) be used, along with standard Frank-Kamenetskii theory. Based on the theory as given in Chapter 9, the maximum dimension r that is permissible without thermal runaway is given by, with slight re-arrangement:

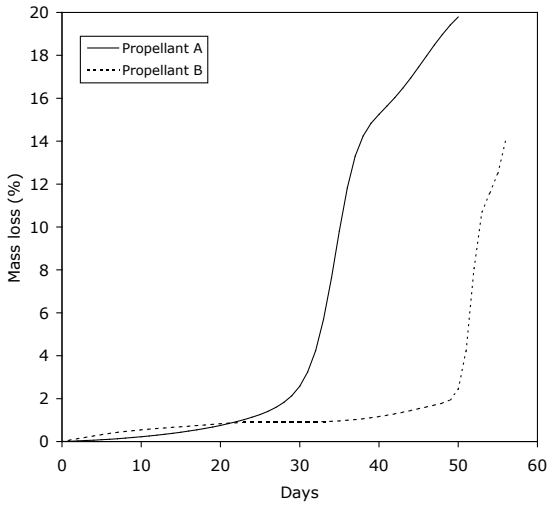

Figure 2 Mass loss of two nitrocellulose propellants, tested at a temperature of 90ºC

$$r = \sqrt{\frac{RT_a^2}{E}}\sqrt{\frac{\delta_c \lambda}{\rho q}}$$

where $q = QA\exp(-E/RT_a)$. The latter heat evolution variable is used since that is what is measured experimentally in the H3 test. van Geel and Verhoeff point out that when the heat release is measured at a standardized, higher temperature T_m, and the end-use ambient temperature is T_a, the relation can be modified to give:

$$r = \sqrt{\frac{RT_a^2}{E}\exp\left[\frac{E}{R}\left(\frac{1}{T_a}-\frac{1}{T_m}\right)\right]}\sqrt{\frac{\delta_c \lambda}{\rho q_{T_m}}}$$

They further assumed that the HRR in the laboratory is measured at T_m = 358 K (85ºC), and that T_a will mostly be 30ºC, but with possible short-term excursions up to 71ºC

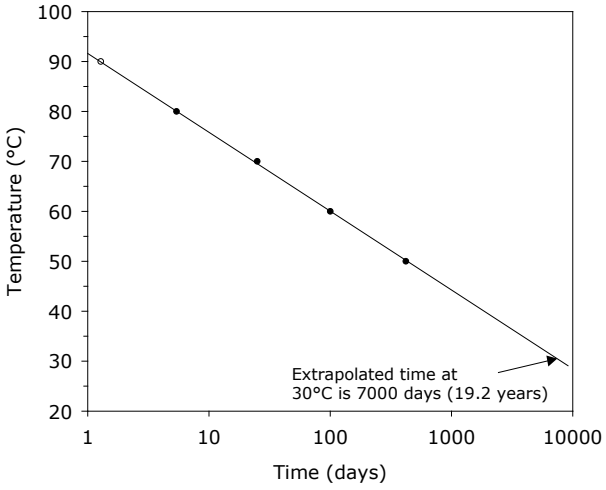

Figure 3 Effect of storage temperature on the lifetime of a commercial propellant (Ball powder K 503) preserved with diphenylamine

(344 K), consequently the latter value is used. Then for values of E in a practical range (between 40 and 200 kJ mol^{-1}), the first factor in the above equation does not vary much, and they suggest that it can conservatively be taken as 6.05. The predictive relation becomes:

$$r = 6.05\sqrt{\frac{\delta_c \lambda}{\rho q_{\max}}}$$

where the value of q_{max} used is the maximum heat release (W kg^{-1}) measured during a 1-week test at 85ºC. For ten different commercial single-, double-, and triple-base propellants they measured q_{max} values between 40 and 200 W kg^{-1}. Safe storage radii were found to range between 0.15 and 0.35 m. If a necessary stabilizer becomes depleted, the HRR measured in the H3 test would shoot up dramatically, however, the method assumes that storage lifetime based on stabilizer depletion will be determined separately and only non-depleted explosives subjected to the HRR testing.

In tests where a small sample is heated isothermally, for very short ignition times, heat losses can be ignored. Then, it can be shown[53] that ignition time data can be represented in the form:

$$\ln(t_{ig}) = \frac{E}{RT} + B$$

where B is a constant for a given substance. For example, Johansson et al.[48] obtained ignition time data for PETN as:

$$\ln(t_{ig}) = \frac{23256}{T} - 44.38$$

valid for $T < 528$ K.

Many explosives fail to conform to Arrhenius kinetics if a substantially wide temperature range needs to be considered. Rogers et al.[49] provided an illuminating example of an explosive comprised of three components which was analyzed extensively both by DSC and in various medium-scale tests. It was found that Arrhenius kinetics could not describe satisfactorily the self-heating behavior, but a reasonable representation was obtained by using an autocatalytic model. A theory has been developed that entails two parallel, Arrhenius-form reactions[50], however, it does not lead to closed-form solutions or approximations. Many explosives become less stable with protracted storage. Chemically, this means that the substance is undergoing an autocatalytic reaction, since the definition of an autocatalytic reaction is one which is accelerated by an accumulation of reaction products. Russian researchers[184] proposed that most thermal decomposition reactions of explosives are autocatalytic. This was demonstrated for several explosives by Tarver et al.[51], who showed that reaction rates increased 3- to 5-fold when gaseous decomposition products were not allowed to escape. They also showed[52] that HMX and RDX decomposition entails three consecutive reactions, NC has a 2-step autocatalytic reaction, while TNT exhibits a 3-step autocatalytic reaction. Some additional practical implications of this are discussed below, under the Henkin Test.

The exceptional sensitivity of explosives can be judged better by considering the quantities needed to cause explosion from runaway self-heating. For example, in Chapter 9 it was seen that generally many kilograms of various common materials were needed for thermal runaway to occur. By contrast, Bowden and Yoffe[53] report that a 1 mg quantity of silver azide will undergo thermal runaway at 375ºC. Similarly, a single crystal of mercury fulminate held at 170ºC will lead to thermal runaway if its thickness is larger than 22 μm.

In terms of chemical families, those containing the nitrate functional group (cellulose nitrate, nitroglycerin, etc.) are of low stability, while those containing the nitro functional group (TNT, tetryl, RDX, etc.) are of high stability. Some data from Rogers[54] illustrate this trend (Figure 4).

Many organic explosives have limited stability, even if stored at room temperature. Some details are given in connection with cellulose nitrate (Chapter 14). But even lead azide, which is a simple, inorganic molecule, shows problematic stability[55]. To prolong its storage life, it is typically stored in an alcohol-water solution. But even stored this way, it gradually decomposes by liberating hydrazoic acid, HN_3.

Sometimes explosives are subjected to a certain amount of heating during packaging. Thus, Persson and Jerberyd[56] presented a model for the detonation of a thin layer of dynamite as it is being heated during ultrasonic welding of the surrounding plastic packaging material. Explosives may also be exposed to heat in various other circumstances and the question then arises if, once cooled back to ambient, they have been substantively altered. Freeder et al.[57] exposed a series of explosives to 75ºC temperature for 1 or 10 days, then cooled them and retested their performance in a drop-hammer test and in the Koenen/BAM friction test. For black powder, black-powder-based explosives, ANFO, and an emulsion explosive, there was no effect. A flash composition, blasting gelatin, and two slurries (RDX and HMX based) showed significant increase in sensitivity. A final group, comprising a single-base propellant, a double-base propellant, a slurry, and an emulsion explosive, showed anomalous behavior: heating for 1 day made performance worse, but heating for 10 days proved less deleterious. The reason for the anomalous behavior was not elucidated.

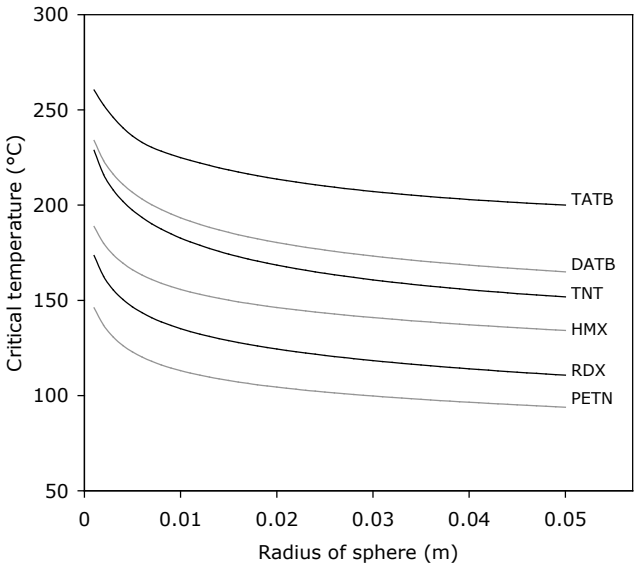

Figure 4 Relative self-heating tendencies of several common explosives

IMPACT AND SHOCK

Impact is usually understood to be created by impulsive mechanical loading, i.e., not created by an existing shock wave. *Shock* initiation of explosives, on the other hand, refers to initiation from an already-detonating substance. *Sympathetic detonation* refers to shock initiation by a detonating substance that is not in intimate contact with the target explosive. The initiation occurs within the body of the receptor, and not at the surface, and it occurs at a point, rather than spread out along a plane[58]. Sympathetic detonation is the principle utilized in card-gap tests, discussed at the end of this Chapter.

Wanted initiation of primary explosives can be by fire, such as from a fuse, mechanical energy such as by a firing pin, or electrical energy as in a blasting cap. But secondary explosives are ones which, by definition, need to be initiated by a shock wave, normally created by the use of a primary explosive. With many secondary explosives, using a form of energy other than shock waves may result in deflagration rather than detonation. Conversely, since primary explosives are highly sensitive to various forms of energy input, it is not necessary to use an initiation source as powerful as a shock wave for them.

Bowden considers that impact can act to initiate an explosive in any of the following ways[59]:
(1) by adiabatic heating of compressed gas spaces
(2) a frictional hot spot on the confining surface or on a grit particle
(3) intercrystalline friction of the explosive itself
(4) viscous heating of the explosive at high rates of shear
(5) heating of a sharp point when it is deformed plastically
(6) mutual reinforcement of gentle shock waves

The impact needed can come from a wide variety of sources. For example, flying fragments of a crystal of an explosive can initiate a detonation. Lead azide can be initiated this way, but not TNT or tetryl[53].

The action of an external impact or an impinging shock wave is highly complex, since mechanical deformations (occurring in both the casing and the explosive) are coupled to shear, viscous flow, and wave propagation phenomena in the explosive. The mechanical work, if converted uniformly to heating the whole mass of explosive, would generally not

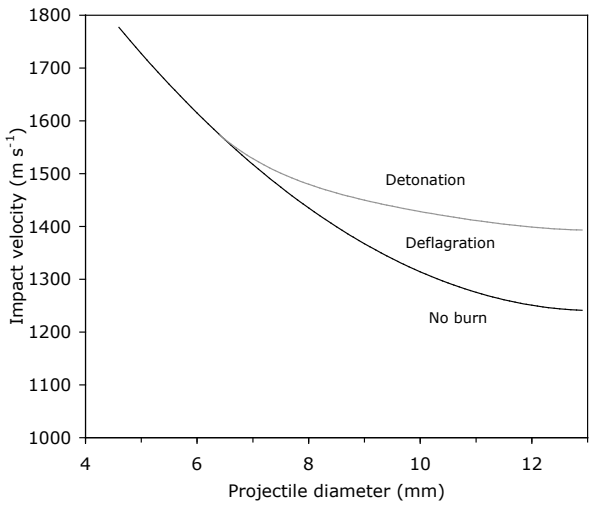

Figure 5 Impact regimes for HMX/polyurethane propellant

be sufficient for ignition. Ignition can occur because the distribution of energy is concentrated and non-uniform[60]; the high pressures and high temperatures thus created then can act as a hot spot to ignite the rest of the material. In liquid explosives, non-uniform distribution of energy commonly occurs due to the presence of gas bubbles[61]. The bubbles may be either in the volume or at the boundary. This bubble can be created as the solid surface is impacting the liquid, possibly aided by asperities in the surface. The bubble is effective in initiating explosion due to the heating effect of adiabatic compression. Some very high pressures can be created in a bubble by applying only modest overall pressure to the volume of substance, since a liquid is nearly incompressible, compared to an air bubble. This rapidly created high pressure causes high temperatures within the bubble. The explosion actually begins in the gas phase, even though the fuel vapor concentration within the bubble may be very low. This initial combustion is analogous to cool flames, with temperatures being in the range of 300 – 500ºC. For liquids, if no bubbles are trapped anywhere, then it is found that impact energies some 3 – 4 orders of magnitude higher are needed for the initiation. In these cases, it is considered that most of the energy is transferred by viscous heating of the plastically-flowing explosive. Médard[3] described an injury that occurred when 20 g of nitroglycerin was dropped 1 – 1.5 m onto a floor. Laboratory experiments were then conducted where glass flasks with 100 g of nitroglycerin were dropped 80 m from a cliff onto a steel armor plate. These resulted in zero explosions in 20 tries and Médard concluded that air bubbles were trapped in the case of the accident, but not in the experiments.

According to Bowden, small voids play a similar role in a solid when gas is trapped in the spaces between crystals. Upon impact, initial plastic flow seals off individual gas packets, then compression can raise the temperature of the gas volume in the same way that it does for bubbles in liquid explosives. The impact energy required to detonate solid explosives, however, is much greater than for liquids. In addition to requiring a high energy, the face of the colliding object ('striker') must be hard enough to plastically deform the explosive, rather than being itself deformed. The hot spot temperature needed to initiate an explosion from impact is similar to that needed to cause initiation from friction. Same as with friction ignitions, grit serves to facilitate ignition from impact, provided the melting point of the grit is higher than the temperature needed for initiating the particular explosive. Frey[62] attempted to create a fairly comprehensive model of initiation through collapse of voids. His solutions were wholly numeric in nature, but he did demonstrate that there is a critical size for a void, beyond which peak temperatures that are reached increase greatly.

The effects of impact are especially complicated for multicomponent explosives. Bowden[63] studied the ignition of black powder (potassium nitrate, sulfur, charcoal) and found that ignition generally occurs at 300 – 350ºC. But the formation of a liquid phase appears to be a necessary precursor, and this occurs at 120ºC, which is the melting point of sulfur.

Bowden's theory, as applied to solids, was contested by Russian researchers[184], who proposed the alternative theory that sizable regions of inelastic deformation (plastic flow) are needed for initiation to occur, and that included voids do not act as a facilitating mechanism for solids. A version of this theory was also adopted by Heavens and Field[64], who conducted extensive experiments on a wide variety of explosives and concluded that, with certain materials, rapid plastic flow leads to the formation of hot spots, which become the locations of ignition. From their drop-hammer experiments, they concluded that plastic flow was the impact ignition mechanism for AP, HMX, PETN, and RDX. US military researchers have had mixed opinions on the matter, with some holding that inelastic deformation of crystals is the main cause of impact initiation in solids[65]. Others[66] however have concluded that gas compression is important, but so is the explosive's tendency to break up into small particles during cavity collapse. A number of theories (e.g., Frey[67]) have been put forth that detonation during impact can originate at a shear band, which is a localized zone of thermal softening that can develop. Experiments have also been devised where direct failure in a shear mode causes initiation[68]. Dienes[69] demonstrated that shear bands can be modeled by an application of F-K theory.

Kondrikov and Tchubarov[70] tested a number of secondary explosives in a drop-hammer test and concluded that there are three stages leading to ignition:

(1) Slow deformation of the pellet under continually increasing pressure, accompanied by a temperature rise of only about $0.8(T_m - T_o)$, where T_m = melting point temperature and T_o = ambient temperature.

(2) Destruction of the pellet, with the energy accumulated during the first stage being released as kinetic energy of the fragments, which fly off as jets of powdered substance; this is accompanied by partial melting of the material.
(3) Pressure begins to rise again in the material that remains; if the velocity of the escaping material in this stage attains a critical value, ignition occurs. The measured critical velocities ranged from 250 m s^{-1} for PETN to 550 m s^{-1} for DINA.

Chaudri[71] showed that causing a rapid fracture of single crystals of sensitive primary explosives by using a high-speed chisel does *not* lead to initiation. He concludes that initiation would only be possible if very high strains could be induced in the crystals, but that this does not appear to be the case. He also presented theoretical calculations showing that the maximum temperature rise that could be caused by inducing plastic flow in explosives crystals is of the order of 20ºC, which he considered as disproving that mechanism. But the temperature rise predicted from friction between grains was on the order of 200ºC, which makes inter-grain friction a much more plausible mechanism. Chaudri's interpretation is that the main mechanisms are:
(1) adiabatic heating within bubbles;
(2) inter-grain friction;
(3) fast gas jets formed at bubbles, when presented with a strong shock.

The initiation by impact is, unfortunately, as much dependent on physical properties of the explosive as it is on its chemistry. For crystalline materials, even size of crystals is an important variable. Figure 6 illustrates the effect for drop-hammer testing of lead azide crystals[72]. When granular material is prepared by pressing, the effect of the pressed density can overwhelm other effects in the system. Seay[73] reports that PETN requires 45 times greater impact pressure to initiate it in single-crystal form (1786 kg m^{-3}) than in pressed form at 1000 kg m^{-3}.

Somewhat surprisingly, it was demonstrated[74] that certain polymer/explosive formulations are more sensitive in drop-hammer tests than is the pure explosive. This tendency was especially strong in polymers having a high glass transition temperature, e.g., polycarbonate or polystyrene. In addition, a low heat capacity, low heat of fusion, and high strength of polymer promoted sensitization. The mechanism was considered to be one of localized, brittle cracking.

As might be expected, sensitivity to shock initiation[107] is decreased by decreasing the temperature or the duration of exposure. The effect of packing density is complex and is considered later in this Chapter. Particle size is also important, there being an optimum size for ease of initiation, with larger or smaller particles being less sensitive. Very small particles give a low sensitivity since hot spots become small. Homogeneous explosives are less sensitive to shock

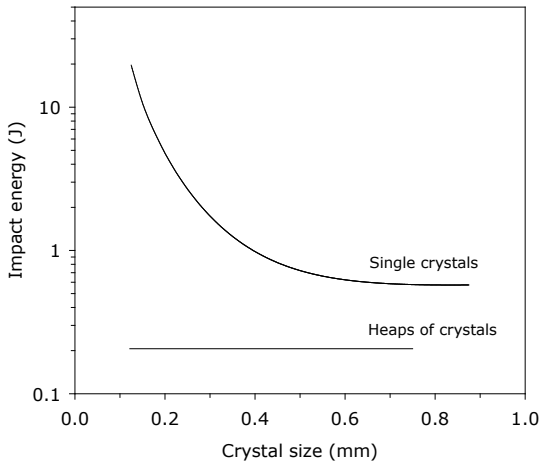

Figure 6 Effect of crystal size on drop-hammer test results for lead azide

initiation than are heterogeneous ones. In tests where the explosive is highly confined, as the packing density approaches the theoretical maximum density, sensitivity to shock greatly decreases. This is because initiation at voids becomes increasingly unlikely[75].

When a projectile hits an unconfined explosive or propellant substance, there can, in general, be three results: (1) no burn; (2) deflagration; or (3) detonation. Anderson et. al.[76] conducted tests on a propellant made of HMX and polyurethane by subjecting specimens to impact from cylindrical gun-fired projectiles of various diameters and velocities. Their results, shown in Figure 5, indicate that for small diameter projectiles, only two outcomes are possible: no-burn, or detonation. For larger diameters, however, a third regime of deflagration becomes possible. The authors computed the critical energy fluence for the results and concluded that it was roughly constant for the deflagration threshold, but not constant for the detonation threshold. The velocities required for initiation were very high in Anderson's study; it is not clear if similar relations are obeyed for more sensitive explosives.

Explosives are commonly tested for impact initiation by use of one of the many drop hammer tests (see below). If the specimen is unconfined, then the failure mode has been found to be radial cracks[77] that are generated at the periphery of the specimen. For shock initiation, the most common test arrangement is a card-gap test.

Theories of impact and shock initiation

Uniform heating of an explosive by a shock wave plays no role in initiation. In general, a uniform temperature rise of only 100 – 200ºC would occur under shocks sufficient to initiate detonation[107]. The essential trait of shock wave heating, instead, is that the heating is not spatially uniform. The increase in internal energy from a shock occurs as visco-

plastic heating and is concentrated in small hot spots of the shocked material. The microscopic mechanism is the collapse of individual pores under shock pressure. The sensitivity to shock has been shown to be not correlated to thermal (self-heating decomposition) sensitivity of explosives[84]. This is not surprising, since it has been learned that the actual reaction mechanisms are different for moderate temperature/pressure decomposition and for shock wave initiation. For some explosives, e.g., liquids, the reaction rates within the heated volume can be modeled by thermal explosion theory[78], but in granular explosives grain burning needs to be modeled.

Friedman[79] provided a one-dimensional treatment where the impact-caused hot spot is approximated as a plate of finite thickness in a substance which is infinite in extent along both directions of the face. The critical half-thickness d_c is found as:

$$d_c = \left(\frac{\lambda (T_h - T_o)}{\rho Q A} \right)^{1/2} \exp\left(\frac{E}{2RT_o} \right)$$

where T_h is the hot spot temperature and T_o is the ambient temperature. A correlation to impact sensitivity as measured by the Explosives Research Laboratory Machine was given as:

$$0.287 \ln h + \ln F + \frac{0.0602E}{300 + 22.9h^{0.574}} + 0.684 = 0$$

where h = drop height (cm), E = activation energy (kJ mol^{-1}) and $F = \sqrt{\lambda / \rho Q A}$. Thus a relation is obtained between drop height and the thermochemical quantities E, Q (heat of reaction), A (pre-exponential factor), λ (thermal conductivity), and ρ (density). Coffey[75] suggested that drop hammer test results can be roughly correlated by noting that G^2h is approximately a constant, where G = shear modulus (N m^{-2}) and h = drop height (m).

Kamlet[41,80] conducted a large number of drop-hammer tests (see Test Methods) on a wide variety of explosives. His tests showed that substances with a higher OB need a smaller amount of energy for initiation, and on that basis they found a relation between oxygen balance and drop-hammer results. For aliphatic compounds, the results were found to depend on whether NO_2 is attached to a nitrogen or to a carbon atom, with the latter requiring higher drop heights for initiation. He also observed that if an aromatic ring has a hydrogen atom bonded directly to a carbon atom of the ring, this constitutes a weak spot for initial decomposition of the molecule. As an example, Kamlet compared TNT and TNB (1,3,5-trinitrobenzene). TNT has an alpha C–H bond, and decomposes at about 200ºC, while TNB does not, and decomposes at about 300ºC. This weakness is reflected in the correlations—for a given *OB* value, explosives with an alpha C–H bond need a smaller drop height for initiation. Note that Kamlet's definition of oxygen balance, OB_{Kamlet}, is not the standard one, however, as discussed above. The correlations of Kamlet's results are:

aliphatic compounds with N-NO_2 group:

$$PE = 5.78 \exp(-0.39 \times OB_{Kamlet})$$

aliphatic compounds with $C(NO_2)_3$ group:

$$PE = 13.88 \exp(-0.54 \times OB_{Kamlet})$$

aromatic compounds, alpha C-H bond present:

$$PE = 5.25 \exp(-0.60 \times OB_{Kamlet})$$

aromatic compounds, alpha C-H bond absent:

$$PE = 13.18 \exp(-0.65 \times OB_{Kamlet})$$

where PE = potential energy for initiation at the 50% probability level (J). In drop-hammer testing, the design of the apparatus has a sizeable effect on the results, thus correlations of this nature should be taken as expressions of trends, not as absolute values of required energy. The drop-hammer apparatus used by Kamlet was the version developed at the Naval Surface Weapons Center.

The theory propounded by the Russians Afanasev and Bobolev in their textbook[184] is substantially different from US methodologies. It is quite convoluted, but basically describes a substance which is compressed to a degree enough to greatly raise its temperature and which then fails in a brittle way. Two separate versions of the theory are formulated, one for thin bodies and one for thick, with separate initiation criteria being given. Applied force is the variable that governs whether initiation will occur, not energy. Roth analyzed the theory in detail in an extensive review article[107] and found it to be less than convincing, nor did he find it to be in tolerable agreement with experimental trends.

Baker and Mellor[81], however, considered that the Russian theories were based on some important experimental work, and the further development must consider these results. The basic finding is that details of the drop-weight testing machine greatly affect the test results. Specifically, if the geometric design is such that the explosive is prevented from flowing out laterally when impacted, initiation fails to occur. This suggests that plastic flow and shear or fracture play a dominant role, and that simply high pressures achieved due to compression alone do not suffice. They also suggested that impact initiation should be viewed as a two-step process: (1) the impact energy, by means of localized material failures, creates hot spots; (2) chemically-reacting hot spots become sufficient to cause a thermal explosion. In line with the first step of this scheme, Baker and Mellor reviewed much of the recent literature where fracture mechanics modeling was used to predict explosives initiation. Their review suggests that a viable theory of some generality might eventually be achieved, but that current efforts to construct a general explanation of explosives initiation on this basis are not yet proving to be successful.

The initiation of an explosive due to the impact of a projectile is experimentally found to depend upon the diameter d of the projectile, with a critical velocity for initiation v_i having the form:

$$v_i = A/d^{1/2} + B$$

where A and B are constants for a given explosive. Andersen[82] has demonstrated that the above relation implies a constant energy fluence for ignition.

Walker and Wasley[83,84] proposed a *critical energy fluence* for initiation concept as defining the ignitability requirements of explosives exposed to shock waves. The concept has meaningfulness only in cases where the impact is delivered uniformly over the front face of the explosive. Thus, flying plate experiments are commonly used, where a projectile impacts upon a flat plate and the flat plate, in turn, applies impact onto the face of the explosive. Walker and Wasley first determined that no correlation existed in a given series of experiments to velocity of flying plate alone; in one case the highest velocity tested showed no explosion, while the lowest did. But correlations based on energy fluence proved successful. The kinetic energy of the plate is simple $\frac{1}{2}mv^2$, where m = mass (kg) and v = velocity (m s^{-1}). Per unit area, the energy of the flying plate becomes:

$$E_P = \frac{mv^2}{2A}$$

Not all of this energy can be transferred into the target to become shock energy. If the plate and the target are made of the same material, then ½ the flying plate energy can be transferred to the target. Otherwise, numerical hydrodynamic calculations are needed. The data developed for the LX-04 explosive show that

$$\frac{E_T}{E_P} = 0.31 - 0.015x + \frac{0.203}{x}$$

where $x = \rho_P/\rho_T$, ρ = density (kg m^{-3}), P denotes plate, and T denotes target. Values lower than 0.5 can be viewed as occurring due an impedance mismatch in coupling the energy. In terms of energy actually received by the target,

$$E_T = \frac{P^2 t}{\rho_o U_s}$$

where E_T = energy fluence (J m^{-2}), P (Pa) = shock pressure, t = duration of shock pressure (s), ρ_o = initial density of explosive (kg m^{-3}) and U_s = shock velocity (m s^{-1}) in the explosive. The quantity $\rho_o U_s$ is known as the *shock impedance*. Note that none of the variables on the right hand side are independent variables—they cannot be specified aforehand, only measured or simulated. Walker and Wasley obtained the following values of critical energy fluence:

PBX 9404	500 kJ m^{-2}
LX-04	1100 kJ m^{-2}
TNT	1400 kJ m^{-2}.

A more extensive tabulation is given in Chapter 14. The concept has also been applied to wedge and card gap tests.

Experimental studies with explosives to test the minimum energy fluence theory were conducted by Howe et al.[85] They conducted tests on PBX 9404 and compared the results to a detailed numerical model, and also to the simplified expression P^2t (Figure 7). The trends were clearly reasonably accounted for. Next, they examined whether an Arrhenius-type self-heating expression could account for the trends; the results (Figure 8) were obviously at complete variance with the expected trends. Small pressure changes imply small temperature changes, yet according to an Arrhenius dependence, these create a very large reaction rate change. Their conclusion was that a hot-spot mechanism is only part of the answer. In addition to the chemical kinetics expressed by applying an Arrhenius form of reaction rate to a hot spot, heat transfer limitations must be taken into account, and these correspond to grain boundaries. Their experimental results also indicated that density and grain size play a strong role, and that values of critical energy fluence are not independent of these parameters. Stresau and Kennedy[86] examined a variety of alternatives to the critical energy fluence criteria, but available data were not extensive enough to suggest an optimal alternative. It has been suggested[87] that the Walker/Wasley criterion is applicable

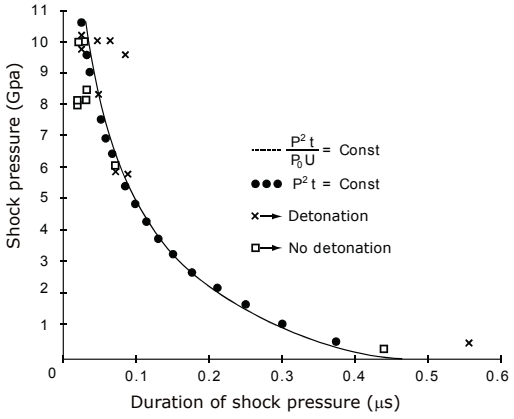

Figure 7 Experimental data for PBX 9404 compared to energy fluence criterion

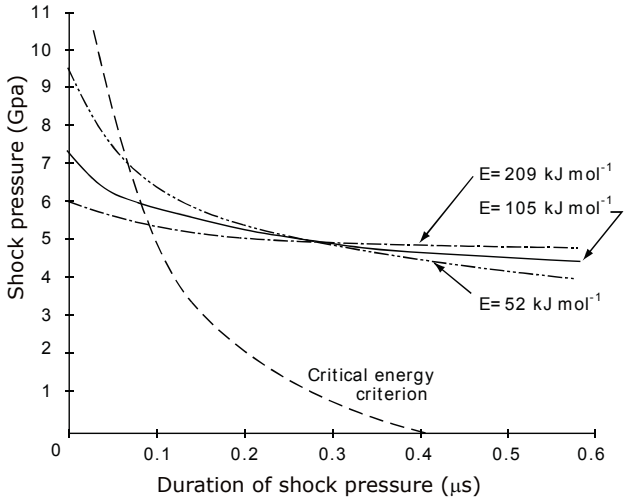

Figure 8 Comparison of experimental results to thermal explosion theory

when the explosive is uniformly exposed over its face, but breaks down when exposed over a partial face area, so that 3-dimensional effects predominate (Figure 9).

Some inconsistencies in the fluence concept were understood once it was learned that the critical fluence is not independent of the area of projectile. Experimental data[88] suggest that if critical energy fluence is plotted as a function of reciprocal area, then a linear plot is obtained (Figure 10), with finite projectile areas requiring more energy fluence than the asymptote for infinite area (zero reciprocal area). The Walker/Wasley theory does not provide for the effect of confinement. Frey et al.[89] demonstrated that for some explosives the degree of confinement will affect the energy fluence needed for initiation.

A modification of the hot spot theory used in self-heating was used by Maiden and Nutt[90] to compute a critical hot spot radius and a time to ignition for shock wave initiation. According to this theory, shock initiation of a given material requires a critical value of the product P^2t, where P = pressure and t = time of pulse. A more detailed approximation for ignition time was also derived:

$$t_{ig} = 4\rho C\mu \frac{T_{ig} - T_o}{\left(P_s - P_y\right)^2} + \frac{2\rho CRT_{ig}^2}{AQE} \exp\left(E / RT_{ig}\right)$$

where ρ = density (kg m^{-3}), C = heat capacity (J kg^{-1} K^{-1}), μ = viscosity (kg m^{-1} s^{-1}), A = pre-exponential factor (s^{-1}), Q = heat of reaction (J kg^{-1}), E = activation energy (J mol^{-1}), R = the universal gas constant (8.314 J mol^{-1} K^{-1}), T_{ig} = ignition temperature (K), T_o = ambient temperature (K), P_s = applied pressure (Pa), and P_y is given by the expression:

$$P_y = -2Y_o \ln \phi_o$$

FLAMES

The earliest weapons contained only black powder and this was ignited with a hot wire or a small flame. Flames can be

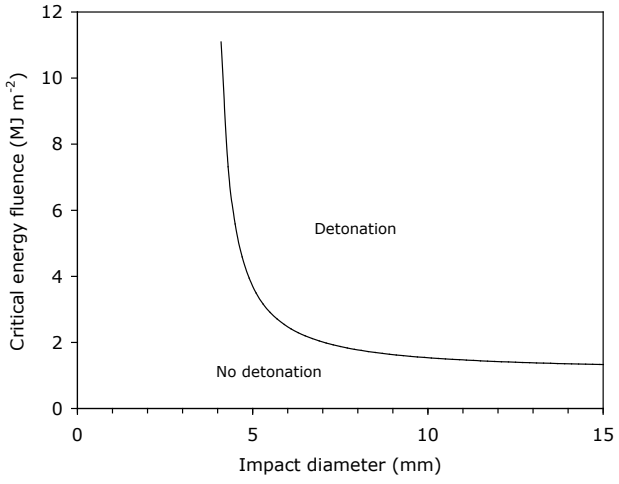

Figure 9 Effect of impact area on critical energy fluence (Composition B tested in flyer-plate experiments)

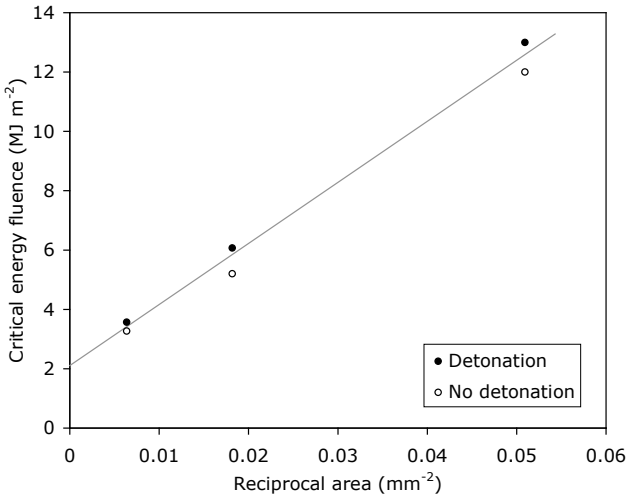

Figure 10 Dependence of critical energy fluence on projectile area for Composition B

used to ignite secondary explosives also, but their trait is that, if so ignited, they will typically burn but not detonate. However, fires of secondary explosives can turn into detonations under some circumstances. There are few systematic studies on the ignition of explosives by flames. Kondrikov[91] reviewed the details of a number of Russian accidents where RDX, PETN, HMX, TNT, or AN detonated after attack by fire. He concluded that one of the following mechanisms is responsible:

(1) confinement or partial confinement;
(2) flame penetration into cracks, slits, or pores;
(3) melting sufficiently large amounts of the explosive;
(4) formation of a vapor or aerosol cloud; or
(5) chemical transformation during initial heating which results in a more sensitive compound being created.

The last mechanism was concluded to have been operative for TNT explosions, where a diazo derivative was postulated.

Initiation or ignition of explosives from flames has most commonly been researched in the context of the military *cookoff* problem, but it is often simulated via radiant heating. In military applications, it can be expected that any place that munitions are located some event can occur, in accident or wartime, that causes flames or hot gases to expose the munitions. In US military work, the cookoff problem is divided into two types:

- *Fast cookoff*. This is simulated by submersion in a large pool fire.
- *Slow cookoff*. This is simulated by testing the explosive in an environment where the temperature rises at 3.3ºC per hour.

Fast cookoff usually produces a less violent reaction than slow cookoff. In slow cookoff, a nearly-constant temperature is established throughout the item; when explosion does occur, the entire device is usually exploded at once. By contrast, in fast cookoff, the temperatures are highly

non-uniform, and reaction first starts in the highest-temperature locations. Involvement of the rest of the item can then take place over a longer time scale than in slow cookoff, leading to lower destructiveness. In basic terms, slow cookoff is very similar to self-heating, except that self-heating studies are often done on bulk (unconfined) material, while slow cookoff testing involves cased explosives.

Traditionally, assessment of cookoff has been by testing. More recently, calculational methods have also been used. The explosive will normally be encased in a metal casing which has thermal conductivity several orders of magnitude higher than for the explosive. Thus, in the calculational methods, the problem is commonly assumed to be of cylindrical geometry, with uniform temperature around the periphery. A first-order solution is not particularly difficult, and methods have been put forth to provide a 1-d solution by spreadsheet calculations[92].

RADIANT HEATING

The use of lasers to ignite explosives has been investigated as a military munitions design option. de Yong et al. have reviewed the literature of this field[93]. Most of the experimental studies involved pulsed lasers producing enormous heat fluxes (on the order of 10^{10} kW m^{-2}) but for very brief time periods (on the order of 10^{-8} s). The ignition is dominated by beam absorption effects, due to the generation of highly absorptive plasmas with these heat fluxes. A minimum beam spot size (typ. 1 mm or less) has been found to exist in laser ignitions and beams focused to smaller diameters do not cause ignition. Despite beam absorption issues, the actual mode of ignition from laser energy has been determined to be thermal, and not involving photochemical or light-pressure effects. In some studies, longer exposure times were also used. In those, it was commonly found that there is both a minimum heat flux for ignition and a minimum fluence. For example, in a study on a pyrotechnic composed of Mg and $NaNO_3$, for exposure times < 2×10^{-3} s, ignition requirement was defined by $E'' \geq 21$ kJ m^{-2}, while for exposure times > 0.1 s, by the requirement that $\dot{q}''_{\min} \geq 1000$ kW m^{-2}. The interpretation of heat flux values from laser experiments is not straightforward, however, due to the typically small beam sizes used, which make assumption of 1-dimensional heat transfer inappropriate. Because of the small beam sizes, actual power levels required to achieve ignition can be tiny—in one series of experiments, ignitions were successfully achieved using a 1 W laser diode and beam diameters of 0.05 – 0.20 mm. For a variety of pyrotechnic compositions[39], laser ignition typically requires an energy fluence of 10 – 100 kJ m^{-2}.

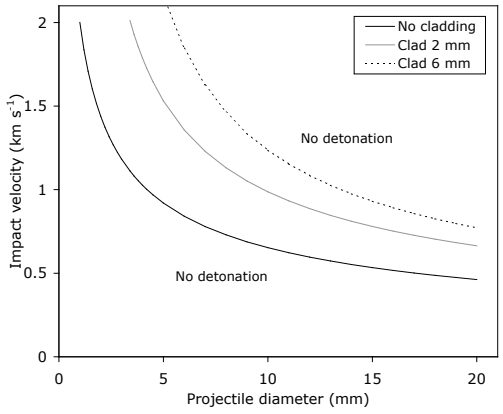

Figure 11 Effect of tantalum cladding thickness on the impact velocity needed for detonation of PBX 9404

Liau et al.[94] reviewed a variety of experimental results on laser ignition of RDX and found close agreement, but only up to 1800 kW m^{-2}; from that point on, up to 6000 kW m^{-2} there were two different trend lines—theory predicted a continuation of the same slope, as did some of the experimental data. But other experimental data reached a plateau at about 1800 kW m^{-2}, and ignition times were roughly constant at 0.03 s for all greater fluxes. Many more studies have been reported on radiant-heating ignition of propellants than of explosives; this is discussed in a later Section, but many of the findings can also have application to explosives.

An issue which is of some interest is whether there is an oxygen concentration effect on the ignition time of explosives or propellants. Explosives with OB ≥ 0 carry their own oxidizer and do not depend on oxygen from the air. Thus, it would be expected that there would be no effect of ambient oxygen concentration. Not much data is available one way or the other to answer this question.

In many practical cases, the explosive is not exposed directly to thermal radiation but, rather, there is an inert layer of some kind in front of the explosive. A theoretical ignition model has been developed[95] for this case when the initiation of the explosive is by purely thermal means.

HOT BODIES IN CONTACT

Explosives and propellants can be ignited by conduction heat flux from a hot body in contact with the surface of the substance. Energetic materials can also be ignited by internal heaters, and this principle is utilized in electrical detonators. In a pioneering study, Jones[96] embedded electrically heated wires in solid explosives and determined the minimum energy needed for ignition. He found that the energy required was directly proportional to the length of the wire. This would imply that the governing variable was the temperature of the hot wire, rather than the energy supplied to it. To a certain extent, this is true, but the thermal capacity (heat capacity × density × wire area) of the wire forms an integral part of the experiment and Jones did not find a constant-temperature criterion when comparing wires of various diameters. Instead, he noted that the energy per unit length of wire is a function of the thermal capacity, and that a minimum value can be obtained by extrapolating the results to zero thermal capacity.

Inami et al.[97] studied the ignition of several propellants from an electrically-heated niobium ribbon which was inserted into the middle of a propellant 'sandwich.' There was a large amount of data scatter, but trends could be correlated by solutions to the heat conduction equation with an Arrhenius heat release term for the solid and a constant-temperature boundary condition. Baer and Ryan[98] studied a similar 'sandwich,' but with a wire running down the length of a cylindrical specimen. They developed a combined heterogeneous/homogeneous model, with one Arrhenius reaction term describing a reaction within the volume of the solid, and a second one pertaining to a surface reaction. Excellent agreement was found with experimental data, but the model is rather unwieldy. Furthermore, it is not evident that the two assumed reactions correspond to actual chemical reactions that occur. More likely, the approach should be viewed as simply empirical fitting of a fairly large number of adjustable constants. A fairly reasonable agreement (errors of up to 2.5×) was obtained with a simpler scheme where no surface reaction was used, but, rather, ignition was taken to occur when a fixed temperature of the wire/explosive interface is reached.

FRICTION

In a classic study, Bowden et al.[99] examined the conditions needed to explode nitroglycerin by rubbing against various surfaces. The experiment involved placing the test material in between a rotating disk and slider. He first determined that the size and shape of the slider did not influence the results. Then, if frictional energy rate (power) is taken as being proportional to (frictional force × rubbing speed), then it turned out that the power was constant for these explosions, with a critical value of (frictional force × rubbing speed) being 20 W. This value was reasonably independent of the actual speed, load, or coefficient of friction used. His next series of tests showed, however, that thermal conductivity of the surface materials was another relevant variable—if conductivity was varied, the value of (frictional force × rubbing speed) needed for explosion did change. Surfaces of lower thermal conductivity required less frictional energy to be expended. Bowden concluded that the governing variable was actually the temperature attained in hot spots on the surface, and that lower thermal conductivity made it possible to more readily reach a high temperature.

For explosives which are in crystalline form, intercrystalline friction can cause initiation if the melting point of the substance is above the temperature at which rapid reactions begin. This condition is usually fulfilled for primary explosives, but not for secondary explosives. It has been found that for secondary explosives, a foreign particle 'grit' is usually necessary, but simple rubbing of clean surfaces suffices to initiate primary explosives. Furthermore, grit particles have the ability to enable explosion only if the grit has a high enough melting point; low-melting point grits do not increase the explosibility. If the melting point of a grit particle exceeds the minimum pertinent to the particular explosive, then increasing the hardness of grit particles serves to increase the ease of explosion.

Most tests that examine the sensitivity of military explosives combine frictional loading with impact, e.g., drop-hammer tests that include sandpaper. Results from 'pure' frictional testing are less often reported, the most common nearly-pure-friction test being the Koenen/BAM friction sensitivity test.

Stab initiation of explosives occurs in some detonators and in tests. Chaudri[100] has demonstrated that the mechanism is frictional in nature.

COMPRESSION

Solid explosives may be initiated by rapidly compressing a gas volume adjacent to the explosive's surface. The principle of adiabatic compression of gases has already been discussed in connection with the ignition of gases. Here, the gas itself (which will usually be air) is not being ignited, but acts upon the solid explosive. Evans and Yuill[101] found that initiation in this manner can readily be achieved for primary explosives, but only partially or not at all for secondary explosives. The compression ignition temperatures that need to be reached for initiation are about 2 to 3 times higher than the temperature values found in direct thermal initiation.

ELECTRICITY

The electrical ignition mechanisms of explosives are of four types[102]:

(1) short-arc discharge
(2) high-voltage arc discharge
(3) resistive heating and semiconductor action
(4) radiation from electric arcs or other high-energy radiant fields

A short-arc discharge occurs when contacts having a potential difference of around 50 V approach within ca. 0.2 μm. The actual resulting arc voltage is 11 to 16 V and the energy is primarily dissipated in heating the anode surface to its boiling point. This creates a vapor cloud which migrates to the cathode. Showers of molten metal usually accompany this discharge. A high-voltage arc discharge occurs at potential differences of more than about 300 V and spacings greater than 5 μm.

In recent years, concern about electrostatic discharge (ESD) initiation of explosive materials was raised due to a 1985 accident where a Pershing II rocket motor was accidentally initiated due to electric spark discharge[103]. Its propellant composition had been considered safe, since prior tests had indicated that Joule-level energies would be required for initiation. Explosives and propellants vary widely in their minimum energy requirements for spark ignition. Commonly, testing is done by simply placing a needle electrode

close to the surface, while holding the substance in a metallic cup to which the other electrode is connected. A spark discharge using a conventional capacitive-discharge apparatus is used. Results from several testing programs using this scheme are given in Chapter 14. These results, unfortunately, are exceedingly dependent on the details of the test. Kirshenbaum[104] examined the performance of various grades of lead azide in a number of these tests; Table 7 indicates that little consistency can be found. Observe, however, that the lowest values reported are much smaller than the lowest MIE values found for spark ignition of gases in air (ca. 2×10^{-2} mJ).

As with the testing of gases, using a low capacitance and a high voltage generally leads to lower MIE values being reported, as contrasted to high-capacitance, low-voltage test conditions. In addition, Kirshenbaum found a strong role of series resistance in the circuit, much as seen in spark ignition studies of gases or dust clouds. The fraction of the nominal energy $\frac{1}{2}CV^2$ that was actually delivered to the spark gap dropped from 80 – 90% for a resistance of 0.15 Ω, down to 10 – 14%, for resistances of 1 kΩ to 1.2 MΩ. Spark gap distance, polarity of the upper-surface electrode, electrode shape, and the metal used for making the electrodes are other factors which have also been found to influence the results. Some factors depend on a highly-specific interaction with the explosive. For instance, for granular materials, a needle electrode has been found to be less effective than a plane electrode, because the spark can 'blow away' the material in the case of the needle[104].

Some testing has been done on electric ignition where both electrodes actually touch the specimen, instead of a spark gap being created between an electrode and the test substance. Ignition can be achieved at much lower energies in this situation (Figure 12), which is termed a *contact discharge*[105]. The mechanism in a contact discharge is ohmic heating, due to high temperatures caused by very small areas of actual contact. A contact discharge is sometimes accompanied by ejection of hot metal particles.

Experimentally it has been found that capacitive discharge of 10 mJ through an electric blasting cap is enough to detonate it if discharged directly across the two legwires[106]. For discharge between a legwire and the metal shell, 30 mJ was found necessary. The charge has to come from some external source, since the small capacitance represented by a blasting cap precludes electrostatic charging from accumulating sufficient charge on the blasting cap itself. The ignition mechanism from an arc is not the same as from a spark. For lead azide, it was found that for spark discharge, the peak probability of ignition occurs at 300 V, and that the probability is nearly independent of the capacitance[107]. For voltages below the Paschen minimum (see Chapter 14), ignitions are also possible, but the probability for any voltage does not exceed 35%.

A viable theory for describing the ignitability of solid explosives from electric spark discharges does not yet exist. Skinner et al.[108] examined single-component explosives and proposed that the mechanism should be largely thermal, and that it should be possible to base analysis on a hot-spot ignition theory. Based on their empirical testing results (tabulated in Chapter 14), they made several correlations to self-heating theory. The best correlation was based on evaluating δ_c for a 20 μm sphere, which was assumed to be the diameter of the hot spot. They solved the expression for critical T_o, then plotted the MIE against $1/T_o$. This was seen to give largely a straight line. Values of the pre-exponential were taken from the literature.

For multi-component propellants, recent studies indicated that compression can have a very large effect and that substances which would have required > 1 J for initiation in a conventional test may only require ca. 10 mJ under certain confinement situations. Specifically, it was found[109] that much lower MIE values will be found if the confinement is sufficiently effective that the hot gases which are formed are prevented from expanding freely. The development of an arc channel in a propellant is complicated, because of its inhomogeneity—there are discrete particles of oxidizer and metal in the polymeric binder, and the three components have widely disparate thermochemical properties. Lee[109] determined experimentally that the arc channel is serpentine (Figure 13), going through the polymeric binder and avoiding the larger particles of oxidizer. The arc channel does not

Table 7 ESD sensitivity of several grades of lead azide, as determined by a variety of test methods

Grade of lead azide	Reported MIE (mJ)
RD1333	4×10^{-7} to $2\times10^{+1}$
service	1.6×10^{-3} to 1×10^{0}
dextrinated	1×10^{-2} to $1\times10^{+2}$
PVA	2×10^{-4} to $2\times10^{+1}$

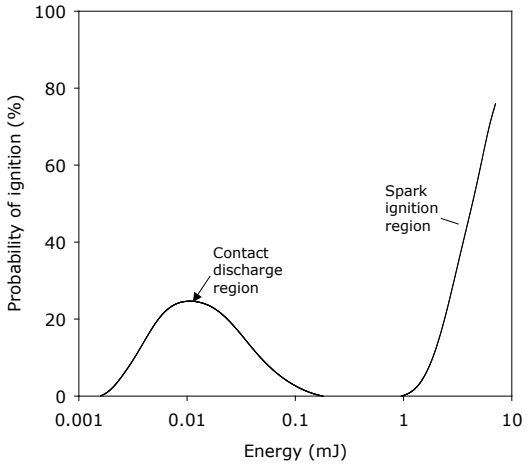

Figure 12 Two ignition modes exhibited by lead azide

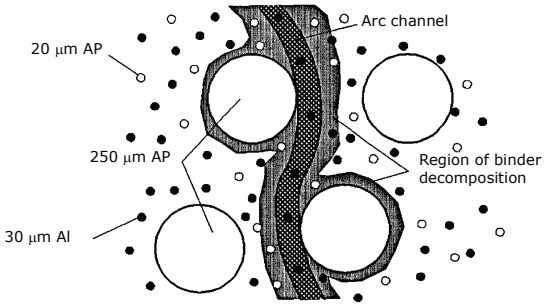

Figure 13 Serpentine arc channel formed in a heterogeneous propellant (typ. width: 140 μm)

avoid the small metal particles, and the conductivity of the metal strongly influences the discharge. During a short-duration discharge, the arc channel expands to its ultimate width largely by compressing the bulk solid, not by ablation of the solid into the channel. Physically, ignition of the propellant takes place adjacent to the arc channel and is governed primarily by three reaction mechanisms: (1) decomposition of oxidizer particles; (2) pyrolysis of the polymeric binder and exothermic reaction between the pyrolysate gases and close-by particles of oxidizer; and (3) reaction of the high-temperature plasma gases with the oxidizer. The latter is especially complicated since, due to the high temperatures involved (ca. 13,000 K), radiation plays a dominant role. Lee suggested some features which a detailed model should incorporate, but actual development of a model along these lines was not undertaken. Lee's work does emphasize that conventional spark discharge studies which expose the surface of a specimen to a spark using small-to-nil confinement cannot be relied upon as giving conservative data for cases where confinement effects are important.

Silver azide has been found to explode at room temperature when a voltage greater than 67 V is impressed across a crystal[110]. The mechanism is understood to involve semiconductor action, not simple ohmic resistivity. Gora et al.[111] conducted extensive studies into semiconductor action for azides. The nature of the metallic contact to the azide surface was found to play a crucial role, whether the contacts are ohmic (allowing free carrier injection) or Schottky-barrier contacts.

A US Navy study on a series of lightning-initiated deflagrations of magazines storing smokeless powder determined that the proximate cause of the explosions was a design of the fiberboard drums that was conducive to internal arcing[112].

LIGHT ENERGY AND IONIZING RADIATION

A number of primary explosive are sensitive to initiation by a sufficient amount of light energy. Results from flash-tube experiments are shown in Table 8[53,113]. The energy density values are obtained by dividing the energy delivered to the crystal by the total surface area of the crystal. Certain nitrides and perchlorates are also susceptible to light energy initiation[107].

Experiments indicate that silver azide is a compound where photochemical excitation can be assigned as the mechanism of initiation. For many other primary explosives, it is not clear whether the light energy is simply being converted to heat, or if a photoexcitation process is involved. Most secondary explosives are organic compounds with covalent bonds. These tend to melt first and then the explosion occurs in the liquid or gas phase. As a result, their sensitivity to initiation from light energy is minimal. For some crystals, e.g., PETN, it has been found that certain intensities of UV light can fracture the crystal without causing initiation[59]. Avrami and Haberman[115] reviewed a number of other studies of light-energy initiation of explosives.

Boddington and coworkers analyzed the problem theoretically by assuming it to be a variation on the self-heating problem[114]. In their theory, thickness plays a critical role, in the same way as in the self-heating problem. This treatment is appropriate for thin materials subjected to very high rates of light heating. For very high heating rates, and with the material in the form of a slab of modest thickness whose front face is irradiated and the back face is kept at ambient temperature, they provided the solution:

$$\delta_c \approx \frac{\beta e^{-\beta}}{e}$$

where the dimensionless heating rate, β is:

$$\beta = \frac{\alpha_s \dot{q}''_e E}{\lambda R T_o^2}$$

The authors did not treat a case analogous to thermally-thick solids being ignited by radiant heating, nor did they

Table 8 Minimum energies for flash-tube ignition

Compound	Formula	Energy for ignition (kJ m^{-2})
nitrogen iodide	$NI_3 \cdot NH_3$	1.6
silver nitride	Ag_3N	2.0
cuprous acetylide	Cu_2C_2	6.3
benzene diammonium nitrate	$C_6H_5N_3O_3$	9.2
diazobenzene perchlorate	$C_6H_5N_2ClO_4$	9.2
ammonium perchromate	$(NH_4)_3CrO_8$	11.0
mercuric fulminate	$Hg(ONC)_2$	16.5
lead azide	$Pb(N_3)_2$	20.

silver azide	AgN_3	26.
mercuric azide	$Hg(ONC)_2$	26.

attempt to use theory to explain the large differences found experimentally in the light energy needed for initiation of various explosives.

Since the 1920s there has been interest in studying the initiation of explosives by radiating them with electrons, neutrons, α-particles, γ-radiation, X-rays, and other high-energy forms of radiation. Gamma radiation has generally been found to have no effect, while modest effects have been found with various other forms of radiation. Avrami and Haberman[115] reviewed a large amount of experimental data on this topic.

SASIN was an explosive developed in a joint effort between Southwest Research Institute and Sandia Laboratories. The explosive comprises silver acetylide and silver nitrate in a solvent which can be alcohol or acetone. The substance can be sprayed onto a surface without detonation, but once it dries it can be detonated by light energy from a powerful source.

CRYSTAL GROWTH

Some of the most sensitive explosives undergo initiation spontaneously, simply due to crystal growth, when crystals are being grown out of a liquid solution. This has primarily been observed with various azides. Chaudri and Field[72] have reviewed a number of research studies in this area. Various theories have been proposed as to why this happens, but it does not appear that a unique explanation is yet in hand.

RF INITIATION

An indirect ignition mechanism is often of concern in blasting operations—the possibility that RF transmissions might induce a voltage into an electric firing mechanism, leading to inadvertent initiation of an explosive charge. Anke et al.[116] studied the problem for several detonator types and produced guidance charts. In general, they found that the portion of the spectrum where the least power is sufficient for detonation is 0.5 – 10 MHz. A transmitter in this frequency range with an effective radiated power of 100 W would need to be about 50 m away to ensure that inadvertent detonation will not occur; a large broadcasting station of 50 kW would need to be about 500 m distant. A British standard[117] exists on this topic. Some additional results were reported by Collett[118].

MODELING DETONATION

As already discussed in Chapter 3, detonation is fundamentally different from normal burning (which is called deflagration). In a deflagration, a combustion wave moves smoothly through the substance leaving reaction products at its conclusion. A detonation is a special hydrodynamic phenomenon which involves shock waves. A chemical reaction is caused by the high speed, high pressure compression of the shock wave, and not by the much slower diffusion of heat or molecules associated with a deflagration wave. A detonation wave may progress in the explosive substance at around 5000 m s^{-1}, and can be compared with the speed of sound in air, which is around 340 m s^{-1} at room temperature.

For about 100 years, the theory to analyze the behavior of explosives has been based on the theory of Chapman and Jouguet (C-J), which strictly applies only to gaseous systems. The C-J theory can answer many practical questions about the behavior of explosives. But it also has failures. For example, it cannot explain why some pairs of isomers show a ranking one way for thermal sensitivity, and an opposite ranking for shock sensitivity. The basic limitations of the theory were eventually found to be (a) the assumption of thermal equilibrium in a shock wave; and (b) the absence of realistic chemistry. The molecules in a shock wave are not in thermal equilibrium, so treating them by classical equilibrium thermodynamics is an oversimplification. Likewise, if many common substances reacting at ambient pressure are known to be poorly represented by global, single-step Arrhenius kinetics, it is not surprising that systems involving highly excited molecules and very high pressures should fail to conform. The width of shock wave progressing through an explosive is typically only ca. 5 nm, which is the span of 15 water molecules. Actual rise times are in the range of picoseconds, although physical instrumentation does not capture such short rise times.

Modern approaches to studying detonations are commonly based on molecular dynamics calculations, in other words, on quantum mechanical calculations for the molecule in question. Needless to say, studies of this type are mathematically and computationally difficult and do not lend themselves to any simple presentation. Bardo[119,120] was the early pioneer of quantum-mechanical theories. These are very computationally intensive and require a much larger number of fitting parameters than classical theories. There is also continuing research on advanced classical-mechanics theories. For example, Ruderman et al.[121] have been studying the ignition of HMX, representing it as a nonlinear viscoelastic solid which is reactive and can also undergo phase transitions to a viscous liquid and to a gas. Politzer and Alper[122] have reviewed the state of the art in molecular dynamics modeling of explosives and placed recent efforts in the context of other modeling strategies. Tarver and Urtiew[123] described a reactive-flow model, where the reaction proceeds in three steps: (1) initial ignition at hot spots, which involves only the amount of explosive represented by its void fraction; (2) reaction of most of the rest of the explosive, involving exothermic chain reactions that form highly-excited gaseous reaction products, which then expand and thermally equilibrate; and (3) slower, diffusion-controlled forms of energy release, such as solid-carbon coagulation or aluminum particle oxidation.

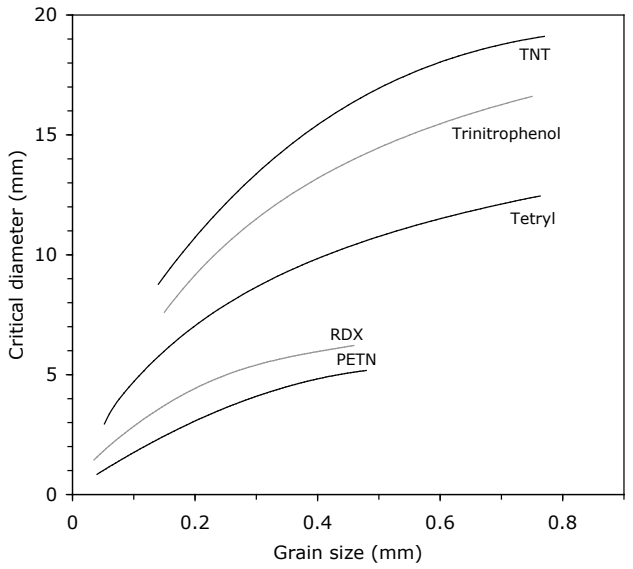

Figure 15 Effect of grain size on critical diameter (density = 1000 kg m^{-3})[184]

IGNITION OF AIR/FUEL-GAS ATMOSPHERES BY CONDENSED-PHASE EXPLOSIVES

In the coal mining industry, it is often necessary to employ explosives for blasting. But coal mines may be 'gassy,' that is, containing a significant amount of methane; thus, a methane explosion may be created by blasting. Consequently, the ignition of air/fuel-gas atmospheres by condensed-phase explosives has been studied. Since even 'permissible explosives' (see below) can produce temperatures of 1500 – 2000ºC, the question of interest is not why the firing of explosives sometimes ignites flammable atmospheres but, rather, why it does not do so every time! Ignition can, in general, be caused by several mechanisms (Figure 14):

- flames
- hot gases
- shock waves, or
- hot particles.

These have been studied by many investigators[124], without simple insights emerging. Coward[126] reviewed in depth the early work in the field, but studies have largely tapered off along with the general reduction in coal-mining safety research. Of the mechanisms, shock waves are probably the most important, especially when in geometries where they can be reflected from a surface, with consequent additive effects. Grant et al.[125] conducted reduced-scale tests in a simulated mine gallery and documented that the oxygen concentration in a methane/oxygen/nitrogen atmosphere is a crucial factor in determining whether a given shot will or will not ignite the atmosphere. They concluded that there are two dominant mechanisms: the shock wave heats the atmosphere to an elevated temperature, but turbulent mixing of the products of detonation has a cooling effect. Ignition by means of incandescent particles ejected from the shothole[126] has been studied by only a few researchers, some of whom doubt the mechanism and consider that ignition will only happen due to impact of particles on solid surfaces and the consequent conversion of kinetic energy into heat. When high explosives are used, the methane/air atmosphere can potentially undergo detonation, not just deflagration. The amount of high explosive needed for this is not large; Benedick[127] demonstrated that it is possible with ca. 2 kg of a plastic explosive (not a permissible explosive).

VARIABLES AFFECTING THE BEHAVIOR OF EXPLOSIVES

The role of *pressure* on explosions is complicated. Since the reactants are at lower pressure than the products, all else being equal, increasing the pressure should decrease the reaction rate (Le Chatelier's Principle). This indeed is what is found for lead azide[53]. But for PETN there are two possible reaction pathways, and high pressure causes explosion, rather than non-explosive decomposition, to be preferred. It turns out that there is a countervailing mechanism due to heat transfer. When an explosive is confined in a rigid casing, the reaction causes the pressure to rise, which would lower the reaction rate. But at the same time, the hot products are retained in intimate contact with the reactants, which they would not be if containment were not provided. In the case of detonations, the main effect of confinement is not thermal, but, rather, directly related to reinforcement of the shock waves. In practice, black powder and smokeless powder will burn, rather than explode, if not confined. Many secondary explosives, however, do not need confinement in order to explode. Even without confinement, if a sizeable pile of explosive material is exposed to slow, gradual heating, then self-heating effects will predominate

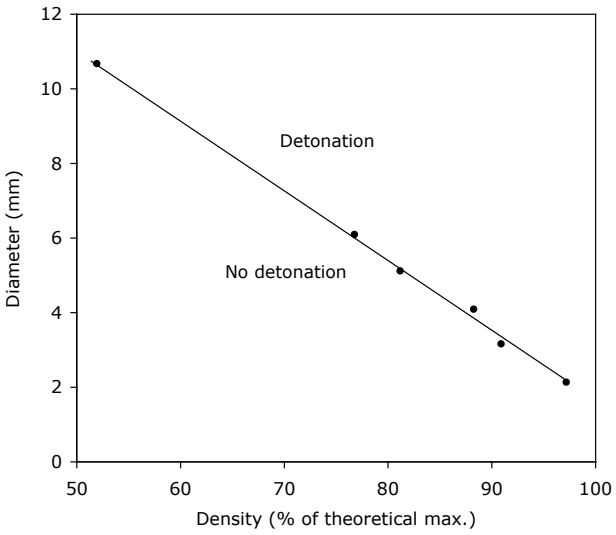

Figure 16 Effect of density on critical diameter ('Group I' - TNT)

and a violent explosion can be expected. On the other hand, some explosives which undergo deflagration within a confinement, may stop reacting entirely once the confinement is breached.

The *physical form* of the explosive affects the minimum energy needed for ignition. Explosives in powder form are much more readily ignitable than are ones which are cast or pressed. *Grain size* has an effect under certain circumstances. For TNT, it has been shown that the energy fluence required for ignition from impact is about 5% lower for fine-grain than for coarse-grain size[128].

For detonation to occur, a minimum *amount* of material must be present. The exact amount depends on numerous factors, but for primary explosives it may be on the order of milligrams, for secondary explosives on the order of grams-to-tons, while for 'non-detonating' substances such as gunpowder and ammonium nitrate it may be hundreds of tons. If a lesser amount is present, a deflagration but not a detonation is possible. There also exists a *critical diameter* of an explosive, and if the explosive is produced in a smaller diameter, detonation does not propagate throughout the substance. This has a practical implication, in that charges intended to be detonated must exceed this diameter. Unfortunately, the critical diameter is highly dependent on grain size and density. Smaller grain sizes give lower critical diameters (Figure 15), but the effect of density is complicated. Price[129] determined that two different behaviors can be found. Figure 16 shows an example of a 'Group 1' material, TNT. Its critical diameter decreases with density (in the explosives field, density is commonly reported as a percent of maximum theoretical density, the latter representing a porosity of zero). By contrast, Figure 17 shows AP, a 'Group 2' material, which exhibits an increasing diameter with density. Price's results only cover a practical range of densities; when extremes of density are investigated, non-monotonic behavior is sometimes seen, as shown in Figure 18 for TNT. Price reports that other Group 1 explosives include PETN, RDX, and tetryl. Other Group 2 explosives are ammonium nitrate and dinitrotoluene. The groups do not exhibit disparate behavior with regards to effect of grain size and temperature on the critical diameter—for both groups, increasing grain size raises the critical diameter, while increasing the temperature lowers it. The critical diameter concept means that certain materials may be 'non-detonable' in laboratory-scale tests, yet detonate in real-scale sizes. Strehlow[130] points out that, in the early part of

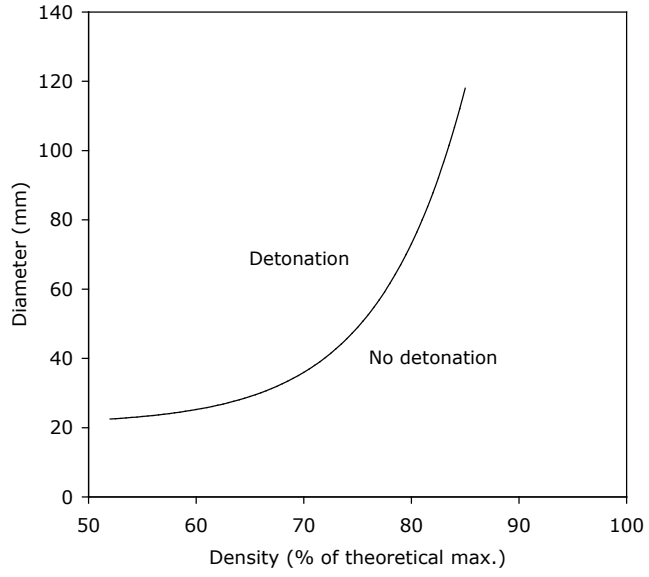

Figure 17 Effect of density on critical diameter ('Group 2' – AP)

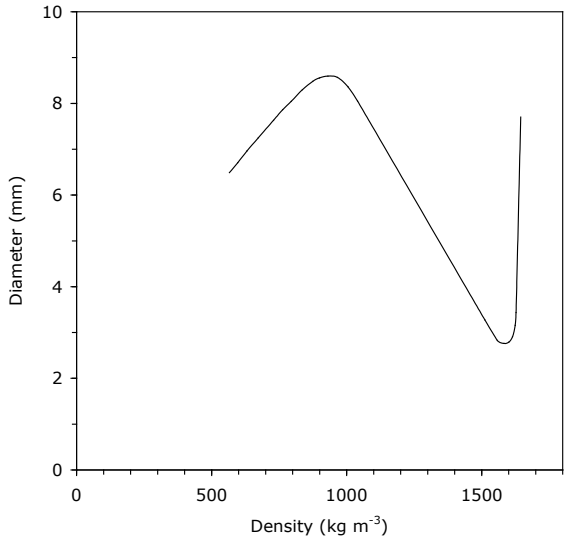

Figure 18 Effect of density on critical diameter (TNT, mean grain size 0.06 mm)[184]

the 20th century, ammonium nitrate (whose history of disasters is reviewed in Chapter 14) was considered 'non-detonable' for this reason.

Increasing the degree of confinement serves to reduce the critical diameter, thus testing to determine the critical diameter is done under conditions of minimal confinement. In some cases, the effect of confinement can be drastic. For example, when ammonium nitrate[131] at a density of 1060 kg m^{-3} is minimally confined (wrapped in plastic tape), the critical diameter is 100 mm; confined in glass, it is 80 mm, while confined in steel, it is below 30 mm. Apart from the density, the mode of preparation of the explosive—cast or pressed—also affects the critical diameter. For thin sheets, a comparable quantity, the critical thickness, can be determined. In early Russian literature, there was a claim that the critical diameter and the critical thickness were related by a simple formula; more extensive test work in the US, however, disproved that[131]. Apart from critical diameter results, the degree of confinement also affects results from gap tests. Most gap tests use a confined acceptor geometry, in which case the sensitivity decreases as the density increases. In one series of experiments[132] where a gap test design was used where the acceptor charge was unconfined, the opposite trend was found—the sensitivity increased as the density increased.

Raising the *temperature* decreases the critical diameter and increases the sensitivity[133]. In a study on AP[134], it was found that raising the temperature from 25ºC to 240ºC decreased the critical diameter from 23 mm to 11 mm.

For some explosives that are hard to initiate, microballoons or small, hard particles with sharp edges and a high melting point are added as *sensitizers*. In addition, impurities can act as sensitizing agents for certain explosives. Substances such as lubricants, waxes, hydrocarbon liquids, camphor, or even water act as *desensitizers* or *phlegmatizers*. The effect of a desensitizer is to quench the explosion after initiation; it does not prevent initiation[53,59]. In many cases, for the effect to be sufficiently beneficial, sizable amounts of a desensitizer have to be added and the desired properties are degraded.

PRACTICAL APPLICATIONS

INITIATING DEVICES

In purposeful firing, a secondary explosive is initiated by an initiating device which typically contains a primary explosive and a base or booster charge. The primary explosive is chosen so that it is easily initiated by a modest amount of externally-supplied energy. It then shock initiates the base charge and the latter provides the shock wave needed to initiate the secondary explosive. But explosives may be initiated by a variety of methods. Initiating devices that produce a flame or flash, but not a detonation are generically termed *igniters*, while those that do produce a shock wave are termed *primers*. The most common means of initiation are the following, which include a few that do not use a primary explosive:

- Friction. This is the simplest initiation device and is used on flares and on some military devices. A matchhead does not detonate nor does it initiate a second explosive, but it comprises a pyrotechnic mixture which is also ignited by friction. The military makes use of stab igniters where the stabbing motion of a conical-shaped pin into a mixture causes sufficient friction for initiation.
- Mechanical impact. The trigger on a hand weapon applies mechanical impact onto the primer composition of the bullet. In the explosives field, any initiating device based on simple mechanical impact is a *percussion primer*. Early compositions of percussion primers were often a mixture of mercury fulminate, antimony sulfide, and potassium chlorate. Primer mixtures today may have lead styphnate, barium nitrate, tetracene, aluminum powder, lead azide, etc.; small amounts of secondary explosives such as TNT and PETN also sometimes show up in a primer mixture.
- Flame. A *safety fuse* is a common examples of initiation by flame. A safety fuse contains a black powder mixture which cannot detonate itself; thus, it is used to initiate a primary explosive, which then applies shock waves to a secondary explosive. In practice, the safety fuse usually leads to a *non-electric blasting cap*, which then initiates the bulk explosive.
- Electric heating. An electric igniter uses a thin Ni-chrome wire (bridgewire) which is rapidly heated by applying an electric current. They can be of two types. An *electric squib* contains only a low explosive and is used for initiating pyrotechnics or propellants. An *electric blasting cap* (commonly called a *detonator* in military applications) contains charges of primary and secondary explosives and is intended to initiate a cap-sensitive secondary explosive which needs a substantial detonating charge to detonate itself. It consists of a copper or aluminum cylinder containing both a primary (e.g., DDNP; formerly, lead azide and mercury fulminate/potassium chlorate mixtures were also common) and a secondary explosive (e.g., tetryl, PETN, RDX). The commonly used No. 8 blasting cap (Figure 19) is 7 mm in diameter and contains 0.3 g of primary charge and 0.8 g of secondary. A firing current of somewhere in excess of 300 mA is normally used. A blasting cap may be used as a means of initiating a detonating cord (also called *detonating fuse* or *Primacord*), where the cord itself contains a high-order explosive, commonly PETN. The detonating cord acts as an intermediate device which propagates detonation into the bulk explosive.
- Exploding wire (in military terminology, exploding bridgewire or EBW). This specialized detonator was developed to impart an immunity to electric detonators against stray voltage or electromagnetic radiation. An EBW detonator does not use a primary explosive

but only a charge of secondary explosive, hence its lower sensitivity to unwanted initiations. An EBW is a particularly energetic form of initiation and can detonate a secondary explosive whereas a normally melting wire would not. The principle is discussed in Chapter 11.

A number of illustrations and practical details of a variety of initiating devices are given by Voreck et al.[135] Commercial detonators are intended to be set off only by application of flame or electricity, but BM[136] documented a number of mishaps where modest mechanical mishandling sufficed.

PERMISSIBLE EXPLOSIVES

In coal mines, flammable methane/air atmospheres will commonly occur, as will flammable coal dust/air atmospheres. Explosives are a convenient way to remove coal, but use of explosives should not result in unwanted explosion of flammable atmospheres which may be spread throughout the mine. Dust clouds will arise from blasting activity, so even if originally there was little dust, after the first blast there is likely to be dust loading that must be allowed for. Early blasting in coal mines involved the use of black powder, and this sometimes had disastrous consequences if a 'gassy' condition was encountered or if a dust cloud arose. It was then noticed that black powder burned relatively slowly and, consequently, produced a fair amount of flaming outside the shothole. High explosives, however, burned more rapidly and were less prone to cause a mine explosion. It was also noticed that the size of the gallery had an important effect on the outcome: gases or dust clouds were much more likely to be ignited if the gallery was narrow. The extreme case is when the explosion vents into a fissure, which is viewed as highly dangerous. Later, it was concluded that ignition of a gas/air or dust/air atmosphere requires a minimum induction period if it is to occur. If the detonation produced by the mining explosive is shorter than this induction period, then ignition will not occur. Explosives having this characteristic were initially developed in 1914 and are termed 'permissible explosives,' also known as 'short-flame' explosives. In 1989, the official term in the US was changed to 'MSHA permitted explosives,' in parallel to the 'permitted explosives' term used in the UK. Methane/air atmospheres are generally more easily ignitable than are dust clouds, but there are enough exceptions to the rule so that candidate permissible explosives must also be demonstrated not to ignite the latter[126]. Permissible explosives may be required not just in coal mines, but in other underground mines where gas or dust hazards exist. Hopler[137] has reviewed the history of permissible explosives in the US.

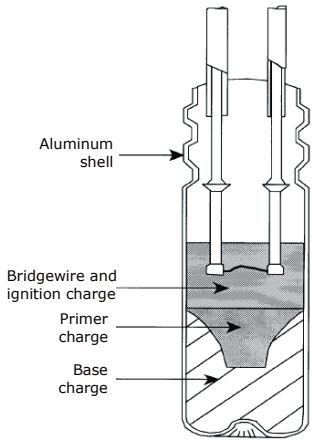

Figure 19 The No. 8 blasting cap

An explosion of methane or dust in a coal mine caused by firing an explosive is an extremely rare event. UK statistics[138] indicate that there are about 6 unwanted explosions per 10^8 shots fired, which is an exceptionally low failure rate. This also implies that tests for permissible explosives must create conditions substantially more favorable towards causing a gas or dust explosion if their safety is to be assessed with a feasible number of experiments.

The allowable duration of the detonation depends on the maximum temperature it develops. All high explosives can be made permissible by adding to it components which reduce the flame temperature. Black powder, however, cannot be made permissible, since it does not detonate and burns slowly. But in the US, since the federal government did not regulate mining safety until 1952, it was still possible to use black powder in underground mining until that date. In general, the principle involved in the design of a permissible explosive is simple. A relation between time to ignition and the needed temperature for the ignition of a methane/air mixture is used. If the time/temperature curve of the explosive is always below the methane/air curve, then the methane/air mixture cannot be ignited. Such a curve is readily obtained for methane, however, obtaining a time/temperature curve for an explosive is more difficult. In practice, the design proceeds in a simpler way. The adiabatic flame temperature for an explosive is not difficult to compute, and this value should no more than 2200ºC, decreased by some suitable safety factor[139]. To ensure that burning time will not be excessive, it is normally sufficient to ensure that the oxygen balance is zero or positive; if OB were negative, this would entail prolonged flaming, since there would be an insufficiency of oxidant within the solid material and oxygen from the air would be used later in the burning process. In general, a flame duration of < 1 ms is required; by contrast, black powder shows 1539 ms, when tested according to BM procedures[34]. In addition to their flame possessing a short time duration, permissible explosives should produce flames of short spatial length, since this minimizes flame extension beyond the borehole, but here the difference between permissible explosives and others is much smaller.

The flame temperature may be lowered by effectively raising the creating ρC of the combustion products. This includes using an excess of fuel in the mixture, incorporating

water molecules into it, or adding substance which decompose endothermically. Physically, permissible explosives are available as granular materials, gels, emulsions, or sheathed explosives. Incorporating a large fraction of ammonium nitrate into an explosive is a common way of making it permissible[140]; this is because of the low detonation temperature of AN. *Cooling salts* (e.g., sodium chloride) are sometimes included in the formulation to reduce the flame temperature and cause an earlier extinction of flaming. Nitroglycerine or nitroglycol are commonly added in small amounts to ensure that a No. 6 detonator will detonate the explosive completely and not just partially[141]. Since permissible status may be achieved by lowering the combustion temperature, sheathing is a way to help an explosive be permissible. This involves a sheath which is either non-explosive (e.g., potassium fluoride, sodium bicarbonate) or of low explosibility and acts mainly as a heat sink. In using permissible explosives, the miner is still responsible for correctly drilling a borehole and placing and stemming the charge therein. Thus, permissible explosives are only 'permissible' if properly fired in boreholes (sufficiently depth, adequate stemming, etc.); if they are fired into open air, methane or dust clouds may be ignited[140]. Finally, the mass of explosive used also affects the probability of unwanted ignition.

There are fewer permissible explosives in the marketplace today than earlier. In the US, the number dropped from 174 in 1952 to 94 in recent years. In general, use of explosives in mining is diminishing, as blasting techniques are being replaced by mechanical ones[137].

BLASTING AGENTS

The US Geological Survey defines blasting agents as "any material or mixture consisting of fuel and oxidizer intended for blasting, not otherwise defined as explosive, provided the finished product, as mixed for use or shipment, cannot be detonated by means of a No. 8 test blasting cap when unconfined." The practical meaning of this is that an explosive designated as a blasting agent will typically require a booster charge for successful detonation, in addition to a detonator. One common form of blasting agent is ANFO (see Chapter 14). Blasting agents do not contain nitroglycerin. Explosives for blasting use which do not fall under the definition of blasting agents are termed *blasting explosives*.

The sensitivity of explosives to detonation from a high-power hunting rifle is essentially identical to that from a No. 8 blasting cap. This was demonstrated by Watson et al.[142] in a study using aluminum-cased No. 8 blasting caps, copper-cased No. 8 blasting caps, and three different hunting rifles. The kinetic energy available from the rifle bullets in these tests ranged from 2400 to 4500 J. They also showed that the results from the two different types of blasting caps were nearly identical.

Table 9 Relative separation distances (m) required for various combinations of donor and acceptor explosives, as determined in Bureau of Mines tests

Donor → **Acceptor ↓**	**AN 1.0 m PE**	**AN 1.0 m steel**	**AN 1.5 m PE**	**AN 1.5 m steel**	**AN 1.0 m steel**	**AN 1.5 m steel**
	Unbarricaded				**Barricaded**	
AN	3.8	5.8	7.0	12.2	1.8	2.3
ANFO	5.8	17.7		46.6	2.4	
ANFO, bagged	8.2	32.9				
dynamite	20.4	50.9				

INSENSITIVE MUNITIONS

If a ship, tank etc. is attacked which contains stored munitions, then the major destruction may occur from the detonation of the stored munitions, rather from direct damage from the attack. Thus, in the US during the mid-1980s, military policies were established to use insensitive munitions wherever possible; other Western countries have also had similar programs[43]. Consequently, much research work was carried out to develop insensitive munitions. These are munitions that can still function properly when fired, but which are unlikely to be detonated by shrapnel, blast, or a fire impinging externally. In the military studies, the objectives have been expressed functionally, rather than in terms of basic energy transfer modes. According to the US Navy[81], the following tests must be successfully passed for munitions to be labeled as 'insensitive':

- fast cookoff—no reaction more severe than burning
- slow cookoff—no reaction more severe than burning
- bullet impact—no reaction more severe than burning
- sympathetic detonation—no propagation
- fragment impact—no reaction more severe than burning
- spall—no sustained burning
- shaped-charge jet impact—no detonation

The above are all large-scale tests, since adequate predictability from small-scale tests has not been considered to be established. A slightly different series of tests has been described by the US Air Force[143]. A recent review of the design issues associated with insensitive munitions has been published by Victor[144]. Insensitive munitions can be created by selecting substances of suitable chemistry or by the addition of desensitizers, or both.

SAFE DISTANCES FOR STORAGE

Given fixed details of the originating detonation and the target explosive, sympathetic detonations are to be expected only up to a certain distance of separation between the pile of explosives originally detonating and the target pile. This concept is embodied in tables of separation distances. Various countries have established such tables, usually based on a small amount of incident data, augmented by expert opin-

ion. In the US, the Institute of Makers of Explosives first promulgated such a table in 1910, with the current version being one published in 1971. This has been adopted by OSHA and BATF as Federal regulations. A modest amount of research has been done on the topic, but not enough to upgrade the tables to the point that they would no longer be primarily expert-opinion-based. A Bureau of Mines study[145,146] produced the results given in Table 9 using several types of originating ('donor') and target ('acceptor') explosives. Both the donors and the targets were equicylinders, with the dimensions specified. The 1.0 m donors weighed 726 kg, while the 1.5 m donors weighed 2452 kg. The end caps on the donors were either a reinforced polyethylene (PE) or a 1.5 mm thick steel sheet. The sand-filled barricades were 0.25 m thick for the 1.0 m donor charges and 0.38 m thick for the 1.5 m charges.

Propellants

The useful function of propellants is that they produce large volumes of gas at a controlled rate. Thus, they differ from explosives, where it is not necessary to limit the rate of reaction. Propellants are used in guns and rockets, but also in various industrial applications (propellant actuated devices) where a high force of short duration is wanted. The peak pressures developed by propellants are considerably lower than by explosives. For rockets, pressures of up to 20 MPa are found, whereas for gun propellants pressures up to 700 MPa. The physical state of propellants may be solid or liquid, although liquid propellants currently have applications only in rocket propulsion.

Propellants for small-arms applications are classed as:

- black powder (potassium nitrate, charcoal, sulfur)
- 'improved,' proprietary derivatives of black powder, with some common examples being:
  - Pyrodex (primarily potassium nitrate, charcoal, sulfur, potassium perchlorate, dicyandiamide, and sodium benzoate, along with wax and wetting agents)
  - Golden Powder, Black Canyon powder (potassium nitrate, ascorbic acid).
- smokeless powder, as three distinct types:
  - single-base powder (NC)
  - double-base powder (NC, NG)
  - triple-base powder (NC, NG, NQ); used only in limited military applications.

In the rocket propulsion field, solid propellants are functionally divided into four classes:

(1) *Single-base propellants*. These comprise only plasticized nitrocellulose as the main ingredient. However, a small amount of stabilizer is added, and other minor ingredients may also be present.
(2) *Composite propellants*. These contain an oxidizer in granular form dispersed throughout an organic binder that acts as fuel. The most common oxidizer is ammonium perchlorate, with potassium perchlorate and ammonium nitrate sometimes also being used. The most common fuel is hydroxyl-terminated polybutadiene (HTPB), but polystyrene, polysulfide, polyurethane, PVC, epoxy, or even asphalt have also been used. A typical formulation can comprise ammonium perchlorate, polybutadiene, aluminum, and a burning-rate modifier such as copper chromite or ferrocene. Another common formulation is based on ammonium perchlorate oxidizer and a Thiokol fuel, the latter being a family of polysulfide rubbers.
(3) *Double-base propellants*. They were discovered by Alfred Nobel, who found that a mixture of nitrocellulose and nitroglycerin produced a reasonably safe, practical propellant of broad applicability.
(4) *Triple-base propellants*. They are similar to double-base propellants, but nitroguanidine is also added into the mixture.

Aluminum is useful due to its high heat of combustion and is often added as a fuel component to single-base and composite propellants. Most practical formulations also include minor ingredients for stabilizing, cross-linking, catalysis of burning, anti-flash, and as aids in processing. Tricalcium phosphate is commonly added to ammonium chlorate-based compositions as an anticaking agent.

A solid propellant composition will contain three 'logical' components: an oxidizer, a fuel, and a binder. However, the number of physical components can be smaller, since the binder is often the same substance as the fuel. Nitrocellulose can be used as a propellant by itself since it effectively comprises all three 'logical' components. The fuel and the oxidizer in solid propellants are in intimate contact: in the case of nitrocellulose, these are simply parts of the same molecule. Where a separate fuel is used, the physical mixture, nonetheless, places fuel and oxidizer molecules into close contact.

The oldest gun propellant, *black powder*, is a multicomponent substance. It is made by grinding potassium nitrate, sulfur, and charcoal individually into fine, uniform powders. The powders are then mixed and milled together, pressed in a hydraulic press, granulated, and finally tumble-polished. The ratio, by mass, of the three components is generally 75:15:10. The combustion products are highly complex and include both gaseous and solid aerosol components. The main product gases are CO_2, CO, and N_2. The white smoke is formed by the solid products, the main ones being K_2CO_3, K_2SO_4, and K_2S.

Black powder has been obsolete for decades in military uses and has been replaced by propellants based on *nitrate esters*, such as nitrocellulose or nitroglycerin. Nitrocellulose is the primary ingredient in *smokeless powder*, so called because it was developed to minimize the large quantities of black smoke emitted by black powder. The term encompasses a wide variety of powders based on nitrocellulose. Usually other ingredients include potassium nitrate or bari-

um nitrate. Recently, attention has been focused on the *nitramine* based propellants (e.g., RDX plus polymeric binder) as insensitive replacements[147].

Liquid rocket propellants may comprise separate fuel and oxidizer sources, or may be a *monopropellant* (a propellant which does not need a reaction partner) such as hydrazine (N_2H_4). In a 'catalytic decomposition engine,' hydrazine decomposes into H_2, N_2, and NH_3 without the need for another reactant in the system. Since hydrogen and ammonia are flammable themselves, further heat release occurs from subsequent combustion reactions. Where separate fuel and oxidizer substances are used, the most common combinations are:

(1) liquid hydrogen (LH_2) with liquid oxygen (LOX or LO_2)
(2) kerosene with liquid oxygen. The grade of kerosene used is designated by NASA as RP-1.
(3) a fuel consisting of either monomethyl hydrazine or a 50/50 mix of unsymmetrical dimethylhydrazine ($C_2H_8N_2$; UDMH; 1,1-dimethylhydrazine) and nitrogen tetroxide (N_2O_4) as oxidizer. Some use is also made of nitric acid (HNO_3) as oxidizer.

Only the third of these combinations is hypergolic, but in practice the hazards may be greater with non-hypergolic pairings. Maximum explosive effect can only occur if a mixed, but unignited fuel/air mixture subsequently is ignited. Thus, if combustion starts immediately upon mixing, the effects may not be as major. In disastrous events, however, the mixing is occurring because of failures of tanks or fuel systems, thus the entire fuel and oxidizer stock is effectively at risk.

Ignition of rocket propellants using LO_2 occurs due to electrostatic discharge as a natural consequence of very vigorous mixing[148]. The mixing is peculiar, since when LH_2 and LO_2 are thrown together, the LH_2 boils while the LO_2 freezes. Conversely, in mixing kerosene and LO_2, the kerosene freezes while the LO_2 boils. No external ignition sources are needed for these combinations when vigorous mixing is provided.

Confinement increases the reaction rate of propellants, more so for gun propellants than for rocket propellants. The sensitivity of unmixed propellants to shock, impact, or friction is generally low.

IGNITION THEORY AND EXPERIMENTAL DATA

For intentional ignitions of solid-propellant rocket motors, three types of igniters are used: (1) pyrotechnic, (2) pyrogen, or (3) hypergolic. A pyrotechnic igniter is a small basket of pyrotechnic material which is ignited itself with an electric squib; once ignited, hot gases and hot particles from it impinge upon the main rocket fuel. A pyrogen igniter is essentially a miniature rocket motor; only hot gases emanate from it onto the rocket propellant. A hypergolic igniter is typically liquid chlorine trifluoride, which is injected onto the propellant; ignition is solely by heterogeneous reaction at the surface. Since the ignition mechanisms vary, it is appropriate that theories of ignition have been developed which emphasize different aspects of the ignition process. The number of theoretical ignition models that have been developed within the propellants community is large, to say the least. For readers interested in the specific details, there have been three reviews that have attempted to list and briefly discuss each of the published theories: Price et al.[149], Kulkarni et al.[150], and Hermance[151]. Hermance's review of 1984 is the most current one, but the publication of new propellant ignition models in the subsequent years diminished considerably. Hermance[151] has grouped theories of propellant ignition into three families:

1. reactive-solid models
2. heterogeneous reaction models
3. gas-phase ignition models.

The reactive solid models share much in common with self-heating theory, as developed in Chapter 9. Heterogeneous reactions do not play a role in the ignition of most other types of combustibles, apart from metals. Thus, the propellant theories of this ilk are basically specialized. Gas-phase ignition is, of course, the type of ignition that is studied for common solids, as presented in Chapter 7. A basic difference is that for common solids the effects of ambient pressure are usually not of interest; the contrary is true for propellant ignition. In addition to elevated pressure, there are further effects related to the rate of rise of pressure; these are also treated in detail by some of the propellant ignition theories.

Some of the reactive-solid models have been of great mathematical elegance (e.g., Liñán and Williams[152]), but Hermance concluded that important trends predicted by them—for example, the pressure-dependence—are at variance with experimental data. Hermance concludes that the best representation is to treat the problem as a gas-phase ignition for all types of propellants (homogeneous, double-base, composite, etc.) that are not ignited hypergolically. For accidental ignitions due to self-heating in storage conditions, the reactive-solid theory would be appropriate. But the needed theory will be of the same type as the ones developed in Chapter 9. The theories developed within the rocket research community have generally been more ambitious but less tractable than the development given in Chapter 9, thus, they will not be reviewed here.

Composite propellants (or pyrotechnics) are unique in their fuel/oxidizer geometric arrangement. Thus, some theories have been developed specifically to model the composite aspects in the ignition process. Summerfield et al.[153] provided the first viable theory of composite propellant combustion. The oxidant and fuel components are both gasified at the surface but do not interact chemically in the condensed phase. A very thin flame forms above the surface, and this flame is laminar, even in generally turbulent flow. The peak flame temperature is reached within 0.1 mm of

the surface. While not conventionally turbulent, the flame is 'granular,' which corresponds to the granular nature of the fuel being burned. Later, Kumar developed a general theory taking into account the physical nature of a composite propellant where grains of oxidizer are embedded in a matrix of fuel[154]. Subsequently Kumar et al.[155] specifically tailored the theory to a propellant where ammonium perchlorate is the oxidizer and polybutadiene-acrylic acid (PBAA) is the polymeric fuel. Solutions were obtained numerically, but Kumar's theory did lead to the explicit conclusion that $t_{ig}^{-2/3} \propto \dot{q}_e''$, unfortunately, as discussed below, experimental data usually do not show a –2/3 power dependence.

Most theories have been based on radiant heating. But Kumar and Hermance[156] formulated a theory for *convective heating* by a stream of hot oxidizing gas. The theory was specifically developed for a composite propellant. The equations were highly complex and the illustrative numerical solutions did not yield simple generalizations. Grain size affects the ignition results and the authors were able to illustrate this in their numerical solutions.

Very few theories provide explicit, closed-form solutions. Bradley[157] considered the ignition of a propellant from an external heat flux (which may be either radiative or convective) and produced numerical solutions and an approximate expression:

$$\frac{QA\lambda T_o}{\dot{q}_e''} = \frac{\sqrt{E'}\exp\left[E'/\left(1+2\sqrt{\tau_c/\pi}\right)\right]}{(\pi\tau_c)^{1/4}\left(1+2\sqrt{\tau_c/\pi}\right)}$$

where $\dot{q}_e''$ is the external heat flux, A = pre-exponential factor, Q = heat of reaction, T_o = initial temperature, λ = thermal conductivity, $E' = E/RT_o$ is a dimensionless parameter, C = heat capacity, and $\tau_c = \dot{q}_e'' t_{ig}/\lambda\rho C T_o^2$ is a dimensionless time. This equation does not give an explicit solution for the ignition time t_{ig}, but it can be solved with simple trial-and-error calculations. One interesting conclusion of Bradley's numerical study was that the order of the reaction does not play a significant role. The computed ignition time varied less than 3% as the reaction order was varied between 0, $^1/_2$, 1, and $^3/_2$.

The heterogeneous ignition condition was modeled by Bradley and Williams[158], who also included an external heat flux in their formulation. In their model, the hypergolic reaction involves a solid and gas that come together suddenly. On the basis of numerical solutions, they proposed that the ignition time should vary as:

$$t_{ig} \propto \dot{q}_e''^{-b}$$

where $b = 2 - \dfrac{8.4RT_o}{E}$

and T_o is the initial temperature of the interface. It is simply the initial temperature if both the solid and gas are initially at the same temperature; otherwise, T_o is to be solved for, knowing the initial temperatures and thermal inertias of the two media. The activation energy E refers to the heterogeneous surface reaction, and it is not exactly clear how it would be obtained experimentally.

Many studies have been published where experimental data trends were established or controlling variables studied, but generally the studies only offer trends, not precise quantitative predictions. Williams et al.[159] reviewed much of the early experimental data on radiant-heating ignition of propellants. The results were seen to follow the trends established in Chapter 7 for thermally-thick solids. In addition, they demonstrated the same finding as obtained in Chapter 7: ignition results from a radiant-heating test cannot be expressed as a constant energy fluence. If energy fluence is plotted against irradiance, the result is not a straight horizontal line but a V-shaped curve showing a distinct minimum at one particular irradiance value.

Propellants carry their own oxygen, but the dominant reaction generally occurs either in the gas phase or at the boundary, not within the bulk of the solid. Thus, propellants might be expected to exhibit an oxygen-dependence more akin to pyrolyzing solids, rather than to explosives. In some cases, however, the solid-state reaction dominates. Keller et al.[160] showed that results of igniting AP/PBAA (copolymer of polybutadiene and acrylic acid) with radiative and convective heat fluxes in pure oxygen and in pure nitrogen atmospheres were indistinguishable, although their data scatter was quite large and a small effect would not have been evident. On the other hand, Price et al.[149] showed a variety of results where there is a large effect of ambient oxygen concentration. A theory by McAlevy et al.[161] for convective ignition of propellants suggests that the ignition time should depend on the oxygen mass fraction as:

$$t_{ig} \propto m_{O_2}^{-2/3}$$

however their experimental results show:

$$t_{ig} \propto m_{O_2}^{-n}$$

where n = 1.2 to 1.5. Kumar and Hermance[162] also conducted a theoretical study of propellant ignition. Evaluated for various material properties, their results typically showed

$$t_{ig} \propto m_{O_2}^{-n}, \text{ where } 1 < n < 2, \text{ for } m_{O_2} > 0.2$$

and

$$n \to 0 \qquad \text{for } m_{O_2} \le 0.2$$

Thus, their theory was much more in line with the experimental data of McAlevy than was McAlevy's own theory. In a similar vein, Kashiwagi et al.[163] obtained experimental results which show a high-oxygen-concentration and a low-oxygen-concentration regime. They conducted an inspired series of convective heating tests in a shock tube, where pure polymers (PBAA and polyurethane) were tested, as were propellants using these polymers + AP as oxidizer. For $m_{O_2} > 0.6$, all four test specimens showed essentially identical ignition time results, with the dependence being:

$$t_{ig} \propto m_{O_2}^{-1.4}$$

But for $m_{O_2} < 0.5$, each system gave a different slope. The two pure fuels showed $n \approx 2.0$ to 4.7, while the two propellants showed $n \approx 0.33$ to 1.0. The authors concluded that at high m_{O_2} values, there are abundant possibilities of oxidation with the gaseous oxygen, but at low values, ignition is longer, and opportunity arises for the solid-state oxygen (when present) to be liberated and to react. Williams et al.[159] gave data similar for polystyrene and a polystyrene-based propellant; both sets of results showed $n \approx 2.0$. An inverse dependence on m_{O_2}, but with a non-constant value of n, was found for a thermal-immersion condition[164], that is, ignition by a stagnant hot gas.

Increasing the total pressure of the atmosphere above the propellant generally decreases the ignition time, but in many cases the relation does not follow a power law[151]. In some experiments[165], no effect of pressure has been found. The early studies of McAlevy[161] showed a theoretical dependence of

$$t_{ig} \propto P_{tot}^{-1.44}$$

while corresponding experimental measurements gave

$$t_{ig} \propto P_{tot}^{-1.77}$$

Very similar results were also reported by Kumar and Hermance[162]. The work of Beyer and Fishman[166] suggests that the pressure dependence becomes small at low heat fluxes (such as might be expected from an accidental fire), provided the value of P_{tot} is not also low. The results of Niioka and Williams[167] on ignition of double-base propellants were similar. They studied two double-base propellants and found negligible effect of going from 1 to 6.8 atm when heat fluxes were below 200 kW m^{-2}. At 2000 kW m^{-2}, however, the higher pressure led to ignition times about 1/10 of time at 1 atm. In a more comprehensive study, Shannon[168] obtained detailed ignition times plots for a number of propellants, covering a wide range of pressures and heat fluxes. The effects of pressure were not well-represented as a power law. Instead, for P_{tot} greater than about 2 atm, there was negligible effect on t_{ig}. For $P_{tot} < 2$ atm, however, the negative exponent was increasingly greater for lower values of P_{tot}. The experiments of Kashiwagi et al. on both pure fuels[169] and on propellants[163] indicate a behavior at very large values of P_{tot} (> 20 atm) where instead of becoming independent of P_{tot}, the ignition times vary according to

$$t_{ig} \propto P_{tot}^{-1}$$

Ohlemiller and Summerfield[170] in a similar study, also show a continued dependence of t_{ign} on P_{tot}, even at high P_{tot} values. Östmark and Gräns[171] found that for TNT, Composition B-3, and Torpex there was a smooth power-law type pressure effect on the energy fluence needed for ignition. But for PETN and RDX there were two regimes: below 2 – 4 MPa, they were very hard to ignite, while at higher pressures ignition became much easier and then the required fluence dropped smoothly with further increases in pressure. The authors noted that all the explosives they tested have a negative OB, and thus they partly react in the gas phase.

The work of both Kashiwagi[163] and Ohlemiller[170] suggests that a combined correlation of the effects of oxygen fraction and the total pressure should not be sought in the use of partial O_2 pressure as a correlating variable, unless only the regime of large m_{O_2} and P_{tot} values is considered, and only approximate results are sought.

For high incident heat fluxes (e.g. heating by lasers), many propellants are sufficiently diathermanous that ignoring in-depth absorption would lead to seriously erroneous results. Figure 20 illustrates this for RDX[172]. The calculations were based on ignoring gas-phase effects. This is seen to be a reasonable assumption at the lower heat fluxes; at higher heat fluxes, modeling of the gas phase would have to be done to produce reasonable predictions. Physically, at high fluxes significant blowing occurs at the surface and, at ignition, the flame is no longer close to the surface but far downstream. This occurs when the ignition temperature reaches the boiling point. Furthermore, at very high heating rates, the surface temperature can surpass the boiling point, since phase equilibrium no longer exists at the surface and the vapor pressure can surpass the atmospheric pressure. Another effect that comes in at high fluxes is a thickening of the vapor zone and, consequently, increased absorption of radiation by the vapors. At the extreme condition for radiation at wavelengths where the explosive is nearly transparent, some highly anomalous effects occur. The surface temperature at ignition does not appreciably rise above ambient, with ignition developing solely at hot spots. A further complication is that propellants often show in-depth absorption which varies greatly with wavelength. For example, for RDX, it was found[173] that the in-depth absorption coefficient β (see Chapter 7) went from 18,000 m^{-1} to 146,000 m^{-1}, as the wavelength went from 9.29 to 10.76 One simplification that is not available for treating the ignition of common solids is usefully applied to propellant ignition: at the high incident heat fluxes of concern in research on propellants, convection and re-radiation terms are normally completely negligible.

Despite these complications, for fluxes that are not too enormous, straight lines can be obtained when ignition time is plotted against the incident heat flux on a log-log plot. Strakovskiy et al.[172] examined 14 different compositions and found that the slope ranged from –0.54 to –0.58; this is very close to the –0.55 power dependence found for common solids, as discussed in Chapter 7. The main difference in the treatment of propellants is that, because of the high heat fluxes involved, $\dot{q}''_{cr}$ can be effectively set to zero. But because of the diathermancy of propellants, Strakovskiy et al. proposed a two-step procedure, whereby the ignition time is initially predicted on the basis of an opaque solid.

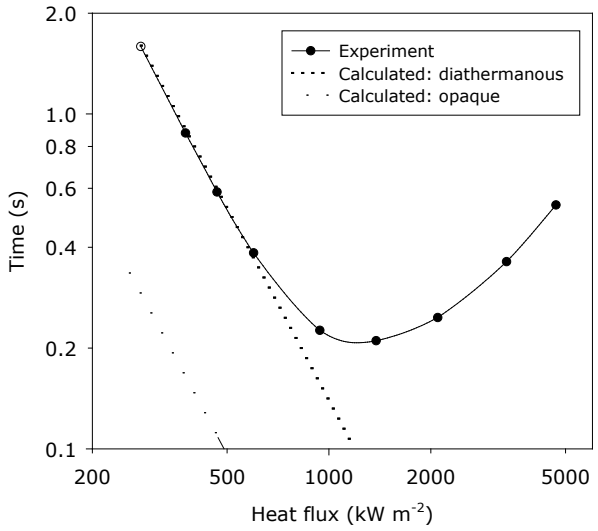

Figure 20 Ignition of RDX propellant with laser radiation at 10.6 μm (1 atm pressure)

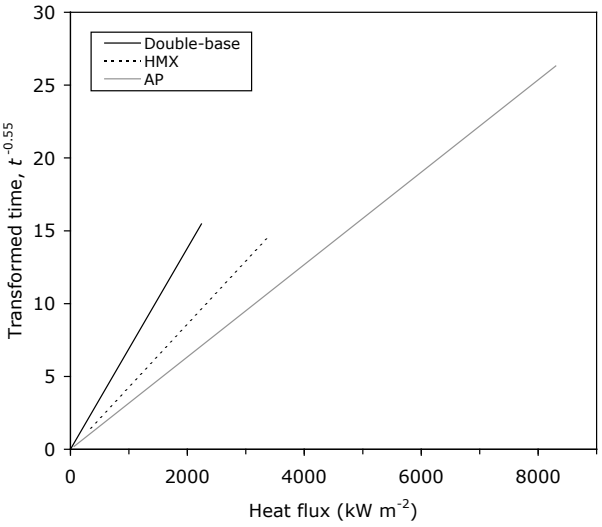

Figure 21 Response of various propellants to high convective heat fluxes and laser radiation

Then, a correction for ignition time is made, taking into account the diathermancy of the propellant.

For many common propellants, however, diathermancy issues can be ignored and straight lines nonetheless obtained. Lengellé et al.[174] studied a number of families of propellants ignited by lasers, hot-gas jets, and other forms of external heat flux. Despite the peculiarities of the laser-ignition problem, by combining results from diverse researchers, they found general correlations showing that ignition could be treated in the same manner as for thermally-thick common solids. The main difference is that, instead of being a constant, the surface temperature at ignition varies somewhat with the applied heat flux, but notwithstanding this, straight lines could be produced as for common solids. Figure 21 shows the results plotted using time to –0.55 power; the authors' plots using –0.5 power also gave results indistinguishable from straight lines. From lowest to highest heat fluxes used, the measured surface temperatures at ignition increased by about 140ºC for each of the propellant families. The differences in slope are accounted for mainly by the different values of thermal inertia, with ammonium perchlorate having the highest thermal inertia and double-base propellants the lowest. The authors concluded that there was no difference in results on the mode of thermal exposure used—radiant or convective—nor whether the radiant source is a laser or an arc-image furnace.

The thermal decomposition of propellants is normally treated by the same theory as developed in Chapter 9. However, it is often found that propellants do not show a constant heat of reaction, that is, at any given temperature, Q is not independent of time. van Geel[175] treats this situation empirically by determining the maximum value of Q that is obtained in testing. This maximum value is used in an equation for determining the critical radius r_c. The value thus determined then comprises an upper limit and is termed the *safe diameter*.

Shannon[168] examined the effect of grain size on the ignition of some composite propellants. Ignition time was about 2× for grains of 150 – 300 μm size, as compared to grains of ≤ 100 μm. He also found that for propellants containing ammonium perchlorate and various polymers, T_{ig} was in the range of 330 – 395ºC at an irradiance of 630 kW m^{-2}.

Pyrotechnics

Pyrotechnics are devices which use a chemical reaction in order to create light, sound, motion, gasses, or smoke. Fireworks are the prime example of pyrotechnics, although the category also includes matches, highway flares, automotive airbag inflators, actuators for airplane slides, and others. Pyrotechnics have military applications, primarily for signaling, but our main concern will be civilian uses, most of which are for the purpose of entertainment.

Most pyrotechnics rely on a physical mixture wherein both the fuel and oxidizer are solid, powdered materials. In a few cases, however, the oxidizer provided in the solid phase is not sufficient for full combustion and additional oxidation takes place using atmospheric oxygen. Liquid-phase materials are not used as commercially sold pyrotechnics, but are sometimes employed in creating special effects for movies. For explosives, there is often an advantage if an oxygen balance close to zero is achieved. For pyrotechnics, however, safety is enhanced if each constituent substance (*not* the whole mixture) has a notably positive or negative oxygen balance. This then assures that the rate of reaction is determined by the slower intermolecular reactivity rather than by the faster intramolecular combustion.

The US government classifies fireworks into *consumer fireworks* and *display fireworks*. Fireworks for use by consumers were designated as Class C explosives until the US adopted the UN classification scheme, under which they are Group 1.4G explosives. Display fireworks are permitted only for licensed individuals and were designated as Class B explosives and are now identified as UN Group 1.3G explosives. The US Consumer Product Safety Commission imposes a number of further regulations concerning the manufacture of fireworks to be sold to consumers. Those are issued in Title 16, Part 1507 of the Code of Federal Regulations.

CHEMISTRY OF PYROTECHNIC REACTIONS

The science of pyrotechnics is rather different from most other aspects of combustion in that it is very poorly developed. Because the commercial marketplace for pyrotechnics is so specialized and limited, there has been little incentive for scientific research. Furthermore, the chemistry is made more difficult because many reactions depend crucially on physical details (e.g., grain size) of the reacting substances. Because of this, the technology has been more of an art than a science, and industry involved is generally secretive of its techniques and knowledge.

A pyrotechnic device normally contains a powder which is a physical mixture of at least two components: a fuel and an oxidizer. Both of these are solids, including the oxidizer. The powder is normally very finely and uniformly ground in order to create optimal propinquity of the ingredients, then packed into some form of casing. While pyrotechnic compositions are required to burn fast, they must not detonate. Such behavior would not be productive towards creating the desired effects and instead would be highly dangerous.

The oxidizer can supply oxygen, chlorine, or some other atom which can oxidize fuels. Common pyrotechnic oxidizers include potassium chlorate ($KClO_3$), potassium perchlorate ($KClO_4$), potassium nitrate (KNO_3), and ammonium perchlorate (NH_4ClO_4). Fuels can include metals, organic compounds, sulfur, etc. Common metals are magnesium, aluminum, or an alloy of magnesium and aluminum. Organic fuels used include anthracene ($C_{14}H_{10}$), charcoal, naphthalene ($C_{10}H_8$), nitrocellulose, red gum, various resins (plastics), shellac, and an almost endless array of other substances.

The adiabatic flame temperatures of many pyrotechnic mixtures are higher than for organic fuels burning in air, but rather similar to organics burning in pure oxygen, namely 3000 – 3500ºC. Mixtures whose function is producing colored effects normally have a much lower flame temperature since many of the latter reactions cannot occur at high temperatures, or they would be overwhelmed by the black-body (i.e., white) radiation of other components.

Despite the paucity of research, some of the basics of pyrotechnics chemistry have come to be well enough understood. Pyrotechnics are generally viewed* as composites where the primary reactions occur in the solid state and are diffusion-controlled. Pyrotechnic reactions fall into three main types:

1) fuel-oxidizer reactions
2) thermite reactions
3) intermetallic reactions

The most common reaction is of the fuel-oxidizer type. However, the oxidizer comes from a solid substance, not from the air. To be useful, the preparation must be reasonably stable. Thus, the oxidizer is usually generated by endothermic decomposition of one of the granular components of the mixture. For example, potassium perchlorate generates oxygen according to the reaction

$$KClO_4 \rightarrow KCl + 2O_2$$

Suppose the composition contains shellac (approx. $C_{16}H_{32}O_5$) as a fuel. Then, a fuel-oxidizer reaction occurs between the O_2 and the shellac.

The most common thermite formulation involves powdered Fe(III) oxide and aluminum:

$$Fe_2O_3 + 2Al \rightarrow Al_2O_3 + 2Fe$$

Another formulation uses Fe_3O_4, which reacts as:

$$3Fe_3O_4 + 8Al \rightarrow 4Al_2O_3 + 9Fe$$

In the thermite reactions, iron oxide acts as the oxidizer and oxidizes the aluminum, which is the fuel. The reaction achieves temperatures of ca. 2200ºC. The reaction is easily sustained since the iron which is produced is a high-temperature liquid which stays in the vicinity of the reactants instead of removing energy from the system as would a gaseous combustion product. Rae[176] studied the minimum temperature needed to ignite various thermite mixtures in a tube furnace and obtained the results given in Table 10. He systematically varied the metal/metal oxide ratios, but only results for the proportion giving the lowest ignition temperature are shown. The ignition temperatures found are all below the melting point of the pertinent metal.

Intermetallic reactions involve an exothermic reaction between two metals. For pyrotechnic applications, these would normally be in the form of a powdered, compressed mixture. Systems exhibiting high heats of reaction include Ce/Zn, Ni/Al, Ni/Al/B, Pd/Al, Ta/B, Ti/B, Ti/B/Al, Ti/C, Zr/B, Zr/C, and others. An example of a device using an intermetallic reaction is the Pyrofuze-type igniter system which uses a platinum or palladium coating on an aluminum wire. When the flow of electric current raises the temperature of the wire, a highly exothermic alloying reaction occurs between the aluminum and the noble metal. Intermetallic reactions are somewhat rare in civilian pyrotechnics, however, they have military applications and have been studied extensively by Hardt[177].

* But see the discussion under 'Chemistry of explosives' above.

Because of the nature of the solid state, the reactivity of pyrotechnic/explosive reactants is often determined by physical factors, and cannot be assessed just be examining the chemical purity of the substance. The physical nature of the substance, in turn, depends strongly on how it was prepared, i.e., its chemical history. McLain[38] points out that in thermite reactions the reaction rate depends on how the Fe_2O_3 was prepared (apart from mode of preparation, it also ages and is quite sensitive to moisture).

Over the centuries, it has been found by experience that many pyrotechnic substances require milling in order to make them effective reactants. Apart from the obvious reduction in size, the milling process also imparts strains into the crystal lattice structure ('lattice looseness'). Actual heats of reaction have been measured and it has been found that the milling increases the heat of reaction[38]. The reaction rates of pyrotechnic compositions are determined much more by the oxidizer than by the fuel. Oxidizers with the lower melting points (or transition temperature, in case of substances showing solid-phase transitions) are more effective than those with higher temperatures.

Certain impurities increase the rate of solid-solid reactions by acting to reduce the eutectic temperature of the mixture. With many compositions, water is such a catalyst and small variations in moisture content affect the reaction rate. The highest reaction rate occurs at a given moisture content and increasing or decreasing it lowers the rate. Thus, the ignition temperature can be affected by both the RH and the storage time of a mixture[38].

The propagation of a gas-phase flame is due to the diffusion of chemical species and heat along the combustion wave. In solid explosives and pyrotechnics, a means also must exist for propagating the reaction. This occurs by heat conduction through the packed, porous mixture. Experimentally, it is found that the mass burning rate is relatively independent of packing density once a certain minimum density is exceeded; mixtures of lower density do not show good thermal contact between grains[38].

The activation energies for pyrotechnic compositions are generally very low, compared to gas-phase combustion reactions. These are often in the range of 13 to 30 kJ mol^{-1}, which is about an order of magnitude lower than for gas-phase combustion reactions. An important issue, however, is that global, single-step Arrhenius expressions tend to have a narrow range of applicability.

Table 10 Temperature needed for a 50% probability of ignition at the most sensitive proportion of reactants

Combination	Ignition temp. (ºC)
aluminum/Fe_2O_3	590
aluminum/Fe_2O_3	525
magnesium/Fe_2O_3	490
magnesium/Fe_2O_3	445
titanium/Fe_2O_3	710

All else being equal, pyrotechnic materials with lower melting points are more easily ignitable[178]. They are also more liable to sustaining unwanted ignitions. Some pyrotechnic powder mixtures are inordinately sensitive to spark ignition, with a little as 0.01 mJ being sufficient[179]. The ignition temperature of the fuel component of a pyrotechnic mixture does not have a significance, since all components of the mixture influence the ignition temperature. There is no standardized test method for ignition temperature measurement of pyrotechnic mixtures and numerical values will depend on the testing technique used, same as with other types of ignition tests.

Much as for explosives, a critical diameter exists, below which steady burning of a pyrotechnic mixture will not occur[178].

McLain[38] has proposed that a theoretical treatment of the ignition of pyrotechnics be patterned after the thermally-thick theory for ignition of solids. In this scheme, the TRP becomes the primary variable to determine. Little, if any, data however appear to be available on the TRP of practical pyrotechnic compositions.

In *theatrical applications*, one sometimes finds formulas which are an exception to the general rule that pyrotechnic substances are mixtures of solids. For example, an exploding volcano can be simulated by dropping glycerin onto potassium permanganate, or by putting a drop of concentrated sulfuric acid onto a mixture of potassium chlorate and powdered sugar[180].

Some *chemical lighting devices* are based on pyrotechnic principles. For example, Coolite light sticks[180] comprise trichlorocarbobutoxyphenyl oxalate, hydrogen peroxide, and bisphenylethynylanthracene, the latter being a fluorescing compound.

PRACTICAL APPLICATIONS

The most common fuels used in pyrotechnic mixtures are magnesium, aluminum, and magnesium-aluminum alloys. Charcoal and sulfur are also commonly used. Common oxidizers are: potassium chlorate ($KClO_3$), potassium perchlorate ($KClO_4$), potassium nitrate (KNO_3), and ammonium perchlorate (NH_4ClO_4). A wide variety of other oxidizers are used, including the chlorates, perchlorates, chromates, bichromates, and nitrates of barium, calcium, sodium, strontium, and ammonium. Metal oxides (Fe_3O_4, Fe_2O_3, MnO_2, Pb_3O_4, PbO_2) are often used, as are some sulfates and iodates. Sulfur is also able to act in certain mixtures as an oxidizer instead of a fuel.

It is rare, however, that a pyrotechnic mixture would only comprise two components, a fuel and an oxidizer. Typical-

ly, 4 to 6 ingredients may be present, determined generally according to empirical experimentation, not fundamental chemistry. One of the additional components which is usually necessary is a binder. Common binders include red gum, dextrin, and various man-made polymers. Other components are often added to produce specific colors.

A firecracker is a particularly simple form of fireworks and may contain only $KClO_3$, S, and Al. The aluminum powder used is firecrackers is a specialized grade known as pyro aluminum which has an especially high surface/mass ratio.

The wanted ignition of fireworks can be accomplished by many means. These include electric matches, electric squibs, or simply a fuse cord made of black powder and paper or twine. In some cases, a *first fire* composition is ignited initially, and this is then used to propagate the reaction to the main charge. A special composition for igniting purposes can also be called *starter mix*, *priming mix*, *primer*, or *torch*.

Highway flares often use a mixture of strontium nitrate with potassium perchlorate, sulfur, wax, and sawdust. A friction igniter is used which may use red phosphorus and a binder such as lacquer or phenol-formaldehyde resin for one surface, and potassium chlorate or potassium perchlorate for the other.

Photoflash flares have a military application for nighttime photography. World War II compositions comprised a mixture[38] of $Ba(NO_3)_2$, Al or Al-Mg, and $KClO_4$. These have a propensity for detonating under impact. More current compositions use $NaNO_3$, Mg, and a small amount of fuel such as varnish.

Where sulfur is used, substitution of the 'flowers of sulfur' form for 'flour of sulfur' can lead to unstable mixtures, since the former contain high amounts of acidic impurities.

Humidity control must often be provided for fireworks manufacture. If the atmosphere is excessively dry, black powder, for example, can be ignited from a static buildup on a person[180].

Test methods

Over the years, an extremely wide variety of tests for explosives has been evolved. The tests described below are ones of more current interest. Médard[3] has described various other European tests of limited usage. Sućeska[181] likewise describes some less-common tests. Fedoroff et al.[107] provide a history of much of the early test method development. Generally, tests for explosives are highly empirical and there tends not to be much correlation between the results from any two test methods. Indeed, traditionally little correlation has been found even between the rank-order results from various sensitivity tests[184]. However, Weston et al.[182] tested 12 different explosives and concluded that if only tests for impact sensitivity are considered, then some rough correlations can be obtained between data from:

- energy fluence in flying-plate test
- small-scale gap test
- large-scale gap test
- run distance to detonation experiments
- minimum priming charge radius required
- critical detonation diameter.

They also showed that correlations of this kind do not extend to ammonium perchlorate-based propellants, which behave substantially differently. Gross and Amster[183] have suggested that there is a rough correlation between the impact sensitivity of explosives and their self-heating behavior (critical temperature for a given size), but according to Russian researchers, such a correlation does not exist[184].

UN TESTS

The UN scheme classifies explosive substances into Class 1, organized into six Divisions:

Division 1.1. Substances and articles having a mass explosion hazard.

Division 1.2 Substances and articles having a projection hazard, but not a mass explosion hazard.

Division 1.3 Substances and articles which have a fire hazard and either a minor blast hazard or a minor projection hazard, or both.

Division 1.4 Substances and articles which present no significant hazard.

Division 1.5 Very insensitive substances which have a mass explosion hazard.

Division 1.6 Extremely insensitive articles which do not have a mass explosion hazard.

To implement this classification, the UN Manual[185] contains a whole battery of tests intended to classify explosive substances. They are organized into 7 series:

Test series 1. To determine if a substance has explosive properties.

Test series 2. To determine if a substance is too insensitive for inclusion in Class 1.

Test series 3. To determine if a substance is thermally stable and not too dangerous to transport in the form in which it was tested.

Test series 4. To determine if an article, packaged article or packaged substance it too dangerous to transport.

Test series 5. To determine if a substance may be assigned to Division 1.5.

Test series 6. To assign a substance or article to Division 1.1, 1.2, 1.3, or 1.4 or exclude it from Class 1. Some of the background of this series of tests is given by Rees[186].

Test series 7. To determine if an article may be assigned to Division 1.6.

Each test series consists of at least two, but as many as 10 tests which might need to be performed to determine a classification question. This is all placed in context via elaborate flow charts which delineate the required testing and

decision-making sequence. Below, we review some of the main ones pertinent to initiation. The entire testing scheme has been developed through a process which is political in nature, and the non-equivalence of tests which are supposedly equivalent has been criticized[187].

DROP-HAMMER TESTS

For practical use of explosives, it becomes important to rate their sensitivity. The sensitivity of an explosive can be defined as the minimum energy that must be imparted to the explosive, within limited time and space, to initiate an explosion of the substance. This energy cannot be measured in a way which does not depend on apparatus details[188]. The impact test is the oldest way of testing for sensitivity, with the first test being one promulgated in 1902 in German railroad shipping regulations; the early-development history has been reviewed by Boyars and Levine[188]. The drop-hammer test is a simple mechanical arrangement (Figure 22, Color Plate 13) whereby a small amount of explosive, usually less than 1 g, is held in a steel anvil and covered by a cylindrical steel striker[215]. A hammer falls upon the striker from various heights. The sensitivity rating is the potential energy which gives a 50% probability of explosion. A stochastic approach is necessary, since it is found that test results have a wide scatter. The potential energy is expressed as:

$$PE = Wgh$$

where PE = potential energy (J), W = mass (kg), g = acceleration of gravity (9.81 m s^{-2}), and h = drop height (m). The units are made clear if it is realized that 1 J = 1 kg m^2 s^{-2}. If in the particular test procedure the mass of the hammer is kept constant, then the sensitivity rating can be expressed simply as the drop height. It has been suggested[189] that the drop-hammer results be interpreted in the following way:

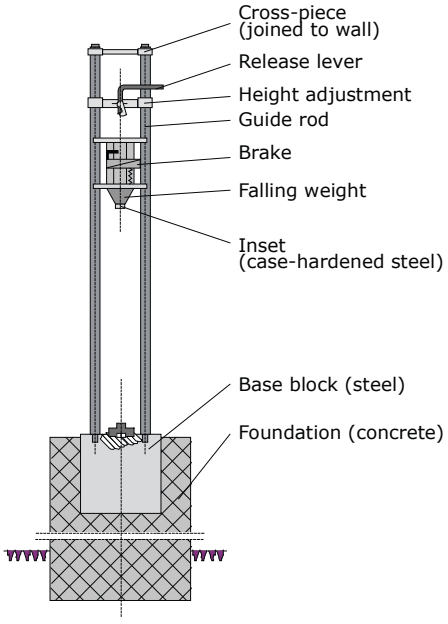

Figure 22 A typical drop-hammer test
(Copyright © 1999 AIChE used by permission)

insensitive:	PE > 30 J
moderately sensitive:	20 ≤ PE ≤ 30 J
sensitive:	5 ≤ PE < 20 J
very sensitive:	PE < 5 J.

In many cases, however, the results of drop-hammer tests are reported not as potential energy, but simply as kg-m or even simply as meters (for a fixed hammer mass).

The drop-hammer test simulates a direct hit onto the explosive and does not address the issue of initiation by a glancing blow. While impact is the way that energy is transferred into the specimen, drop-hammer tests provide substantial sample confinement and may cause initiation through other modes, such as adiabatic compression or hot spots. If one should conclude that dropping hammers is a very crude way of quantifying explosives, the opinion would be one that was already expressed by explosives expert Prof. Frank Bowden[59]: "Hitting a solid with a hammer…is perhaps an experiment more proper to a carpenter than to a physicist."

The reason that results from different drop-hammer tests commonly disagree is largely because not all of the potential energy is first converted into kinetic energy and then into energy of deformation of the explosive. A fraction of the energy is also converted into elastic strain energy of the drop hammer itself and of the anvil. These two pathways do not contribute to initiating the explosive. Coffey et al.[65] in fact consider that in common drop-hammer tests the bulk of the potential energy is realized as elastic deformation energy in the machine and does not go towards plastic deformation of the explosive. They point out[190], however, that at high velocities the fraction of energy going into elastic deformation of the machine itself becomes small, so test types should be preferred that are of the high-velocity type (greater than 8 m s^{-1}).

The drop-hammer test has been published for solids by ASTM as E 680[191] and for liquids as ASTM D 2540, but the UN has standardized on the German BAM version as its Test 3(a)(ii). Ranking of results from drop-hammer tests differs from another widely used explosives sensitivity test, the gap test, since the initiating event—being mechanical rather than a detonation—provides much lower pressures, but over a longer time scale.

KOENEN/BAM FRICTION SENSITIVITY TEST

Developed by Koenen[192] at Germany's Bundesanstalt für Materialforschung und Prüfung (BAM), in this bench-top test, designated by UN as Test 3(b)(i), a 10 mm^3 sample is placed on a rough porcelain plate (Figure 23). On top of the sample is placed a porcelain-tipped arm which can be weighed down with various weights. A reciprocating mechanism drives the plate back and forth for a distance of 10 mm. The load arm does not move in the horizontal direction. The test result is the lowest force at which there is one explosion in 6 trials. An explosion is defined as "report, crackling, sparking, or flame." Typical results are: lead az-

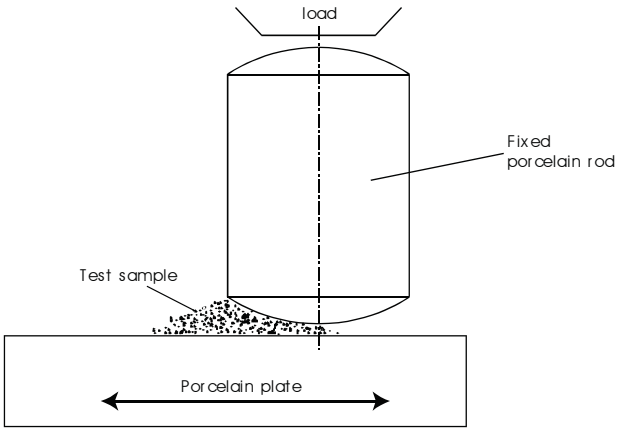

Figure 23 BAM friction sensitivity test
(Copyright Springer-Verlag, used by permission)

ide, 10 N; PETN 80 N; RDX, 120 N; TNT, 360 N. Some additional values have been reported by Moody[193]. The maximum load is 360 N, so specimens which do not initiate with this load are reported as "greater than 360 N." Bazaki and Kubota[194] studied ammonium perchlorate and related compounds in this test and examined correlations between its results and those from other explosives tests. Generally, positive correlations were found to most tests, but no highly predictive relation emerged. Négyesi[189] published a small database of UN impact and friction test results for 36 compounds that are not intentional explosives but may be susceptible to explosion under impact or friction conditions. Most impact test results resulted in non-explosion, with only 5 compounds showing measurable values. Friction test results ranged from 20 to 346 N. The test is sometimes known as the Julius Peters friction test, since the Peters company was its first commercial maker. The Koenen/BAM friction sensitivity test should not be confused with several other tests also invented by Koenen.

CARD-GAP TEST

The card-gap test evolved from simultaneous studies done at US and UK explosives research laboratories in 1953[46]. The test was further developed by the Bureau of Mines in 1968[195] by providing it with instrumentation, and naming it the 'instrumented card-gap test.' Subsequently, numerous researchers have proposed modest variants to the test method. Its purpose is to rank explosives according to their sensitivity to shock initiation. It is a simple mechanical arrangement where a gap, comprised of a variable thickness stack of metal or plastic cards, separates a standardized 'donor' charge from the target 'acceptor' charge. The acceptor charge is butted up to a witness plate, and the damage to the latter is judged by the test procedure. Explosives which are sensitive require a high gap value, while insensitive ones, a low one. The UN Manual[185], provides for three versions of the test. Test 1(a) places the test substance into a steel cylinder of 48 mm OD and 400 mm long. The donor charge, 'booster' in UN's terminology, can be a 50 mm cylinder of either RDX/wax or PETN/TNT. The donor is

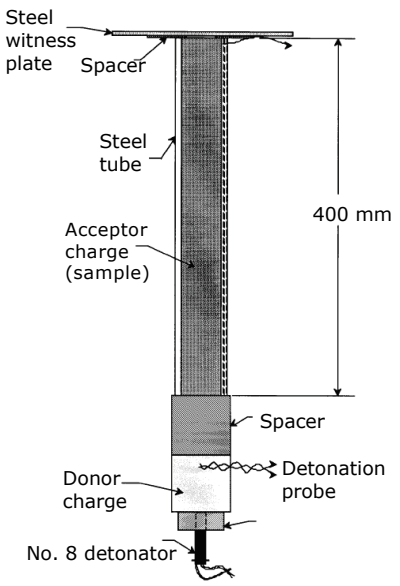

Figure 24 The UN gap test, Test 2(a)

initiated by a No. 8 detonator. This version uses no gap spacer. Test 2(a) is basically identical, but includes a 50 mm thick PMMA spacer (Figure 24); thus the conditions are less severe than for Test 1(a). Test No. 7(b), is dimensionally quite different and is used for qualifying extremely insensitive detonating substances (EIDS).

Apart from the UN versions, there are dozens of variants of the gap test in use. The US Armed Forces use the card gap test described in TB 700-2[196]. ASTM D 2539[197] is a card gap test for liquid monopropellants. Price[198] has compared results from several of the more common gap tests.

READILY COMBUSTIBLE SOLIDS

UN Test N1 for readily combustible solids uses a nonmetallic, non-combustible triangular trough, wherein the substance, which must be in powdered form, is placed (Color Plate 14). The trough width is 20 mm, height 10 mm, and length 250 mm. A flame is applied for 2 min to one end of the powder train. The substance fails, i.e., is classified as a combustible solid, if it ignites and propagates combustion for 200 mm during a 20 min period. The combustion may be either flaming or smoldering.

PYROPHORIC SOLIDS

UN Test N2 is a very simple test not requiring any apparatus. Some 1 – 2 mL of the test substance (which must be in powder form) is dropped from a height of 1 m onto a noncombustible surface. The substance is classified as pyrophoric, if it ignites during the drop or within 5 min of settling.

PYROPHORIC LIQUIDS

UN Test N3 for pyrophoric liquids uses only a 100 mm diameter porcelain cup as the test apparatus. A 5 mm layer

of diatomaceous earth or silica gel is first placed in the cup. Then, 5 mL of the test liquid is poured in. The substance is classified as pyrophoric if ignition occurs within 5 min. If ignition does not occur, then the second part of the test is executed. Here, 0.5 mL of the substance is placed on an indented filter paper. If ignition or charring of the filter paper occurs within 5 min, then the substance is also classified as pyrophoric.

WATER-REACTIVE SOLIDS OR LIQUIDS

The UN criteria for classifying a substance as a water-reactive substance is that either spontaneous ignition occurs upon combining with water, or that flammable gases are evolved at a rate greater than 1 L per kg of substance, per hour. The accompanying Test N.5 describes four simple procedures for combining a substance with water. No description is given of how the rate of flammable gas evolution might be measured, nor how the gases should be analyzed for flammability.

OXIDIZING SOLIDS

UN Test O1 for oxidizing solids involves pouring a pile of the substance, which must be in powdered form, onto a low-conductivity non-combustible board. The substance is first mixed with dry, fibrous cellulose in a ratio of 1:1 or 1:4 of sample to cellulose, by mass. The pile is ignited with a Nichrome wire applied for 3 min. Three reference substance must also be tested, which comprise potassium bromate, mixed 3:2, 2:3, and 3:7 with cellulose. The substance is classified into one of the Packing Groups of Division 5.1 if any of its burning times are shorter than those of any of the reference substances.

OXIDIZING LIQUIDS

UN Test O2 for oxidizing liquids uses a small pressure vessel equipped with a Nichrome wire igniter. The substance is combined 1:1, by mass, with dry, fibrous cellulose. Three reference substances are used, 50% perchloric acid, 40% sodium chlorate solution, and 60% nitric acid, in each case combined 1:1 with cellulose. The main test result is the time it takes for the pressure to rise from 690 to 2070 kPa (gauge). If the test substance shows a pressure-rise time less than any of the three reference substances, then it is classified into one of the three Packing Groups of Division 5.1

US MILITARY STANDARD TESTS

In the US, explosives tests were initially developed at the Bureau of Mines during about 1910 – 1940. After World War II, much of the development activity became localized at the US Army's Picatinny Arsenal in New Jersey. Many of these tests are for categorizing various capabilities of explosives which are outside the interest from the point of view of ignition. The ones related to ignition include: stability, friction sensitivity, heat sensitivity, and impact sensitivity.

The standard tests of the US military currently are grouped into three main documents, each of which contains numerous different test methods: (1) Department of Defense Ammunition and Explosives Hazard Classification Procedures[196]. This document does not describe any unique military tests; instead it authorizes the military to use the tests of the UN Manual[185] and provides administrative details implementing these. (2) Military Standard MIL-STD-1751 (USAF)[199] describes numerous physical performance tests that explosives for US military use must meet. (3) Military Standard MIL-STD-650[200] is a collection of basic chemistry laboratory tests for explosives, a few of which are pertinent to initiation.

The primary test methods of ignition interest are described below. These are not the entire repertoire, and the standards describe a number of more specialized methods. Additional methods described in MIL-STD-1751 pertinent to initiation include: Gas chromatographic reactivity test; Friction sensitivity test; Hot wire initiability test; Impact vulnerability (flying plate) test; Thermal detonability (bonfire) test; Card gap sensitivity test; Small-scale gap test (SSGT); and Stab initiability test. The Friction sensitivity test is similar in general principles, but not in operating details, to the Koenen/BAM friction tests. The gap tests are similar in principle to the UN tests described above. Additional methods described in MIL-STD-650 pertinent to initiation include 75ºC and 100ºC oven stability tests and a reactivity test.

VACUUM STABILITY AND CHEMICAL DECOMPOSITION TESTS

Testing for the storage stability of explosives can be done by any of the tests for self-heating or unstable materials discussed in Chapter 9. But there are also some methods specifically developed for the testing of explosives. Since the production of any gaseous species in significant amount is an indicator of instability, laboratory testing can simply consist of monitoring the increase in pressure of a sample placed in a closed vessel which is heated to a desired temperature. The earliest was Farmer's test of 1920. It comprised a glass beaker in which 5 g of substance is placed. The beaker was evacuated and placed in a constant temperature bath at the desired temperature. After 40 h, the test is stopped and the volume of gas produced is determined by a change in manometer reading. This was followed in 1921 by the Italian Taliani test which was rather similar in principle and became widely used. This has evolved into the Vacuum Thermal Stability test (Test 1 of MIL-STD-1751; also Method 503 of MIL-STD-650) which is regularly used by the US military. The early history has been given by Boyars and Gough[201], while later development has been described by Simmons[202]. The apparatus is a test tube which immersed in a heated liquid bath. A long capillary connects the test tube to a mercury cup. The test tube is charged with 0.2 g of a primary explosive (1.0 g, if per Method 503) or 5 g of secondary. The capillary is then

evacuated and the mercury height recorded. A calibration procedure relates the mercury height to the pressure within the test tube and, therefore, to the volume of gas that is liberated by the specimen after evacuation. The test is run at 100ºC for 48 h (for 40 h if per Method 503). The Method 503 procedure also allows a variant of running at 120ºC. To pass the MIL-STD-1751 criteria, the specimen must evolve no more than 2 mL gas, per gram of test substance. The Chemical Reactivity Test developed by the Lawrence Livermore National Laboratory can be viewed as a modern offshoot of this test. Gas chromatographic analysis is made in the LLNL test in order to quantify the major decomposition products.

LABORATORY SCALE IMPACT TEST

The version of the drop-hammer test described as Test 2 in MIL-STD-1751 (Figure 25) was developed by the Bureau

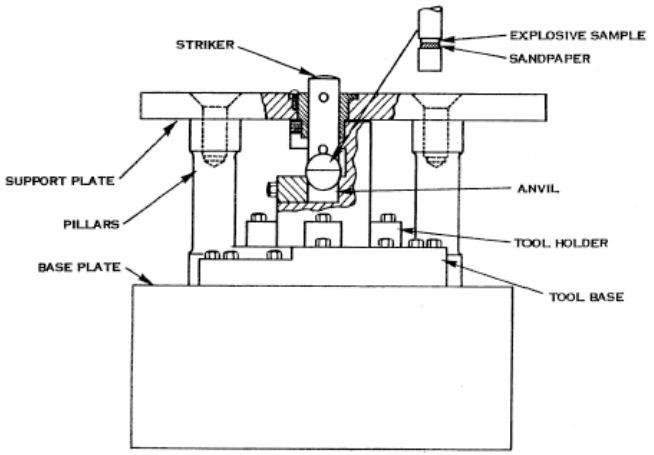

Figure 25 MIL-STD-1751 Test 2 for impact

of Mines during World War II. Hammer weights of 2, 2.5 or 5 kg are available, with a maximum drop height of 3.2 m. The sample consists of 35 mg of material resting unconfined on a piece of sandpaper and is weighted down by a cylindrical steel striker. A total of 25 drops are made with each new drop height to be used being selected according to an 'up-and-down' procedure developed for this test. The final reported value is the drop height which causes explosion at the 50% probability level. There is no specific pass/fail criterion for the test. Method 505 of MIL-STD-650 describes a similar, but not identical, test.

ELECTROSTATIC SENSITIVITY TEST

Test 4 within the MIL-STD-1751 series was developed by the Bureau of Mines in the early 1950s[203]. It uses a phonograph needle as an 'approaching electrode' that, when activated, springs down and punctures and penetrates the sample. The second electrode is a steel support cup for the specimen. There are several procedures within this test method. One procedure uses a 20 mJ discharge (a 0.002 mF capacitor charged to 4.5 kV). There must be no firing in 25 tests,

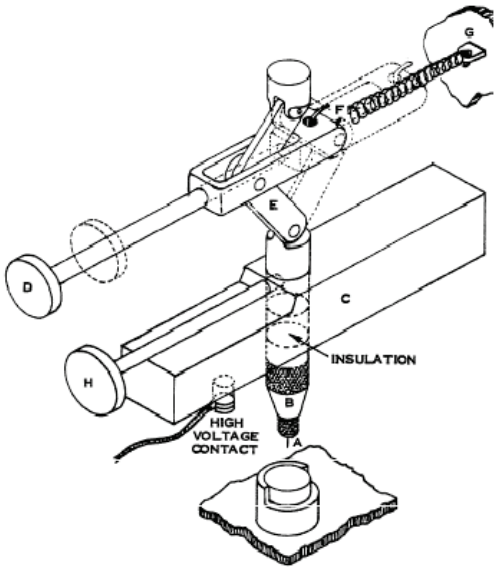

Figure 26 MIL-STD-1751 Test 4 for electrostatic sensitivity (A–needle electrode; B–actuating rod; C–guide housing; D–handle; E–toggle assembly; F–spring; G–wall hook; H–release rod)

with failure determined by the severing of the electrical tape which is used to tape down the top of the specimen. Other procedures are of a screening nature and do not have associated pass/fail criteria.

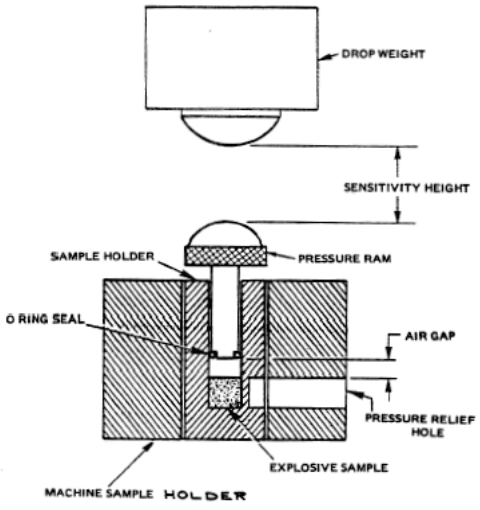

Figure 27 MIL-STD-1751 Test 12 for adiabatic sensitivity

ADIABATIC SENSITIVITY TEST

Test 12 in MIL-STD-1751 (Figure 27) is a modified drop-hammer test whereby the hammer compresses a volume of air, which, in turn, provides pressure to the sample. A 1 g sample is press-loaded into the sample cup, which is compressed by the force of the drop-weight dropping onto the pressure ram. The sample is packed to the same density as intended for the as-used explosive. The operating procedures and the treatment of data and results are similar to Test 2 of the Standard.

COOKOFF TESTS

The initiation of explosives when engulfed in an ongoing fire, or when sustaining another form of unplanned temperature rise, is termed 'cookoff.' There has been a wide variety of variant methods described, but most use a physical arrangement that resembles a pipe bomb with heaters attached to the perimeter (Figure 28). Test 13 in MIL-STD-1751 is a small-scale cookoff test intended as a screening test to find out the sensitivity of munitions to being detonated by unintended heating. It consists of a small steel bomb, 62.5 mm dia. and 127 mm tall, half-filled with the test explosive. When filled, a lid is tightly screwed on and the bomb is placed in a steel heating well. Three thermocouples are located inside the sample space and a pressure gauge is fitted to the bomb.

In general, explosives behave differently when presented with an environment where the temperatures rise fast or slow, thus two types of tests are found to be needed. The US Navy Variable Confinement Cookoff Test was developed at the Naval Surface Warfare Center, in Indian Head MD to simulate a slow cookoff of explosives[205]. The fixture comprises a steel tube clamped between two steel endplates. The steel tube is lined inside with an aluminum tube in order to improve heat transfer uniformity; the inner tube is filled with the explosive to be tested. External heaters heat the assembly at a rate of 3.3°C per hour. The test is concluded when the confinement bursts. A number of other small-scale tests, most of which resemble a pipe bomb in arrangement, have been described by de Yong and Redman[206] and by Kondrikov[207].

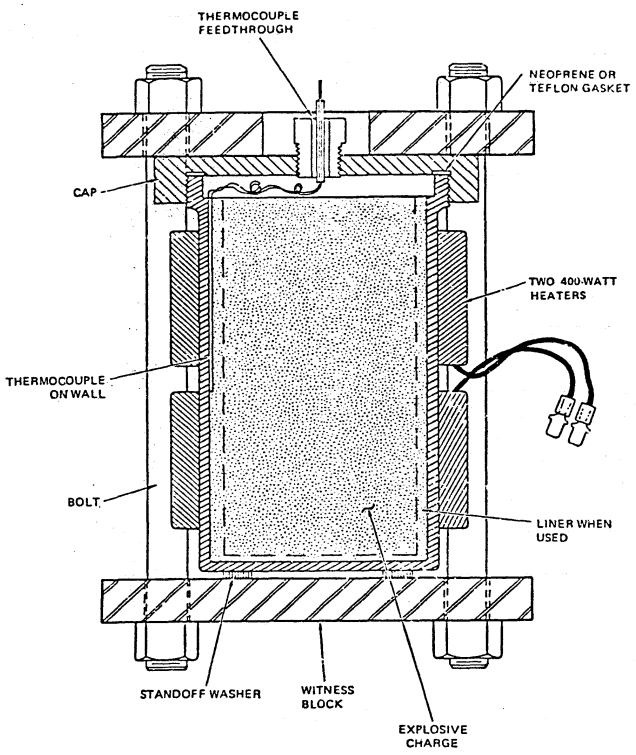

Figure 28 The small-bomb cookoff test developed at the Naval Weapons Center[204]

SHOCK INITIATION SENSITIVITY TEST

Test 14 in MIL-STD-1751 (commonly known as a Wedge test) is intended to determine the sensitivity of a high explosive to shock initiation. The principle is that it takes a certain run distance within the explosive for a shock wave to create a detonation. The testing is highly specialized and the monograph of Gibbs and Popolato should be consulted for details.[208]

HENKIN TEST FOR EXPLOSION TEMPERATURE

In this test[209] a milligram sample of the explosive substance is placed in a hollow copper cylinder (i.e., the tube of a No. 8 blasting cap), loosely capped, and lowered into a Wood's metal bath which is at some pre-selected temperature. An ingenious electric circuit is used to time the explosion. One lead of a circuit connects to the sample case, while the other lead to the cap; when the explosion blows the cap off, the timer is stopped. Times as short as 50 ms can be determined; at the other end of the scale, a maximum time of 1200 s is used. The small quantity of explosive used gives

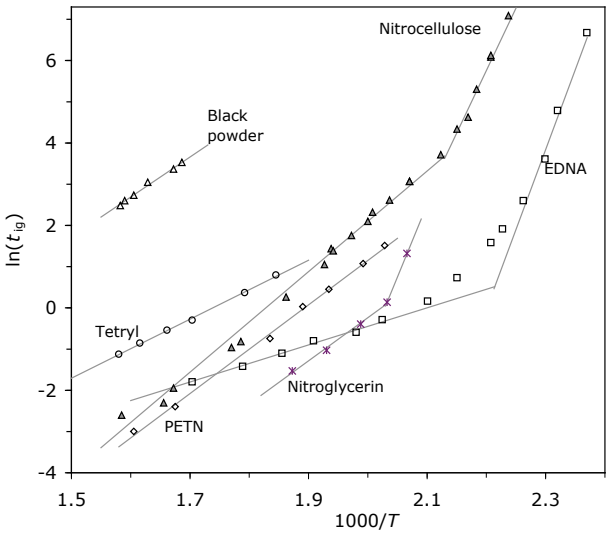

Figure 29 The relation between temperature and ignition time in the Henkin test (25 mg specimens, except nitroglycerin, which was 3 mg)

rather high minimum temperatures for explosion. For example, cellulose nitrate is reported as 175ºC, in contrast with 141ºC being determined for larger samples in the Setchkin furnace[210]. Henkin et al. mainly used the data not for absolute values but to obtain effective values of the activation energy according to the Semenov relation:

$$\ln\left(t_{ig}\right) = \frac{E}{RT} + C$$

where C is a constant. For most explosives, they found a straight-line relation when plotting ln (t_{ig}) as a function of $1000/T$, where T = temperature (K), as shown in Figure 29. Many explosives (EDNA, nitrocellulose, and nitroglycerin in Figure 29) show a low-temperature slope and a different high-temperature slope, indicating that there are two different values of E pertinent to two different temperature regimes. The numerical value of E (kJ mol^{-1}) is obtained by multiplying the slope by R (8.314 J mol^{-1} K^{-1}). The factor of 1000 in the x-axis variable means that the units of E come out directly as kJ mol^{-1}, instead of J mol^{-1}. The test conditions in the Henkin test are such that the values of E are determined for a rather high temperature regime, typically 200 – 300ºC. Many explosives show initial exothermic activity at temperatures lower than the range which is encompassed in the Henkin test; the Henkin data would not be appropriate for those situations. In the cases where the Henkin test shows a high- and a low-temperature regime, the low-temperature values are the ones that will probably be more pertinent to actual explosive performance. Brill and Brush[211] conducted a modern series of experiments in a similar vein and concluded that the 'high-temperature' values of E are effectively spurious, since heat transfer, not chemical kinetics, is the rate limiting mechanism in that regime.

Method 506 of MIL-STD-650 describes the US Army version of the Henkin test. This differs in that the quantity of explosive used is 20 mg and an 'explosion temperature' is defined as the temperature at which t_{ig} = 5 s.

The Henkin test is done under unconfined conditions. Catalano et al.[212] studied explosives confined to a rigid anvil so that products of combustion were not able to escape until the ultimate explosive release. They got entirely linear plots of $1/T$ vs. ln(t_{ig}) over the full range of temperatures studied. The slopes, however, were at strong variance to results computed by using published, single-step Arrhenius kinetics values. Thus, their conclusion was that multiple reaction steps must be considered. The Los Alamos National Laboratory[213] uses a variant of the test where a 40 mg specimen is lightly confined in an aluminum shell.

SENSITIVITY TO INITIATION

The original sand bomb test was developed by the Bureau of Mines[215] in 1916. Method 507 of MIL-STD-650 (Sand test bomb) uses the same concept, but with a complex procedural scheme. It is a test for primary explosives used to determine the minimum amount of detonating materials that will initiate an 0.4 g sample. The test explosive is put into a No. 6 or No. 8 blasting cap and compressed with a plunger by applying a pressure of 20.7 MPa. A safety fuse is crimped onto the end of the blasting cap, the cap is placed into a steel bomb, and the bomb cavity filled with 200 g of sand which has been sieved to have a narrow size range. The fuse is lit and after the explosion the size is sieved and the mass of sand that has been pulverized is determined. There are a number of sequences to this test where the test explosive is fired alone and in conjunction with lead azide and tetryl. The results are reported either as "sensitive to flame initiation alone" or as the mass of tetryl needed for initiation.

PERMISSIBLE EXPLOSIVES

The testing of permissible explosives was originally done by the US Bureau of Mines but is currently under the jurisdiction of the Mine Safety and Health Administration (MSHA). The test series was reorganized in 1989 and the tests that currently must be passed[214] include an air-gap sensitivity test (to ascertain that the explosive can be successfully detonated), a rate-of-detonation test (to determine if an undesired tendency exists for partial detonation), a pendulum-friction test (to determine if the explosive is excessively sensitive), a toxicity test (for personnel safety), and most importantly, two gallery tests. These involve firing a special steel cannon into a test gallery. In 'Test 7,' the gallery is filled with an 8% methane mixture while in 'Test 8' the gallery contains 4% methane plus a dispersion of coal dust. A different series of tests is prescribed for sheathed explosives. The early history of testing permissible explosives was described by Munroe and Tiffany[215].

OTHER TESTS

Apart from the more common tests discussed below, Avrami and Hutchinson[216] have discussed some less commonly used friction tests. Tests that were used by the Bureau of Mines are described by Mason and Aiken[217].

PENDULUM FRICTION TEST FOR GLANCING BLOWS

The Bureau of Mines developed a test[215] where an anvil holds 7 g of explosive, while a swinging pendulum is released and pushes a friction shoe past the explosive 18 times. The glancing blow represents a weight of 20 kg released from a height of 1.5 m. A smaller-scale version of this test was also developed.

NOL THERMAL SENSITIVITY TEST

This test method was developed for the US Department of Transportation as a possible means of identifying hazardous materials. A 2.1 µL sample is enclosed in a 63.5 mm length of stainless steel tubing which is then pulse-heated by a capacitive discharge. The apparatus is capable of heating up to 1000 °C. The induction period for the explosion to occur is determined by using the tubing itself as a resistance thermometer. The primary variables reported are the threshold initiation temperature and the temperature

achieved at 250 μs. Some typical results are given in Chapter 14.

BUREAU OF MINES TEST FOR OXIDIZING SOLIDS

In 1972, the Bureau of Mines described a method[218] for examining the ignition and burning propensity of solid, inorganic oxidizers when mixed with sawdust. The test uses a metal channel, 50 mm wide, 25 mm high, and of an unspecified length (apparently, 178 mm). The test substance, which must be in powdered form, is mixed with red oak sawdust in varying proportions, ignited with a propane torch at one end, and a burning rate is determined. Apart from this terse description, the BM publication provided very few other experimental details. Consequently, test development was continued at General Electric Co.[219]. The GE report contains detailed performance data on 16 oxidizers.

LLNL STEVEN TEST

One of the latest impact tests that has become popular in the US research community is the Lawrence Livermore National Laboratory's Steven Test, developed by Steven Chidester[220]. The test explosive is confined between a 3.175 mm steel front plate and a 19.05 mm steel back plate. A 60.1 mm diameter steel projectile is fired from a gas gun onto the target and pressures developed are monitored with two embedded gauges and four external gauges. The results are presented as a plot of impact velocity vs. average overpressure, as measured at the external gauges, located 3.05 m away. Unlike some other impact tests, the Steven test has a definite threshold velocity, below which zero overpressure is recorded. This allows ranking the results on the basis of the threshold velocity, with less sensitive explosives showing a higher threshold.

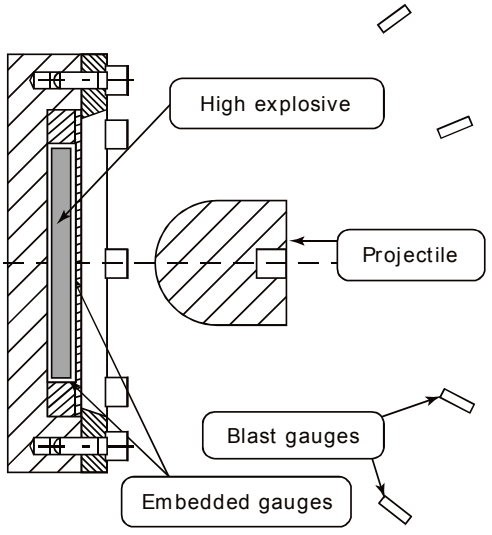

Figure 30 The LLNL Steven Test for impact

Frank P. Bowden and A. D. Yoffe, **Initiation and Growth of Explosion in Liquids and Solids**, Cambridge University Press, Cambridge (1952). This was the first book to examine explosives from a fundamental science point of view. In addition, it is an outstanding example of brilliant, yet clear and engaging technical writing. Prof. Bowden was also thesis advisor to Philip Thomas, who went on to become the foremost fire science researcher in the 1950s and '60s.

Tadeusz Urbański, **Chemistry and Technology of Explosives**, 4 vols., Methuen/Pergamon, New York (1964-84). **Encyclopedia of Explosives and Related Items**, B. T. Fedoroff, et al., eds., Picatinny Arsenal, Dover NJ (1960-1983). The two most comprehensive works on explosives are now a bit old, but no more recent works have been anywhere near as comprehensive. Urbański's covers the subject from a chemist's perspective, while Fedoroff's from a weapons designer's. Both contain a huge amount of information but are short on organization.

Josef Köhler and Rudolf Meyer, **Explosives**, 4th ed., VCH, Weinheim, Germany (1993). This standard reference is a 'pocket encyclopedia' of explosives and is a good first reference for finding brief information about explosives, including trade names from various countries. It has been kept up-to-date by frequent revisions.

Brigitta M. Dobratz, and Patricia C. Crawford, LLNL **Explosives Handbook: Properties of Chemical Explosives and Explosive Simulants** (UCRL 52997), Lawrence Livermore National Laboratory, Livermore CA (1985). F. L. McIntyre and R. M. Rindner, **A Compilation of Hazard and Test Data for Pyrotechnic Compositions** (ARLCD-CR-80047), US Army Armament R&D Command, Dover NJ (1980). These are the two most comprehensive data compilations for explosives/pyrotechnics. The Dobratz tome focuses on thermochemical data and properties of explosives, while the McIntyre book contains mostly ignition/sensitivity data for pyrotechnics, but with some basic thermochemical properties.

The following three monographs are wholly (Sućeska's) or primarily (Yoshida's) devoted to descriptions of test methods for explosives, oxidizers, reactive and hypergolic substances. Muhamed Sućeska, **Test Methods for Explosives**, Springer-Verlag, New York (1995). Tadao Yoshida, **Safety of Reactive Chemicals**, Elsevier Science, London (1987). Tadao Yoshida, Yuji Wada, and Natalie Foster, **Safety of Reactive Chemicals and Pyrotechnics**, Elsevier, Amsterdam (1995). The second Yoshida book supplements, not replaces, the earlier work.

Alexander Beveridge, ed., **Forensic Investigation of Explosions**, Taylor & Francis, London (1998). This is a modern guide to investigating criminal explosions (accidental explosions receive only limited attention), with emphasis on

chemical analysis techniques and on organization aspects of large investigations.

The following two books on pyrotechnics are similar, both being rather brief and focusing mainly on the basic science aspects. Joseph H. McLain, **Pyrotechnics: From the Viewpoint of Solid State Chemistry**, The Franklin Institute Press, Philadelphia (1980). John A. Conkling, **Chemistry of Pyrotechnics: Basic Principles and Theory**, Marcel Dekker, New York (1985). A brief but useful introduction to the chemistry of pyrotechnics is: N. Kubota, Propellant Chemistry, *J. Pyrotechnics* No. 11, 25-45 (Summer 2000).

The following two books cover both the science and the technology aspects of pyrotechnics. Alexander P. Hardt, **Pyrotechnics**, Pyrotechnica Publications, Post Falls ID (2001). This is the most current textbook on fireworks that is of significant size and scope, but it is not quite as current as the imprint date would imply, since the author died in 1989. A. A. Shidlovskii, **Principles of Pyrotechnics**, English translation, American Fireworks News, Dingmans Ferry PA (1997). A good English translation of a classic Russian textbook first published in 1964.

Karl O. Brauer, **Handbook of Pyrotechnics**, Chemical Publishing Co., New York (1974). Offers information primarily on hardware, rather than chemistry. John Donner, **A Professional's Guide to Pyrotechnics: Understanding and Making Exploding Fireworks**, Paladin Press, Boulder CO (1997). Well illustrated, this may be the best reference on the construction of some popular fireworks. Donner has written several earlier editions of this book, under slightly different titles.

D. Harrington, and J. H. East, jr., Accidents due to Misuse of Explosives (IC 7259), Bureau of Mines, Pittsburgh (1943). A useful review of blasting accidents and their causes.

Jack R. Gibson and Jeanne D. Weber, **Handbook of Selected Properties of Air- and Water-reactive Materials** (RDTR-144), US Naval Ammunition Depot, Crane IN (1969). While now quite old, this is the only compilation of properties of pyrophoric and water-reactive substances.

The following textbooks are good general references on rocket propellants: George P. Sutton and Oscar Biblarz, **Rocket Propulsion Elements**, 7th ed., Wiley Interscience, New York (2001). Stanley F. Sarner, **Propellant Chemistry**, Reinhold Publ. Co., New York (1966). Bernard Siegel and Leroy Schieler, **Energetics of Propellant Chemistry**, Wiley, New York (1964).

NFPA has issued a number of publications giving safety advice on explosives, propellants, and pyrotechnics. NFPA 495[221] covers safety precautions in the civilian sector concerning handling and storage of explosives. One of the data items provided in NFPA 495 is the American Table of Distances for Storage of Explosives, as originally compiled by the Institute of Makers of Explosives. A separate table of distances is provided for ANFO. NFPA 1124[222], originally NFPA 44A, describes safe manufacturing, handling and transportation practices of consumer fireworks. NFPA 1123[223] covers the safety practices to be used by licensed technicians in staging outdoor public fireworks displays. NFPA 1126[224] describes safety requirements for staging of fireworks displays in connection with theatrical performances. Three standards pertain to model rocketry operations: NFPA 1125[225] deals with manufacturing of rocket motors, NFPA 1122[226] provides general safety precautions for model rocketry, while NFPA 1127[227] gives guidance on high-power rocketry operations.

Highlights and summary of practical guidance

An ignition source can constitute any form of heat or a form of energy (for example, kinetic energy) which can become converted into heat. Energy sources can be characterized by at least four main characteristics:

1. the temperature
2. the total energy supplied
3. the rate at which it is supplied, or the time period over which it is delivered
4. the area over which it is delivered.

Dealing with a phenomenon where there are at least four controlling variables can be complex. In many cases, even more than four variables come into play. For example, in radiative heating, the wavelength distribution of the radiation is important. In convective heating, air velocity affects the outcome, not just temperature. Solid objects (i.e., fire brands) often have an extremely irregular heat flux distribution, so the whole concept of energy supplied over a fixed area loses meaning. Because of complications of this type, it is rarely possible to treat ignition sources as simple black boxes supplying energy. Instead, it is necessary to study details of various ignition sources that have been found to be important in actual fires, and to examine how they interact with different types of combustibles.

Ignition sources consisting of radiant heat flux or a hot air stream (convective heating) are relatively simple. The main issues with sources of this kind involve aspects of proper design of test apparatuses. Otherwise, the heat fluxes can be

treated in a simple way according to elementary heat transfer theory. Thus, simple radiant or convective heating has already been treated in the preceding Chapters under the different material types and is not further studied in this Chapter. Flames, burning buildings, and other similar heat sources require some study before they can be described by their heat fluxes. Thus, these ignition source types are included in the present Chapter. Even though principles governing ignition sources are often poorly known, this Chapter is devoted to examination of ignition source principles, to the extent that they can be established. Specific information dealing with practical ignition sources (for example, candles, cigarettes, matches) is presented in Chapter 14.

The ignition potential of hot, incandescent or burning particles is very poorly known. In certain cases, particles of less than 0.5 mg can ignite some dry forest fuels. Fuel gas/air mixtures, under extreme circumstances, can be ignited by a 1 μg burning magnesium particle. But the probability of ignition decreases as the particle size decreases. There have been a number of studies on this topic, but taken together, they do not allow one to evaluate the probability of ignition, as a function of characteristics of the igniting particle and the target material. General research on fire brand ignitions is presented in this Chapter, while more specific details focusing on various target materials are given in Chapter 14.

Electrostatic charge build-up is likely to occur when motion is involved. The motion can involve rubbing of solids or flow of insulating liquids or powders. The flow of pure gases does not lead to static charge buildup. Systematic understanding of electrostatic ignitions is also often limited, although there has been much empirical research.

Perhaps the most difficult to understand ignition source has been electric current. The basic principles governing ignition from electric current are treated in this Chapter; details of ignitions associated with wiring, connectors, appliances, etc. are taken up in Chapter 14. Despite its importance for understanding real fires, research in this area was nearly non-existent until the 1970s and is still scattered and incomplete.

Introduction

Ignition sources can be of two types: (1) self-caused; or (2) external. Examples of self-caused ignitions include hypergolic, pyrophoric, and unstable substances; self-heating; and some others. For these ignition types, there is no difference between the igniter and the ignited. Thus, these have all been considered under appropriate chapters above. In this Chapter we give detailed consideration to external heat sources, that is, sources which are not one-and-the-same as the item being ignited. In electric arc tracking, the identity of the heat source and the item being heated is perhaps less clear, but nonetheless this form of ignition is treated in Chapter 7.

An external ignition source can basically be anything which can generate or deliver an adequate amount of heat. In practice, this includes a wide variety of devices, situations, and substances. In this Chapter we consider those ignition sources that have been studied sufficiently so that some systematic trends are known or some practical guidance is available.

High ambient temperatures

In desert climates, surprisingly high temperatures can be achieved in interior spaces which are neither insulated nor ventilated. A temperature of 101ºC has been measured[1] under such conditions in Tucson, Arizona, when the outdoor air temperature was 49ºC. A similarly extreme temperature of 93ºC was measured on the exterior surface of a roof in Saudi Arabia[2].

In less extreme climates, a study of attic temperatures[3] in Mississippi showed an outdoor air temperature of 40ºC, with corresponding interior temperature of 58ºC. At the same time, the exterior surface temperature of the black-asphalt shingle roof was 78ºC. In Wisconsin, with an outdoor air temperature of 35ºC, peak interior temperature of 54ºC was recorded, with the corresponding exterior surface temperature being 76ºC. Even these extreme temperatures are normally not a problem for stable, solid materials. Self-heating materials, on the other hand, are very sensitive to ambient temperatures and that topic is dealt with in Chapter 9.

According to a study by Bowes[4], the temperature in ships' holds were found to attain 39 – 48ºC for prolonged periods of time when a ship is traveling through tropical areas, although sustained air temperatures are only 29 – 38ºC. Above-deck temperatures[5] almost never exceed 40ºC.

Hot solids or liquids

This category of ignition sources encompasses a broad array of heating configurations, with the two most common examples being:

a) a large hot surface coming into contact with the large surface of the ignitable solid; or
b) a small, hot object falling onto a large ignitable surface.

Common examples of small, hot objects which can act as an ignition source include aerodynamically buoyant burning objects (generally called firebrands or flying brands), engine exhaust particles, and hot, molten, burning, or incandescent metals. Hot metals typically can be generated from friction or impact, from steelworking activities (e.g., hot rivets), from arc welding, or from other sources of electric arcing. Smoldering objects may also be placed in the category of small hot objects. However, there is not much general, systematic knowledge concerning their ability to act as ignition sources. The most common example is a cigarette and its characteristics are treated in Chapter 14. A flying brand may also extinguish during its flight and land on a target as a smoldering object. Some general aspects of smoldering behavior are treated in Chapter 7.

LARGE HOT SURFACES IN CONTACT—THEORY

For a hot surface to be considered 'large,' the minimum width or length dimension should be much greater than the thermal penetration depth (see Chapter 7) of the ignitable solid. A classic example of a large hot surface coming into contact with an ignitable solid is a clothes iron. The analysis of this category of problem is actually not simple. The interface between the hot object and the ignitable object will assume a temperature that is relatively constant for locations far away from the edges of the hot object. This interface temperature (i.e., the surface temperature of the ignitable object) can be approximately computed using standard heat conduction theory. At the moment of contact, the surface temperature of the ignitable object becomes identical to the surface temperature of the hot object. This temperature T_i will be lower than the original surface temperature of the hot object, but higher than the original surface temperature of the ignitable solid. It can be solved as[6]:

$$T_i = \frac{T_h\sqrt{(\lambda\rho C)_h} + T_c\sqrt{(\lambda\rho C)_c}}{\sqrt{(\lambda\rho C)_h} + \sqrt{(\lambda\rho C)_c}}$$

where T_h = temperature of the hot object (ºC), T_c = temperature of the ignitable object (ºC), and the thermal inertia term $\sqrt{(\lambda\rho C)_h}$ refers to the hot object, while $\sqrt{(\lambda\rho C)_c}$ refers to the ignitable object. The solution for the interface temperature, however, is not exactly the answer that is wanted. Far away from the edges, the surface of the ignitable object will be getting heated to the maximum temperature. However, since a hot surface is in direct contact there, no oxygen can get to this place. Where ignition can take place is at the edges of the hot body, since oxygen is available there. That temperature, however, is lower than the interface temperature computed by the above equation.

In practice, the situation may be more complex yet. We have tacitly assumed that both the hot object and the ignitable object have hard, impermeable surfaces. However, by significant heating the ignitable object may melt or pyrolyze and, thereby, open up cavities or voids. Oxygen may then get into these voids. A plastic foam can be an example of an ignitable object which deforms during heating. Also, given enough time, the pyrolysis may proceed through the thickness of the material and break out the other side where oxygen may be present. This is common when heating appliances are improperly placed on combustible floors and the appliance chars a hole through the floor. Flaming combustion often occurs from below the floor.

SMALL HOT OBJECTS—THEORY

Studies on specific categories of hot objects are presented in several sections below. These are mostly either purely empirical or employ a theory for aspects other than ignitability (e.g., aerodynamics of burning brand flight). There have been only limited theoretical attempts to predict ignition of various substrates upon which a small hot object may fall. Examples include forest floor litter (Jones[7]) and surfaces upon which welding spatter falls (Hölemann[8]). These efforts have been based upon the application of either the inert or the reactive hot spot theory, presented in Chapter 9. It is relatively easy to make the required calculations, however, the realism is uncertain since:

(1) There has been no experimental validation of the theories.
(2) Most practical problems violate the basic assumptions incorporated in the theories. The theories all assume that the hot particle is in full, intimate contact with the substrate, and that the latter is infinite in extent. In the case of fibrous materials such a vegetation, the contact between a small particle and the substrate is likely to be at only a few, tiny spots, not along the whole periphery of the particle. In the case of particles landing on a solid surface, again contact will be limited, unless the material melts or burns enough to envelop the particle. Even then, the front-face conditions of the substrate do not approximate an infinite solid.
(3) The experimental data discussed below indicate that the problem is largely probabilistic, but there exists no theory that incorporates probabilistic aspects.
(4) Necessary thermophysical data for the target material, especially the thermal conductivity, may be lacking.

An example on the use of the self-heating theory to predict the ignition potential of molten aluminum particles falling onto barley grass is given in Chapter 14.

AIRBORNE BURNING OBJECTS (FLYING BRANDS)

Many types of fires generate small burning particles which flow along with the gaseous combustion products. When such particles have the capability of setting additional fires, they become firebrands. The basic aerodynamics is that the brand first gets lofted by the plume of fire gases to a high elevation. The available lift decreases as the plume gets progressively cooler at higher altitudes. Eventually, a terminal height is reached. If there were no wind, the brand would simply burn up vertically above its generation point and no spot fire could result. However, wind acts to carry the brand horizontally away from its origin point. Whether or not a combustible particle has the potential of setting a fire depends on the interplay of several factors:

- a particle must be generated (burned off, broken off by air velocity)
- it must get heated to ignition
- it must not burn up completely before it lands on the potential target, and it must carry enough remaining heat of combustion in order to be able to actually ignite the target.

Under a given set of conditions, there will be an optimum mass of particle that can set the most remote spot fires. This will depend not only on the aerothermodynamic aspects of the fire environment, but also on the shape of the object. A firebrand with a shape that creates a significant amount of aerodynamic lift is the most hazardous firebrand.

Table 1 Terminal velocity of potential firebrand materials (tested unignited)

Material	Terminal velocity ($m\ s^{-1}$)
bark of paper birch	5.6
frond of palmetto palm	4.6
leaves	1.3 – 2.24
moss	3.5 – 4.5
pine cones	8.6 – 16.5
pine needles	2.9 – 4.1

Some basic characteristics of forest materials acting as firebrands were studied by Clements[9]. Terminal velocities, as determined in laboratory drop-tower experiments (on unignited materials) are listed in Table 1. Clements also examined the burning times of cones from various pine species by keeping the specimens suspended in a vertical wind tunnel. The flaming times were relatively short, but some very long glowing times were recorded (Table 2).

Table 2 Flaming and glowing times for pine cones in flight (averages for 25 trials)

Pine species	Flaming time (min)		Glowing time (min)	
	Avg.	Max.	Avg.	Max.
loblolly	0.36	0.83	4.09	6.83
longleaf	0.44	1.20	7.50	13.49
shortleaf	0.15	0.53	2.95	4.60
slash	0.32	0.56	6.13	10.42

The length of time during which a firebrand will flame increases with increasing size of brand. Muraszew[35] conducted experiments on natural vegetation items, wood cylinders, and cedar shingles. For all three categories, he found that the flaming time could be represented as:

$$t_{fl} = 25\left(\frac{V}{S}\right)^{5/4}$$

where t_{fl} = flaming time (s), and V/S = volume/surface ratio (mm). The latter was used instead of a diameter so that irregular-shaped brands could be correlated. After a wood brand has ceased flaming, there still remains a glowing phase and brands can ignite target fuels in the glowing phase, although they become progressively less effective.

IGNITION OF BUILDINGS

A 1960 Japanese study found that, within cities, most spot fires are located within 700 m of the originating fire from which brands were launched[10]; a number of these fires were caused by very small brands which were blown in by the wind through small gaps between roof shingles. In the Sakata City Fire[11] of 1976, brands of 50 mm size were found to have traveled up to 1800 m in a prevailing wind of 12 m s^{-1}. More recently, the investigation of a major hotel fire in Japan revealed that fire spread to surrounding areas was mostly by means of fire brands. Brands of 50 mm size were found[12] to have traveled up to 450 m; brands up to 300 mm size were found at shorter distances[13]. Japanese researchers also determined that mass fires which show extremely high rates of spread are mainly dependent on fire brands for these fast spread rates In the Great Hakodate Fire of 1934, fire spread rates of 1000 – 1400 m h^{-1} were attributed to transport of fire brands. An empirical relation was evolved between wind velocity and the rate of spread of an urban mass fire propagating by means of fire brand transport (Figure 1)[14].

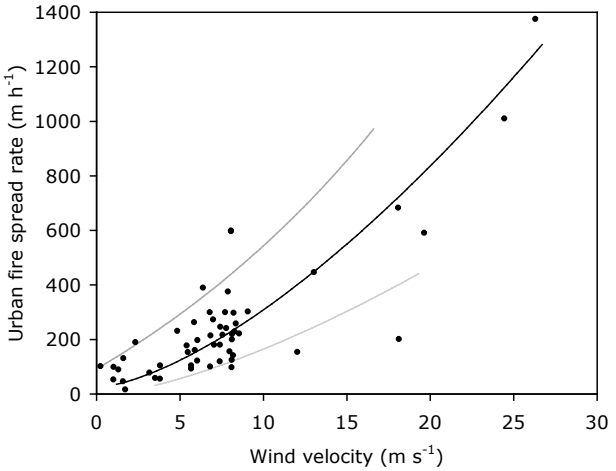

Figure 1 The spread rate of Japanese urban mass fires driven by fire brand propagation

A laboratory study to characterize brands generated by burning roofs was reported by Waterman[15]. Wood shingle roofs were found to be much more effective in producing brands than were roofs covered with asphalt shingles, built-up roofing, or cement-asbestos shingles. Brands comprising asphalt shingles themselves were found to be rarely produced and of little ignition potential; the hazard from asphalt-shingle covered roofs was mainly from brands generated by the supporting wood decking. When an existing wood shingle roof was over-covered by another material, the production of brands was also reduced. When a non-zero wind velocity was present, the generation rate of brands was dramatically increased, by up to an order of magnitude (travel distances of brands were not examined in this study).

Full-scale house burns to quantify the generation of fire brands from burning single-family houses were conducted by Vodvarka[16]. The houses were all of ordinary wood-frame construction. He observed that generation of large amounts of brands was roughly related to the time for fire to vent through the roof—earlier venting caused greater generation. The amount of sizeable brands found was small, but brands of 37 mm width were found up to 75 m away. The limited generation is surprising, since one house had a wood shingle roof, while two more of the five test buildings had wood shingle roofs that had been over-covered by a asphaltic

roofing. In these experimental studies, Vodvarka found that fire brands were mostly generated by roof components: shingles, tar paper, or portions of burnt wood decking.

Vodvarka also discussed some accidental fires. In one bowling alley fire, brands as large as 0.3 m^2 were being lofted even though the structure did not have a wood shingle or shake roof and brands of 100 mm diameter were being carried out as far as 275 m. Fire brands from the burning building started a grass fire 240 m away and structures 120 m away appeared to be in imminent danger of fire brand ignition and had to be wetted down by the fire service. In an accidental fire of a factory building having a slate tile roof, significant brands were found to have been generated and grass ignition occurred up to about 200 m away. This fire, however, had a strong wind of 9 m s^{-1}. In a warehouse fire, tar paper brands traveled over 600 m, crossed the Ohio River, and ignited a roof fire and two awnings. In a factory fire, brands from asphaltic built-up roofing ignited roof fires 800 m away, while additional brands were found 1600 m distant. In an accompanying survey, Vodvarka obtained 250 responses from a questionnaire to fire chiefs asking to list the experiences in their jurisdictions. The most interesting results are given in Table 3.

Table 3 Material first ignited by fire brands from burning buildings, from survey by Vodvarka[16]

Material first ignited	Percent
roof covering	54
vegetation	22
interior of structure	10
trash	8
other	7

Wood roof shakes and shingles have been highly problematic for three reasons: (1) their propensity to generate fire brands is greater than that of any other common building component; (2) they are more readily ignitable than most other roofing materials; and (3) they are exceptionally well aerodynamically shaped. Because of these traits, a wildfire which starts with vegetation and then ignites houses which are roofed with non-fire-retarded wood shakes can generate a conflagration of spot fires well ahead of direct spread of the vegetation fire. Statistics from the 1961 Los Angeles conflagration showed that at a distance of 25 m away from the flame front of a vegetation fire, a roof with some FR properties was 8 times less likely to be lost than one having untreated wood shakes[17]. When compared to the preceding conflagrations in 20th century North America, it was found that the number of buildings lost in the *largest* conflagration not involving wood shakes was less than the number lost in the *average* conflagration which had involved wood shakes. It was also determined that the maximum *spotting distance* (distance at which a secondary fire is ignited by firebrands) recorded from wood shakes was 13 km (8 miles). After the 1991 Oakland Hills fire, it was estimated that each burning house having a non-FR wood shake roof ignited 10 other houses[18].

No fundamental differences exist between the firebrand capabilities of wood shakes versus shingles, nor do differences exist according to whether the cut is edge grain or cross grain, nor if redwood or cedar, nor if heartwood or not. It is difficult to treat a wood shake successfully with fire retardants so that the treatment withstands the adverse effects of water and sunlight for the life of the roof. Nonetheless, some shakes are commercially available these days which have obtained a Class B rating according to ASTM E 108[19]. Roof sprinklers are sometimes proposed for protecting readily ignitable roofs, but these may not be a reliable tool against conflagrations, since the water supply may run dry at a crucial time.

Several laboratory studies exist where the ignition potential of firebrands was examined. Waterman[20] used the Class C brand specified in the ASTM E 108 roof test (see Chapter 7). This brand is a 3 g wood piece, sized 38 ◈ 38 ◈ 20 mm, with one saw-kerf cut across each of the two large faces. The cuts were found to be an important factor in promoting the occurrence of ignition. They simulate large fissures which naturally develop in burning wood pieces. In addition, he studied 0.6 g brands measuring 19 ◈ 19 ◈ 20 mm and several other small brands. Because wind aids the ignition process, several wind conditions were explored: steady at 0.9 – 1.4 m s^{-1}; steady at 2.3 – 2.7 m s^{-1}; alternating calm/bursts at 0.9 – 1.4 m s^{-1}; and alternating calm/bursts at 2.3 – 2.7 m s^{-1}. In addition, tests were run with superimposed radiant heat fluxes of 0 to 8.4 kW m^{-2}. The study was done probabilistically, with probabilities being tabulated for each experimental condition. The results were voluminous, but the main findings were:

- With moderate wind and no imposed external irradiance, 38 mm brands were able to ignite all building materials except Class C-rated roofing and unpainted solid-wood sheathing. They were also able to ignite paper, cardboard, and heavy cloth such as canvas and burlap. Some thinner fabrics resisted ignition. Carpets (both wool and thermoplastic) and fabric/foam upholstered furniture composites typically did not ignite.
- The 19 mm brands ignited canvas, and denim, but did not ignite any construction materials. Paper and cardboard were marginally ignited, requiring a specific wind condition for ignition. Imposed radiation caused ignitions to occur that were not possible without imposed radiation.
- Splintered wood ignited more readily than solid wood.

The RH was not controlled in Waterman's study, nor were elevated ambient temperatures considered. Thus, his findings do not represent the lower limit possible for brand ignitions. Laboratory studies to adequately establish lower-limit conditions as a function of temperature and RH do not exist, but in an old Japanese study, researchers found that glowing wood brands of about 10 mm diameter sufficed to

effectively ignite flat surfaces of building materials such as solid cedar or wood shingles[21]. FRS studied the ignitability of red cedar wood shingle roofs by firebrands[22] and identified the crucial role of a small amount of radiant heat flux on the firebrand ignitability. When 4 kW m^{-2} heat flux was applied, an 0.5 g wood brand sufficed to ignite the roof and maintain flame spread. Without the radiant heat flux, a 100 g wood brand was required. The studies cited above, however, suggest that a 100 g brand would be far greater than the minimum needed, but the relative effect of radiation that was found is nonetheless instructive. Much smaller brands can suffice for ignition in *cracks and corners*, than is required for a flat surface, as discussed in Chapter 14 under *Wood*. The studies discussed in Chapter 14 did simulate high ambient temperature, low RH conditions typical during wildland fires.

IGNITION OF WILDLAND FIRES

In a 1941 study[23], a list of firebrands was put forth, ranking them in order of importance as ignitions of forest fires. Most to least important, the list was given as:
(1) broadcast slash pile burning
(2) large bonfires or burning slash piles
(3) small campfires
(4) burning matches (kitchen matches)
(5) lighted safety and book matches
(6) pipe heels
(7) locomotive sparks and glowing embers
(8) cigarettes
(9) cigars
The list was based on a qualitative review of mostly unpublished studies.

Eucalyptus trees shed strips of bark which are highly efficient as firebrands. It has been documented in Australian wildland fires[24] that spotting distances of 8 – 10 km (5 – 6 miles) are common for high-intensity eucalyptus fires and that spotting distances of 19 – 24 km (12 – 15 miles) were found. An extreme spotting distance of 30 km (18 miles) has been cited[25] in connection with eucalyptus forest fires; this required very strong winds estimated at 90 – 100 km h^{-1}. By contrast, 2 km is the largest spotting distance recorded in Australia for Monterey pine forests, since Monterey pines do not produce aerodynamically well-shaped brands. Size of brand is important in producing long-distance spotting; a brand must remain burning for upwards of 30 minutes in order to produce a spot fire 16 – 24 km (10 – 15 miles) away[26]. In a US study[27], burning California chaparral has been noted to cause ignitions up to 6.5 km (4 miles) away, while mixed-conifers forest fires up to 21 km (13 miles).

PREDICTION OF SPOTTING DISTANCES

The distance away from a main fire that a secondary fire is ignited by brands is termed the spotting distance. To predict spotting distances accurately would require detailed knowledge of:

- The physical characteristics of brands;
- Their burning behavior (including interactions between wind and pyrolysis/combustion of the brand);
- An aerodynamic theory that can predict travel trajectories of particles that change size, shape, and temperature during travel. This travel has three distinct phases which would need to be predicted: (1) lofting, (2) downwind propagation, and (3) deposition or, alternatively, burnout while still airborne.
- A theory that can predict the ignitability of various targets from brands.

Every one of these components is exceptionally difficult, but a small number of studies do exist on the general topic. The last component, a theory of ignition from firebrands, is basically non-existent, apart from the very simple theories discussed at the start of this section. Even empirical research studies are few; the available ones were summarized above or in Chapter 14 under the relevant target fuels: *Dung*, *Fabrics*, *Forest materials and vegetation*, *Paper products*, *Upholstered furniture*, and *Wood*.

An Australian equation[28] has been offered as a simple predictive model for maximum spotting distance:

$$L = r\left(4.17 - 0.033W\right) - 0.36$$

where L = average maximum spotting distance ahead of source fire (km), r = rate of forward fire spread (km h^{-1}), and W = fuel load (tons/hectare). The equation is easy to apply, but it is not clear what are the limits to its validity.

The effect of wind on combustion of airborne objects—which would be pivotal for any comprehensive fire spotting theory—has only been studied to a very limited extent. Refined fluid-mechanical theories of spotting distance begin with the work of Tarifa[29,30] in the 1960s. In a series of wind-tunnel experiments, he characterized the burning of wood particles as a function of wind velocity. As a wood particle burns in air, the consumption of the fuel is such that both the effective density and the effective diameter progressively decrease. Thus, various ways can be used to represent this particle change, but the simplest is just the ratio $m(t)/m_o$, which will be a decreasing function of time, and where m_o = initial mass. A good representation of Tarifa's data is:

$$m(t) = m_o\left[1 - \left(0.0024 + 0.00038\,u\right)t\right]$$

where u = wind speed (m s^{-1}) and t = time (s). The decrease of mass with time stops being linear when the particle stops glowing combustion. This event is velocity-dependent and, at high velocities, the brand burns up completely. But for lower velocities it can be approximated that glowing combustion stops when $m = 0.2m_o$ and after that point, the decrease in mass of the burned-out char particle proceeds more slowly. Other researchers identified that low-density brands are more likely to burn to completion than high density ones[18], but an expression is not available that usefully incorporates the original density. Tarifa collected a great deal of other information in various laboratory tests with firebrands and, on that basis, proposed a theory for spotting

distance. No scheme was provided for users to perform their own predictions, but he did perform calculations which indicated that 22 mm pine spheres have a maximum travel distance of 4.4 km before final break up. Actual spotting distances would be less than that.

Most of the time that a brand made of woody material is in the air, its burning is in a glowing, rather than flaming, mode. In still air, a brand would be able to burn in flaming mode for a substantial length of time, but experiments[24] indicate that firebrands do not flame very long when being subjected even to modest winds. At a wind speed of 4.4 m s^{-1} (10 mph), the flaming time may be 20 – 50% of its value in still air. In some tests, brands which went from flaming to glowing in a wind then re-erupted in flaming when taken out of the wind. This is due to excessive dilution of the pyrolysates being evolved from the brand by high air velocities. Ellis[31] found that eucalyptus bark, even in constant wind, sometimes tends to repeatedly switch between flaming and glowing combustion.

The brands presenting the most problems (i.e., largest spotting distances) are the ones which can generate substantial aerodynamic lift, such as shakes and eucalyptus bark strips. But these are hard to study, both experimentally and theoretically, and only a few workers have even attempted this. More common have been studies of blunt shapes, typically spheres and cylinders. Lee and Hellman[32] analyzed data on burning wood spheres and found that the sphere's radius, at any instant in time, is mainly governed by speed of the air flowing by it. They gave an expression for the radius r (m) as a function of time:

$$\left(\frac{r(t)}{r(0)}\right)^2 = 1 - 1.15\times10^{-14}\left(\frac{u\,t}{r(0)}\right)^{2.5}$$

where u = wind speed (m s^{-1}).

Working in the 1970s, Muraszew and coworkers were the most active US group endeavoring to produce a spotting distance model. Despite studying a number of aspects of the problem in great detail, their efforts did not lead to a usable model. In one study[24] they performed experiments on cylinders and flat plates and provided some expressions for their shrinkage with time under several wind conditions, but were not able to derive a general expression based on a wind speed. The examined how the density decreases with burning time and concluded that (provided wind speed is greater than 2.3 m s^{-1}) a speed-independent density decrease law holds[33]:

$$\rho(t) = \rho_o \exp\left(-t/7600D_o\right)$$

where ρ = density (kg m^{-3}), t = time (s), and D_o = initial volume/maximum cross-section area ratio (m). For brands to be carried a long distance, it is necessary that they be lofted to a significant height. They noted[33] that it is difficult to attain the needed heights from a pure convective plume and that swirl appears to be an essential component. They also developed a strategy for a comprehensive mathematical model[34,35], but the effort was not continued beyond its early stages.

Other investigators have produced models or sub-models with more extensive numerical solutions, but without any closed-form approximations or real-scale validation[36-38]. One nearly-closed-form model was developed at the US Forest Service by Albini[39] and consolidated by Chase[40]. Three options were provided: (1) 'torching tree', (2) pile burning, or (3) wind-driven fire types, and a series of equations is given for each which can solved in a spreadsheet. Equations for the third option were subsequently simplified by Morris[41]. The third option of a 'wind-driven' fire involves firebrands lofted by a *line thermal*[*]. Albini assumed that the brands are non-aerodynamic, and that the thermal is strong, that is, a temperature rise is considered which is not small compared to the ambient temperature (in degrees K). Making a number of other reasonable, but unproven, assumptions, he demonstrated[42] that the maximum lofting height h_{max} (m) is:

$$h_{\max} = 1.73\sqrt{E/P_a}$$

where E = the thermal's energy per unit length (J m^{-1}) and P_a is the ambient pressure (Pa). The horizontal distance that the brand travels until it leaves the thermal is determined by H_e, the vegetation cover height, and the wind velocity. In addition, the wind speed profile—logarithmic, power law, etc.—has a major influence. This model was not developed, nor should it be used, for highly aerodynamic brands such as wood shakes or eucalyptus bark, nor for long-distance spotting. A model which described long-distance spotting would need to include fire whirl phenomena and the representation of large-area crown fires. Albini later developed a theory and a computer program[43] for predicting the maximum distance of spot fires from brands generated by a crown fire.

While a circular plume rarely represents forest fire burning, Woycheese[18] presented a simple model for the lofting and burning of *spherical* wood brands in a circular fire plume. It predicts that the maximum particle diameter d_{max} (m) which can be lofted is:

$$d_{\max} = \frac{143\dot{Q}^{0.4}}{\rho_s}$$

where ρ_s = density of wood (kg m^{-3}) and $\dot{Q}$ = heat release rate of fire (kW). Thus, for example, if ρ_s = 500 kg m^{-3}, then the maximum diameter of a brand that can be lofted by a 50 MW fire is 22 mm, while a 3000 MW fire can loft 111

[*] A 'thermal' in meteorology is a suddenly released buoyant element. The buoyancy remains confined to a limited volume of fluid, which, as it rises, becomes detached from the source that produced it. A plume, by contrast, is generated by a sustained source of buoyancy. In a plume, the buoyant region never separates from the source. A line thermal is one which is 2-dimensional and infinitely long.

mm. Also, for particles of diameters $d > 44\dot{Q}^{0.269}\rho_s^{-0.782}$ the maximum lofting height h_{max} (m) is:

$$h_{\max} = 2.70\dot{Q}^{0.616}\rho_s^{-0.36}$$

Another, more complicated expression pertains to the lofting of small particles, but these are less likely to be the safety concern. The maximum spotting distance x_{max} (m) is:

$$x_{\max} = 2.42GU\dot{Q}^{0.452}\rho_s^{-0.42}$$

where

$$G = \frac{0.090\dot{Q}^{0.368}\rho_s^{-0.28} - 0.108\dot{Q}^{0.2}}{U} + \frac{0.987Q^{0.01}}{U^{0.05}}$$

$$\text{for } 0.23 \le U\dot{Q}^{-0.2} \le 2.32$$

and

$$G = 1$$

$$\text{for } 2.32 \le U\dot{Q}^{-0.2} \le 4.64$$

U = wind velocity (m s^{-1}). As an example, if the wind speed is 15 m s^{-1} and the fire is 1 GW (10^6 kW), then $U\dot{Q}^{-0.2} = 0.95$. Assuming ρ_s = 500 kg m^{-3}, G = 1.05 and x_{max} = 1440 m. It should be noted that, while the theory is relatively sophisticated, Woycheese did not undertake comparison with experiments. Many firebrands are flat objects, for example wood roof shakes, and cannot be approximated as spheres. Woycheese et al.[44] subsequently extended the theory to *disc-shaped* brands, although this work did not produce a closed-form expression for spotting distance.

EXHAUST PARTICLES

The exhaust from the engines of automobiles, trucks, locomotives, farm equipment, etc. can discharge burning carbonaceous particles. These have been known to cause ignitions of vegetation and other combustibles. Trains are a particular likely source of ignitions since not only can firebrands be ejected, but the motion of a train creates a local wind that can help a smoldering fire transition to flaming[48]. In an early study, Fairbank and Bainer[45] found that, in extreme cases, particles as large as 14 mm by 33 mm have been ejected from engines. They first performed laboratory tests on the particles themselves, and found AIT values of 540 – 550ºC for 1 g samples containing particles larger than 0.6 mm and 475ºC for smaller particles. Then, in field tests, they designed an ingenious transportable furnace able to expel hot particles onto test vegetation. The particles flamed for only a short time, then were ejected while glowing. A collection comprising 2 g of particles was ejected in each ejection, irrespective of size. A summary of the results is given in Table 4 and Table 5. For the larger particle sizes, the probability values given in Table 4 may be slightly too low, since the authors only tallied whether or not a test caused a fire and did not further itemize if more than one target location was ignited in any particular test; for the smaller sizes where ignition was a rare event, this factor would not come into play. The actual furnace temperatures used for the tests reported in Table 4 were varied to suit the ignitability characteristics of the type of vegetation being ignited. The largest fraction of the runs were conducted at

Table 4 The effect of particle size on the probability of ignition

Size (mm)	Avg. mass (mg)	Probability of ignition (%)
5.6 – 9.4	50	0.75
4.3 – 4.7	20	0.3
2.3 – 2.4	2.0	0.03
0.6 – 1.2	0.5	0.003
< 0.6	0.01	7×10^{-5}

Table 5 Effect of RH on the furnace temperature to which 4.3 – 4.7 mm particles needed to be heated in order to ignite vegetation

RH (%)	Minimum temp. (ºC)
10 – 29	700
30 – 39	925
40 – 50	1040

750 – 1000ºC, but for some trials temperatures as low as 650 or as high as 1250ºC were used.

Fires were started at up to 9 m away from the test furnace discharge, although glowing particles were visible as far as 18 m away. The authors also conducted experiments where burning carbon particles were deposited on cotton flannel cloth. In the worst cases, holes were burned through the cloth, but actual ignition of the cloth did not occur. In these experiments, the authors learned that the amount of scorching was dependent not only on the temperature and the size of the particles, but also on the type of carbonaceous material. Cotton batting, however, was readily ignited when held 0.5 m behind an exhaust pipe.

Maxwell et al.[46,47] examined exhaust particles from diesel engines as a potential ignition source for wildland. They experimentally generated exhaust particles showing, in some cases, flaming combustion for over 40 s and glowing combustion for over a minute. Temperatures of 400 – 450ºC had to be attained for particles to ignite in a glowing mode. In tests using 1.5 – 2.0 mm particles, 12 out of 186 trials produced glowing or smoldering ignitions of cheat grass (*Bromus tectorum*), while 3 trials resulted in flaming ignitions. The particles averaged about 2 mg in mass, but neither the temperature to which the particles were heated nor the RH of the target fuel were specified. The particles used showed a flaming period of up to 40 s and a glowing time of up to 60 s. In scanning electron microscope studies, they found that the particles were extremely irregular and 'spiky,' thus they doubted that a hot-sphere theory would be adequate. The particles contained a variety of elements and compounds, but CaO tended to be most prevalent mineral constituent. They also found a substantial organic liquid component (up to 2/3 of the total mass) which was determined to be motor oil. The authors concluded that to avoid wildland ignitions, a distance of at least 6 m was needed

from the exhaust to the vegetation. They also observed a notebook was accidentally ignited by 3 mm particles at more than 5 m from the exhaust of a test engine; the ignition, however, was not sustained. Notwithstanding the laboratory tests, Ford[48] deprecated the possibility of extremely small particles being able to start forest fires and pointed out that, in his experience at the California Dept. of Forestry, the minimum particle size found to be an actual cause of forest fires was 3 mm.

The US Forest Service operates a test station in San Dimas, California for testing of spark arresters on engines. They conduct the tests according to SAE test procedures[49-52] and make the results available in a two-volume book of approved-equipment listings[53,54].

WELDING SPATTER

Welding spatter is a well-known source of ignition. The Welding Handbook[55] advises that: "Many fires are started by sparks, which can travel horizontally up to 35 feet from their source and fall much greater distances. Sparks can pass through or lodge in cracks, holes, or other small openings in floors and walls. Materials most commonly ignited are combustible floors, roofs, partitions, and building contents including trash, wood, paper, textiles, plastics, chemicals and flammable liquids and gases. Outside, the most common combustibles are dry grass and brush."

The most famous fire loss caused by welding spatter was the General Motors factory in Livonia, Michigan which burned down in 1952[56]. In that loss, small hot particles from a cutting torch ignited a tray holding a rust-inhibiting liquid of rather low flash point (36.5ºC open cup).

The size of particles ejected from arc welding operations varies widely. In one Japanese study[57], most of the particles were under 0.1 mm, and very few over 0.5 mm. But in another study[58], where a thermographic camera was used to examine the size/temperature/distance relationship for welding spatter, the bulk of the particles were found to be in the range of 1 – 3 mm, although a number of sub-0.5 mm particles were found and two particles (out of hundreds) were found in the range of 6 –7 mm. These differences reflect differences in the collection/identification techniques used and the true particle size distribution presumably includes both the tiny particles and the large ones. Particle temperatures of about 1850ºC were found very near the welding rod. At 1.0 m below, particles were at approximately 1592ºC. From the 1-m location to the lowest drop investigated, 2.8 m, the temperatures decreased very slowly, being an average of 1572ºC at the 2.8-m location. A simple model of convective cooling would indicate that smaller particles cool faster than large ones, but in their experiments the authors did not find any significant effect of particle size on the temperature. Tanaka[59] showed that particle sizes are much greater for oxy-acetylene cutting operations than for arc welding. His experimental data for flame-cutting slag showed no effect of drop distance on measured temperature, with a constant temperature of 2100ºC being obtained. For slag produced by arc welding, he found a slowly decreasing temperature with fall distance. A temperature of 3500ºC was found at the welding location, dropping to 2700ºC in 0.5 m and to 2200ºC in 5 m.

The size of welding spatter particles does not depend on the size of welding rod used[57]. Hagiwara et al.[60] found that the number of particles produced increases when welding current is increased, but the size distribution does not vary appreciably. Most particles in their study were below 1.0 mm, but a small fraction of 3.0 mm particles was found. The amount of spatter produced does vary with the type of coating used. Deep penetrating rods such as the AWS XX11 series spatter more that the filled rods like a XX24 due to the arc action and the thickness of the slag.

The propensity of welding spatter to ignite various materials was tested by Hagimoto et al.[57], as shown in Table 6. They also determined that many particles fractured into pieces if they landed on a concrete or wood floor.

Table 6 Ignitability of various fuels from welding spatter

Target fuel	Particle dia. (mm)	Ignition time (s)
acrylic batting	1.1	< 1
cardboard, corrugated	2.5	7 – 8
cotton cloth	3.1	5 – 6
cotton wool	0.9	< 1
ethanol	1.1	< 1
gasoline	1.4	< 1
kerosene	1.5	NI
kerosene-soaked cloth	1.3	< 1
newspaper	2.5	4 – 5
oil, light	2.0	NI
oil, light, soaked in cloth	1.9	< 1
polyurethane foam	0.9	< 1
polystyrene foam	1.3	3 – 4
sawdust	1.5	< 1*
wood shavings	1.9	4 – 5

* smoldered after 4 – 5 s
NI – no ignition

Tanaka[59] measured the propensity of welding slag to ignite sawdust, simulated by using steel balls of different diameters. He found that 550ºC was the minimum temperature of a steel ball needed for ignition, but that moisture played a major role when specimens had non-zero moisture content. From the experiments (which spanned a particle size range of 3 – 11 mm), a general relation was found:

$$MC = aD + b$$
$$a = 16.46 \log T - 45.06$$
$$b = 5.02 \log T - 13.71$$

where MC = maximum moisture content (%) for ignition, D = particle diameter (mm), and T = particle temperature (ºC). This relation is shown in Figure 2; it should not be used

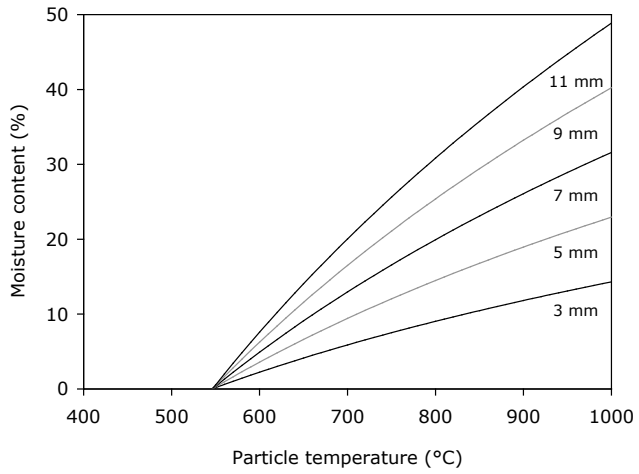

Figure 2 Relation between moisture of sawdust and size and temperature of spherical steel particle needed for ignition

below MC = 9%, which was Tanaka's lowest experimental value.

Okegawa et al.[61] examined the distances to which spatter from oxy-acetylene cutting and electric arc welding operations can travel laterally. When cutting operations were conducted at heights up to about 12 m, the lateral travel distance (including the bounce distance after the first collision with floor) was roughly similar to the welding height, but for larger heights, the travel distances were less than the welding height. In the presence of wind up to 5 m s^{-1}, peak travel distances increased by about 1/3. Cutting greater thicknesses of metal tended to propel particles to somewhat greater distances. The authors then created flammable gas atmospheres and found that arc welding and gas cutting operations readily ignited gasoline, methanol, benzene, and propylene oxide atmospheres, although particle sizes were not measured in the experiment. Particle sizes were measured by Kinoshita et al.[62], who found that a minimum diameter of 0.8 mm was needed for arc welding slag particles to ignite toluene/air mixtures, while 2.0 mm was needed for acetone/air mixtures. In another study[60], it was found that 0.9 – 1.4 mm particles could readily ignite a number of organic vapor atmospheres, but the minimum size needed was not explored.

BRANDS EJECTED FROM FIREPLACE

A British study[63] examined the potential for burning particles from a fireplace to set alight combustible materials. The investigators used particles of coal, which they ignited with a Bunsen burner and then dropped onto various materials in a simulated crevice geometry. A small, unspecified, air flow was used. When testing cotton wool, they found that even the smallest brand they could generate, 0.005 g (about 2 mm diameter) inevitably caused ignition. This is not surprising, since when the material is of low density, fluffy, or finely divided, ignition becomes very easy. This was the historical principle of the tinder box for starting fires using sparks from striking steel against flint. The tinder itself could be any fluffy, low-density combustible material. They also found that a tight-woven cotton rug (1200 g m^{-2}) could not be ignited with the largest brand used, 12 mm diameter. For other brands, the results are given in Table 7. The scrim was more easily ignitable than its surface weight would suggest because it had a brushed-nap finish.

Table 7 Probabilities of ignition of materials from fireplace brands

Material	Brand mass (g) needed for a given ignition probability	
	P = 50%	P = 10%
viscose rayon net (18 g m^{-2})	0.045	0.028
newsprint, layers (55 g m^{-2})	0.065	0.04
cotton (120 g m^{-2})	0.15	0.08
hessian scrim (220 g m^{-2})	0.11	0.04

In practical cases, the question will generally be not whether the brand can ignite a lightweight or fluffy material, but whether the ignition will be carried on to a further substance of heavier density. For example, fireplace brands may ignite and burn up a rug fringe, without the fire propagating to the rug itself.

FRICTION AND MECHANICAL SPARKS

GENERAL PRINCIPLES

Heat generated from friction can serve as an ignition source. Friction is also the cause of small luminous objects being emitted (mechanical sparks). There is a significant overlap between friction and impact, and impact involving friction is covered in the present Section. 'Pure' impact, without friction, is considered in a later Section. The ignition of explosives from friction is treated in Chapter 10.

Most studies on frictional ignition have dealt with ignition of combustibles in the form of flammable gas atmospheres or dust clouds. Because of the high temperatures that can be created, bulk solids can also be ignited, but few studies of those exist. In the 19th century, a common frictional ignition source used to be overheated bearings on rail cars. During the 20th century, frictional ignition of cotton within cotton gins was studied to a limited extent[64].

When two solids are placed together, they do not make uniform contact, since surfaces are always uneven on a microscale. The points of contact are limited and occur where the highest protuberances are found. If the solids are now rubbed against each other, heating occurs primarily at the high spots. The temperature rise is surprisingly high and is, in general, only limited by the melting point temperature of the lower-melting solid. This limit does not apply if one of the materials (e.g., many metals) can be easily oxidized and the oxidation reaction is highly exothermic[65]. Perhaps unexpectedly, a liquid applied between the surfaces does not

prevent the high temperatures. If sufficient properties of the system (surface condition, thermal conductivity, velocity, etc.) are known, then theories exist[66] which allow the interfacial temperature to be calculated. These data will rarely be available, and even if the temperature of the asperities could be calculated, this does not suffice to determine the ignition potential. Thus, the problem is usually approached empirically rather than theoretically. The lifetime of the hot spots is only a few milliseconds or less, thus ignitions directly from the surface hot spot are not able to ignite most gas mixtures. Ignitions become more likely when heated spots break off the surface and become 'mechanical sparks.'

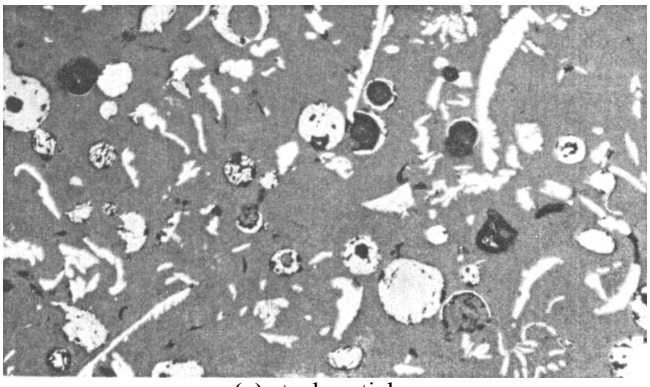
Powell[70] suggests that for many substances it is a good assumption to take the friction coefficient μ as ≈ 0.5. The friction energy developed can then be evaluated as 0.5 × force × rubbing speed. Benz and Stoltzfus[67] considered that an ignition criterion can be expressed as pressure × velocity, or power per unit area (W m^{-2}). Their results obtained in high-pressure, gaseous O_2 environments are discussed in Chapter 13. To be an accurate expression of power delivered in frictional heating, the expression should also contain the friction coefficient. However, Benz and Stoltzfus conducted limited studies to determine friction coefficients and found that the value varied greatly with temperature and, consequently, with interface heating conditions. An ASTM publication[68] has compiled relative data on the pressure × velocity product needed for ignition of a number metal/metal combinations in a high-pressure, pure-oxygen atmosphere.

Billinge[69] studied 106 UK accidents involving ignitions of gases, vapors, or dust clouds due to friction and impact and, on that basis, divided the accidents into three categories:

(1) low energy; can be caused by hand tools. Typical energy: 10 J.
(2) medium energy; can be caused by powered hand tools. Typical energy: 1 kJ.
(3) high energy; can be caused by major collisions on land or sea. Typical energy: over 1 MJ.

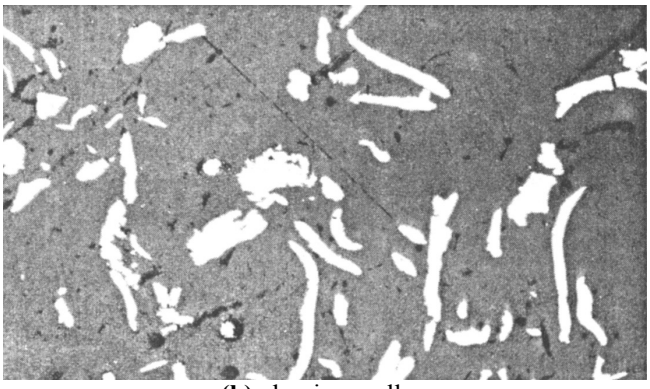
Gasoline vapors were reported to have ignited from hammers, boot nails against a concrete floor, metal tools dropped to the floor, and various more energetic sources; Billinge, however, expresses some doubts as to the accuracy of investigation for the lowest-energy of these causes. A screwdriver punching through a metal lid of a can of floor polish was able to cause a flammable vapor ignition. Propane was ignited by a metal wrench against a pipe joint. Ethylene was ignited by unscrewing a valve from a pipe. Hydrogen and carbon disulfide have been readily ignited from low energy actions. Methanol has been ignited from a rubber belt rubbing against a copper tube. Solvents have been ignited by friction between cellulose film and a roller. Grain dust proved readily ignitable from low-energy contact of tramp metal against pipes and hoppers. Flour dust has also ignited from causes where no impact component was involved—overheated motors and overheated pulleys. Corn and sugar dusts have ignited from similar rubbing incidents. Ammonium perchlorate and aluminum powder both have ignited from scraping hand tools. Substances involved in UK case histories studied by Powell[70] and Billinge are summarized in Table 8. From this orientational listing it should not be inferred that every substance can be ignited by a low-energy impact of every moving object listed against every target; detailed case histories should be consulted for specifics.

Table 8 UK case histories on ignitions caused by low-energy friction/impact activities



Object moved	Object struck	Substance ignited
aluminum hand tool boot or shoe nails brass rod metal pipe connector steel hand tool various heavy metal objects moved	brickwork caked material concrete steel	ammonium perchlorate carbon disulfide cellulose lacquer denatured alcohol diazonium salt ethylene gasoline grain dust hydrogen LPG paint thinner propane thermite town gas

Mechanical sparks are small incandescent particles (typically, 0.1 mm) created by impact forces or friction or grinding. Some grinding sparks photographed by Blickensderfer et al.[71] are shown in Figure 3. Friction between two objects raises the temperature at the point of contact. Since contact is not smooth, high forces produce high temperatures and can lead to hot fragments of material breaking off. In the case of impact, the kinetic energy is converted to heat energy and the process is otherwise identical. If the material is oxidizable, once a surface is opened up by breaking off material, heating can also occur due to oxidation at the virgin surface, but this relative contribution to heating has not been separately quantified.



When sparks are generated by impact, it is not generally possible to relate the ignition probability to the potential energy imparted into the colliding solids. The vast bulk of the energy goes into causing elastic and plastic deformations in the solids, which do not contribute to the possibility of igniting a gas or dust cloud. Only a tiny fraction of the energy is released in the form of incandescent particles that may be incendive.

The propensity of materials to cause incendive sparks is related to the *melting point* of the material which has the lowest melting point of the rubbing materials. Since the contact area temperature cannot exceed this value, lower melting point materials tend to be safer.

The metals most likely to cause sizeable sparks upon impact or friction are cerium, zirconium, titanium, and uranium; similar tendencies are predicted in some other elements—samarium, thorium, yttrium, etc.—but these are only rarely used[72]. Depleted uranium has been added to military projectiles specifically to produce sparking[73]. The rare-earth elements cerium, lanthanum, neodymium, and praseodymium are used in making *misch metal*, which is used for cigarette lighter flints, where their sparking propensity is deliberately utilized.

(a) steel particles

(b) aluminum alloy

Figure 3 Grinding particles (100× magnification) from two metal types; particles were mounted in epoxy, then ground and polished to show their cross-sections

Temperatures of certain sparks have been measured optically (Table 9). These values can be misleading in actual applications, since the environment of interest is a fuel/air mixture, not air alone. Studies have indicated that the temperature of mechanical sparks is lower in fuel/air mixtures than in pure air. For example, steel sparks produced by a grinding wheel that were measured at 1850ºC in air, had a temperature of 1750ºC in a methane/air mixture, and less than 1500ºC in mixtures of air with town gas, hydrogen or acetylene[70]. In a nitrogen atmosphere, under the most extreme conditions, a temperature of about 1400ºC can be attained by the friction mechanism, but generally particles may not be visible at all[74] or will only reach a dull-red temperature[71].

Increasing contact pressure, up to a certain point, increases the temperature of the spark. Sparks produced with low contact pressures normally neither reach their melting point nor burn. In most cases, it would appear that actual combustion of the flying particle is taking place and not merely incandescence due to high temperatures. For the same pair of materials, the temperature of grinding-wheel sparks is lower than of mechanical-impact sparks, but the incendivity of grinding-wheel sparks is generally higher than that of impact sparks; presumably this is due to the higher abundance of sparks in a grinding operation.

Table 9 Temperatures of mechanical sparks created in air

Striking object	Target material	Temp. (ºC)	Ref.
mild steel	rusty steel	1730 – 2380	75
mild steel	concrete	2530 – 2730	75
mild steel	rotating grinding wheel	1600 – 1730	75
mild steel	rotating grinding wheel	1730 – 2130	78
alloy steel	rusty steel	1530 – 1980	75
titanium	rusty steel	2030 – 2900	75
titanium	NA	2100 – 2400	76
pyrophor bar	NA	2400 – 2700	76
magnesium	NA	3700	76

Apart from direct heating due to friction, an additional effect can occur with certain materials. Substances which can undergo a local oxidation sustain additional heating and can build up to much higher temperatures. The most common form of this is a *thermite* reaction, occurring between rust (iron oxide) and aluminum. The thermite reaction is discussed in Chapter 10. A thermite-type spark is visually distinguished by a white flash, rather than a small, darker-colored spark. It has been shown that thermite caused sparks can ignite many flammable dust mixtures, not only gases[77].

The *size distribution* of particles generated by rubbing steel against a ceramic grinding wheel[78] has been found to be 40 – 140 μm, with most particles being in the 60 – 100 μm range.

IGNITION OF FLAMMABLE GAS ATMOSPHERES

As a potential ignition problem, mechanical sparks have been recognized for a long time in coal mines. The mines commonly have pockets of methane and other flammable gases which can be ignited if a suitable ignition source arises. Hand picks, coal mining machinery, and rock-against-rock are all causes that have led to mine explosions. The possibility of such ignitions was already known in connection with some early coal mine machines in 1786, although the first mine explosion definitely attributed to spark ignition did not occur until 1896[79]. In the 18th century, it was common in some mines to use a 'Spedding steel mill' for lighting purposes[80]. This was a rotating steel wheel against which a piece of flintstone rubbed, creating a shower of

Figure 4 A Spedding steel mill of the 18th century

bright, long sparks (Figure 4). Accusations were made that such sparks can ignite methane/air mixtures in mines, but tests much later[81] showed that this was not possible.

Coal mine explosions from sparks have been relatively rare, since steel-against-rock sparks are only marginally incendive for methane/air mixtures. During the 1920s it was already identified that friction of quartzitic or micaceous sandstone against other rocks or against metal was typically needed for ignition. Since quartz is known for its piezoelectric characteristics, theories have been proposed relating the ignition from quartz surfaces to electrical effects, but these have not won much acceptance. Later studies[82,83] identified at least a dozen factors which must be considered in determining whether a mechanical spark will be incendive towards a flammable gas or dust cloud atmosphere:

(1) type of fuel
(2) composition of the gas or dust mixture
(3) anvil material
(4) striker material
(5) geometry and roughness of the impacting surfaces.
(6) angle of contact between striker and anvil
(7) frequency of striking
(8) length of striking contact
(9) pressure applied at the interface
(10) energy expended at the point of striking
(11) direction of travel of sparks
(12) nature of the spark: size, temperature, and possibility of strong exothermicity.

Tools cutting into harder rock are more likely to produce incendive sparks than when cutting into softer rock. Striking rock bearing iron pyrites produces dull red particles that start to rapidly oxidize in air and become a brilliant shower of yellow sparks. Despite the copious amount of sparks produced, it was found impossible to ignite methane/air mixtures with such sparks, apparently because they were too short-lived[84]. Negative results were also obtained for ironstone. Furthermore, it was found that when ignition of methane/air atmospheres occurs, upon rare types of vigorous, concerted blows given to sandstone rock, a shower of sparks is not emitted, rather, there is seen only a localized yellow flash at area of impact.

The susceptibility of gases to mechanical-spark ignitions varies greatly with the gas. Mixtures containing a significant component of hydrogen are relatively easily ignitable, whereas methane/air mixtures less easily. A methane concentration of 6.4 – 7% leads to the most incendive conditions[83]; this is leaner than the stoichiometric value of 9.5%. For pentane, the most ignitable concentration is 3.2%, which is richer than the stoichiometric value of 2.6%. For hydrogen, the most easily ignitable concentrations are 10 – 20%, with there being no real peak; the stoichiometric concentration is 30%.

On the order of 50 J impact energy is required to ignite optimum-concentration methane mixtures from a magnesium alloy weight falling onto rusty steel at the optimum angle[83]. By contrast, steel-upon-rusty-steel caused no methane ignitions even at 1000 J energy; about 400 J was found sufficient to ignite hydrogen atmospheres.

Even 'non-sparking' tools made from materials such as copper-beryllium can ignite various flammable atmospheres, if struck against a surface where aluminum particles are lodged on rusty steel. It is has been shown, however, that for ignition to occur, particles of aluminum must first be lodged onto a rusty steel substrate, then struck with another object; striking rusty steel with an aluminum tool is *not* sufficient[75]. This is because a hard collision is required and aluminum, being a soft metal, easily deforms. Striking aluminum-containing paints may be lead to ignition, but only if the surface is preheated and only then under certain circumstances. In one series of tests, such paints were used to coat rusty iron surfaces, then struck with a steel rod[85]. It was found that, with certain paints, bright sparks could be produced, but none were incendive in a town gas mixture. When the painted surface was heated, the brightness of sparks generally increased, but still only non-incendive results were obtained. But other studies showed that most tools, even rubber hammers, struck against a preheated (ca. 175ºC) steel plate painted with aluminum paint were able to ignite various gas mixtures[105].

The current understanding is that the ignition of methane/air mixtures by a frictional contact of two surfaces requires a surprisingly high temperature of 1200 – 1250ºC to be attained[79]. This explains the propensity of quartzitic rocks for mechanical-spark ignitions, since they are one of the few rock types which do not disintegrate at this temperature[86]. Also, it explains why ignitions are not seen against brass (T_{mp} 900ºC) and not readily with copper (T_{mp} 1085ºC), but

more readily with steel (T_{mp} 1450ºC). Such high temperatures needed for ignition also indicate that friction-generated sparking is not very incendive. On the basis of high-speed photography studies, Blickensderfer[87] documented that the ignition normally arises from the hot streak caused on the rock, rather than from the more visible shower of sparks emanating. He was able to model the ignition process by representing the details of the surface heating process, then evaluating the consequences according to the gas ignition requirements of heated area vs. temperature. In some carefully arranged experiments[88], the shower of sparks was also shown independently to be incendive, but this is a moot point, since incendive sparks were only produced from rocks where the hot surface was already capable of causing ignition

Rae[86] conducted experiments where he rubbed a quartz slider against a quartz wheel at various speeds and pressures to determine the potential to ignite a methane/air atmosphere. His results showed that ignition corresponded to $\mu \times$ mass $\times$ rubbing speed = 0.67 $\times$ 114 kg m^{-1} s^{-1}, where 0.67 is the coefficient of friction. This can be converted to power by noting that 1 N = 9.8 kg m s^{-2}, so that $\mu \times$ force $\times$ rubbing speed = 76.4 kg m^{-1} s^{-1} $\times$ (9.8 kg m s^{-2}) = 749 kg m^2 s^{-3}. But 1 kg m^2 s^{-3} = 1 W, therefore the power needed for ignition was 749 W. He also noted that the melting point of pure quartz is 1700ºC, but that quartzitic rock has a melting point around 1250ºC. Some synthetic materials commonly used as grindstones include silicon carbide (carborundum) and aluminum oxide (corundum). These can withstand higher temperatures than can quartzitic rocks, and Rae also obtained ignition data for them. The results were similar for carborundum as for quartzitic rocks, but corundum required about 2200 W for ignition. In earlier tests at the same laboratory[88], it was found that 269 W sufficed for ignition in one case when using 'Derbyshire grit' sandstone, although 400 W or higher was a more typical outcome. These results are all rather approximate, since the coefficient of friction is not a material constant but depends on the actual conditions at the interface[89].

Later in the same laboratories, Cutler and Brearley[90] used a steel cube held against a rotating steel disc as the ignition machine. They considered that the coefficient of friction varied over time, so they presented their results simply as the minimum load, in newtons, needed for ignition at two different rubbing speeds (Table 10). In all cases, stoichiometric fuel/air mixtures were used and test duration was 4 min. The authors point out that they consider their results for diethyl ether to be anomalous, since, under most conditions, this is a very easily ignitable vapor. According to constant-power scaling, the required load at 20 m s^{-1} should be ¼ of that at 5 m s^{-1}. The results, however, do not follow the this dependence. It has also been suggested[71] that ignition propensity should be proportional to (pressure)^2×(speed)^4, but again this apparently holds only in very limited experiments. Thus, in general, it can be concluded that increasing the pressure or the rubbing speed is likely to result in more incendive conditions, but quantitative predictions are likely to be possible only within narrowly-defined experiments.

Table 10 Load required for ignition of fuel/air mixtures by using a rotary rubbing machine

Fuel gas	Min. load for ignition (N)	
	At 5 m s^{-1}	At 20 m s^{-1}
hydrogen	120	<120
propylene oxide	250	500
ethylene	250	600
methanol	850	625
diethyl ether	900	600
propane	1100	800
acetone	1200	500

Many experiments on grinding operations have been reported[91], where it was found that a minimum velocity is needed for the sparks generated to be incendive to gas/air mixtures. Incendive sparks from steel at less than 1 m s^{-1} are considered not possible[92]. But it does not appear that the minimum velocities as measured have much absolute significance—the details of the experimental rig are of paramount importance. A study by the Bureau of Mines[93] indicates that, using conventional US mining machines, it is not feasible to reduce velocities sufficiently to appreciably decrease the probability of ignition simply by this strategy.

The effect of angle on the incendivity of an impact was studied by Titman[83,94] who found that the worst case is around 50° (Figure 5). For worst-case conditions involving an aluminum smear on a steel plate, impact/sliding velocities of about 2 – 3 m s^{-1} are necessary to ignite a methane/air atmosphere[95].

For a specified particle temperature, a minimum mass of particle is required to ignite a given fuel/air mixture. Bowd-

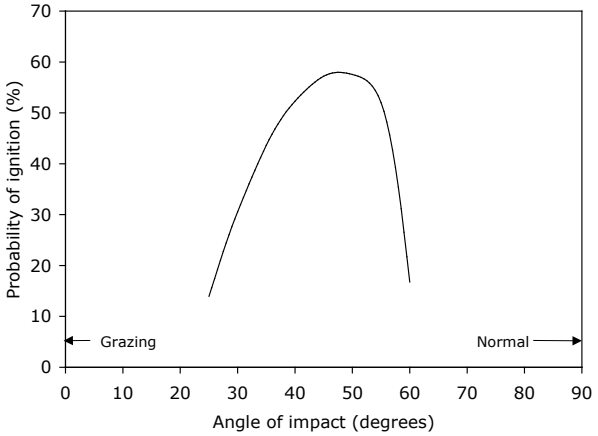


Figure 5 Effect of impact angle on the probability of igniting methane/mixtures by an aluminum-alloy weight falling upon a steel plate

en and Lewis[65] provided illustrative data on some readily oxidizable metals (Table 11). The results were obtained by heating the particles on a surface maintained at 1100ºC, and then permitting them to ignite and reach their combustion temperature. They point out that the mass required is inversely related to the heat of combustion, although the relation is not particularly linear. Under the same conditions, beryllium, carbon, iron, spongy platinum and black platinum were not able to cause ignitions at all. The data are presented at 6.8%, because they found that, in their experiments, this was the most-readily ignitable concentration. In a related study[96] where methane concentration was varied, Bowden found that most of the metals showed a marked increase in mass needed as methane concentrations moved farther away from 6.8%. But for aluminum, magnesium, and pyrophor bar, no change in the mass needed was found over the entire range explored, 5 to 9%.

Table 11 Minimum mass of a burning metal particle needed for the ignition of 6.8% methane in air

Metal	Min. mass (µg)	Heat of comb. (MJ kg^{-1})
aluminum	< 1	31.06
magnesium	< 1*	24.73
titanium	4	19.6
zirconium	6	12.03
pyrophor bar	18	--
cerium	85	7.77
thorium	108	5.29

* In SMRE tests[97], a 0.5 µg magnesium particle of 80 µm diameter was sufficient for ignition.

Bowden also noted that the order of incendivity shown above was *not* duplicated in experiments where metals were pressed against a rotating wheel. In fact, he was unable to cause ignition with aluminum and magnesium at all under these conditions. This was attributed to the fact that these soft metals smeared, rather than launching broken off particles. Titanium did launch small particles, but the particles themselves failed to ignite. Roughly, he concluded that the incendivity of metals in a grinding situation is proportional to their brittleness, not their heat of combustion.

It has been found that, when struck by steel tools, pyrite-bearing rocks readily produce a brilliant shower of sparks, but that the sparks are much less incendive than ones from sandstone rocks. While in experiments, pyrites have required heating to only 200 – 300ºC for oxidation of powdered material to proceed rapidly enough so that flaming of the sulfur component occurs, ignitions in practice have been very rare. The actual ignition mechanism, in contrast to other steel/rock impacts, was found to be the generation of a significant cloud of pyrite dust in the air, a small amount of particles not being able to ignite a methane/air mixture[98]. An experimental study where 30,000 strikes of steel against pyrite were made produced copious sparks but no ignition of 7% methane/air atmospheres[79]. Despite the lesser likelihood, disastrous explosions nonetheless have occurred due to mining tools striking pyrite deposits.

If rock particles are sucked into a ventilating fan (e.g., in a coal mine) in the presence of a flammable atmosphere, an incendive spark may be emitted. The effect of particle size on spark-producing tendencies was studied[99]. It was found that the most powerful sparks were emitted from particles of 3 – 6 mm size. Smaller sparks were emitted from particles of 1 – 3 mm and 6 – 10 mm, with no sparks for particles smaller than 1 mm or larger than 10 mm. The size dependence will vary somewhat with test conditions, nonetheless, the results can be viewed as at least rough guidance.

A coal mine explosion took place when a magnesium alloy drill fell onto a steel surface. Subsequent laboratory testing[100] showed that an explosion in a methane/air atmosphere requires as short a drop as 0.5 m of a 16 kg machine. The sparks seen comprised flaming magnesium particles, not just glowing. A repeat of the tests by dropping a steel machine onto steel plates caused sparks, but no ignitions for drop heights up to 2.3 m. Further testing[101] showed that the steel plate must be rusty, with no ignitions found otherwise. The tests also showed that rust acts due to a thermite mechanism and not due to its rough or abrasive qualities. Other studies[102] showed that ignition can be obtained with clean steel at very high impact velocities (greater than 250 m s^{-1}). Explosions were also found possible by dropping magnesium weights onto brass, but this was fairly difficult and generally required either two successive impacts or dirty surfaces. The reactions involved in dirty surfaces were not explored in detail, but might have been of the thermite type. The Bureau of Mines investigated in some detail a mine explosion triggered by breaking roof bolts and collapse of roof[103]. Laboratory studies, however, were unable to reproduce the conditions needed for ignition by impact involving the particular type of rock and grade of steel.

An old study[104] groups elements into two groups with regards to their potential for incendive sparks:

High sparking potential

calcium, carbon, cerium, copper, iron, nickel, potassium

Low sparking potential

aluminum, beryllium, cadmium, gold, lead, magnesium, palladium, platinum, silver, tin, zinc.

Aluminum, copper, and magnesium do not produce sparks from grinding operations. However, aluminum produces sparks in impacts and magnesium is especially problematic in this regard[105]. Carbon steel against a carborundum grinding wheel produces sparks which ignite carbon disulfide; however, most other substances, including diethyl ether, methane, acetone, ethanol, and benzene are not ignited. The sparking propensity of mild steel and high-carbon steel is the same. If aluminum foil is placed on rusty steel and struck with a hard object, flammable gas mixtures can be ignited much as from aluminum smears[106].

Table 12 Probabilities of ignition for impacts of various materials against quartzitic sandstone

Moving material	Impact energy (J)	Percent ignitions			
		15% hydrogen /air	4% ethylene /air	3% propane /air	7% methane /air

lamp glass	117	47	5.5	2.8	0
bottle glass	117	39	0.72		

Desy et al.[107] constructed an impact testing machine whereby a head of a chosen material hit a blow onto a target plate made of rusted steel. The angle of contact was at 5º off-normal and the contact velocity was 48 m s^{-1}. The frictional energy dissipated in the contact tended to vary from run to run, due to wear on the head, but was roughly 20 – 35 J. All aluminum alloy heads showed a finite probability of ignition of a 6.4% methane/air mixture, although harder alloys generally exhibited a higher probability than softer ones. No ignitions occurred using structural steel, stainless steel, brass, or fiberglass heads. Aluminum heads were also unable to cause ignition when an aluminum target was substituted for the rusted steel.

Higher machine speed and blunter tool surface lead to a higher probability of ignition. This is due to larger heated areas that are created at higher velocities, not due to raising of peak temperatures. Various other practical matters pertaining to the ignition of methane atmospheres by coal-mining tools have been reviewed by Trueman[108]. Much empirical research has gone on in the coal mining field to develop tools and techniques which reduce the ignition probability. The design of the tool surfaces and the optimized incorporation of water sprays are two salient prevention strategies.

Ignition of flammable gas atmospheres by mechanical impact sparks was studied by Powell[109]. He constructed a rig for simulating the impact of boot nails and other impacting objects onto quartzitic sandstone (Table 12) and steel targets (Table 13). The mixture fractions were selected to correspond to near-worst ignitability conditions. No ignitions were observed against steel targets with methane and propane mixtures. In some cases up to 500 trials were conducted, but there is a lot of randomness evident in the results. In all cases, however, it was seen that the incendivity of the mixtures ranked as:

hydrogen > *ethylene* > *propane* > *methane.*

Magnesium/aluminum alloys become significant more hazardous as a means of producing incendive sparks when the fraction of magnesium rises in the alloy[83], as shown in Figure 6. The hazard stays roughly constant once the composition exceeds about 11% Mg.

Cerium is particularly prone to producing incendive sparks, and this is the reason that cerium alloys are used as cigarette-lighter 'flints' or 'pyrophor bars.' These typically contain 38% cerium and the remainder being rare earth elements. Very small pyrophor sparks are able to ignite methane/air mixtures, with data from Rae[110] being shown in Figure 7. Note that microgram weights suffice and that the leanest mixtures are the easiest to ignite. The temperature of a burning particle was estimated as about 2500ºC. Burning duration of particles in the range 30 – 80 μg was found to be ca. 20 ms, but surprisingly no systematic effect of mass

Table 13 Probabilities of ignition for impacts of various materials against mild, rusty steel

Moving material	Impact energy (J)	Percent ignitions	
		15% hydrogen/air	4% ethylene/air
tool steel	117		90
silver steel	117		0
mild steel	117	42	13
spring steel	117		25
aluminum bronze	117		0
copper-beryllium	117		0

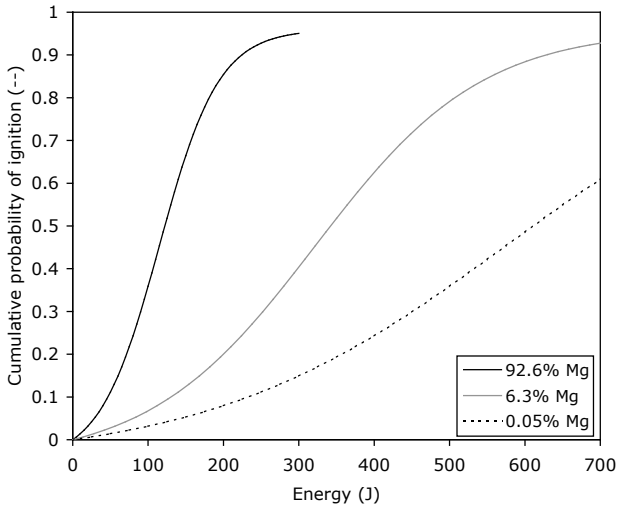

Figure 6 Probability of ignition of a 6.4% methane/air atmosphere by a glancing blow of light alloys on rusty steel

was seen. For other materials tested, ignition of a 5.6% methane mixture with magnesium particles required about 1 μg, while iron pyrite required about 1000 μg (1 mg).

The potential of sparks to ignite flammable gas mixtures has generally been found to increase with increasing *diameter* of the particles. The study of Homan and Sirignano[111] was discussed in Chapter 4. They found that for aluminum particles, a minimum diameter of 0.02 mm was needed for methane/air mixtures. For steel sparks it was found that particles as large as 0.2 mm could be generated and that these were the most incendive[79]. The most incendive of particles tend to ignite mixtures which require about 0.15 mJ for an electric spark to ignite.

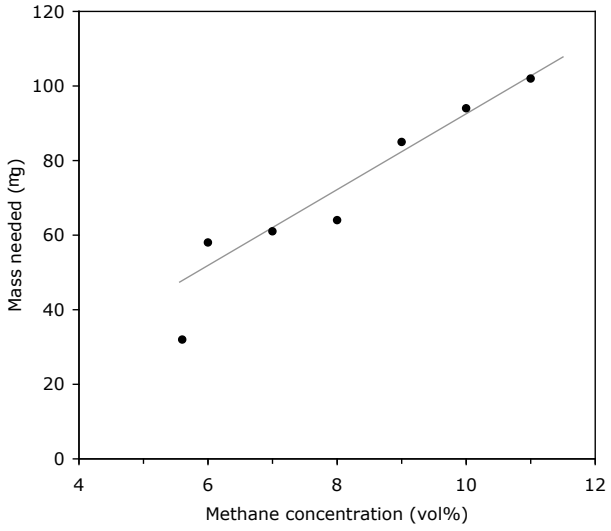

Figure 7 Mass of pyrophor particle needed for ignition of methane/air mixtures

The Bureau of Mines concluded that incendivity of grinding sparks is proportional to the radiance of the spark 'shower' and conducted extensive tests to measure this radiance[112]; the results are given in Table 14.

In actual fire incidents, grinding sparks have ignited ethylene, methanol, and oil vapor[69]. Lean mixtures are more easily ignited by grinding sparks than are rich ones[88]. *Sand blasting*[113] creates numerous, but 'dull,' sparks and tests have shown that these are unable to ignite a propane/air atmosphere.

Campbell[114] conducted large-scale tests to investigate the possibility that dragging metal in an airplane crash might ignite vapors and aerosols of flammable liquids on asphalt or concrete runways. Combustible mixtures were created using spray nozzles attached to the drag sled, and proof-

Table 14 Radiance of spark showers of various metals, as determined by Bureau of Mines

tested using electric spark plug ignition. The test conditions varied were slide speed, slide time, bearing pressure, fuel type and metal type. Despite a large amount of data collected, the main conclusions were straightforward:

- Aluminum (2024-T3 alloy) did not cause any ignitions at speeds up to the maximum explored, 18 m s^{-1}.
- A minimum pressure of about 125 kPa was needed to generate incendive sparks.
- Speed did not greatly affect the results, down to the lowest speed used, 2.2 m s^{-1}.
- Significant differences were not found for ignitability of gasoline, kerosene, JP-4 fuel, or SAE No. 5 lubricating oil.
- Alloys readily causing ignitions at pressures above 125 kPa were titanium (Ti-100A), magnesium (FS1), chrome-molybdenum steel (SAE 4130), and stainless steel (AISI 347). When using one of the steels, generally higher speed, pressure, or time were required for ignition to occur, in comparison to titanium or magnesium. Titanium was somewhat more incendive than magnesium.
- An asphalt surface was marginally safer than concrete. The aggregates in both were slag or limestone, and a higher propensity to ignition would have been anticipated had quartzitic aggregate been used.

Campbell attributed the lack of ignitions from aluminum to the fact that luminous particles were not observed in the drag sled experiments. To further explore the incendive traits of aluminum, he used a grinding wheel to grind the same aluminum alloy in a darkened room. Only rare, tiny, and barely luminous sparks were observed.

'*Non-sparking*' tools for coal mining are made out of brass, bronze, aluminum, wood, etc., which are materials that do not readily produce a burning spark. Powell[115] concludes that no 'non-sparking' metal is safe if it is struck against sandstone or quartz-bearing rock or concrete. Also, small particles can become imbedded in the surface of any tool and then the active surface will be of the inclusion, not of the base material. In the petrochemical industry, studies and experience[116] indicated that (1) it is possible for sparks from hand tools to ignite vapors of petrochemicals; but that (2) it is extraordinarily rare that this will happen, i.e., that the probability of hand-tool sparks being incendive to petrochemical vapors is extremely small. Thus, it was concluded that the only value of non-sparking hand tools may be psychological, but that they are not necessary for actual risk reduction. This recommendation was motivated by the fact actual fire ignitions have been caused in the petrochemical industry by 'non-sparking' tools[118]. Powell points out that steel-against-steel impacts are a hazard in methane/air atmospheres only if the steels are very hard and if a considerable amount of energy (> 250 J) is available[70]. Methane, however, is among the less-readily ignitable gases, so different conclusions may apply to more readily ignitable gases. Power tools can readily ignite some gas mixtures, so their use must be carefully controlled. The US Navy[105] concluded that there would be no reduction of risk from use of non-sparking hand tools in the explosives industry. Overall, however, Powell considers that non-sparking tools have merit, even if they will not prevent all ignitions[70].

IGNITION OF DUST CLOUDS AND LAYERS OF POROUS MATERIALS

The effect of the melting point of the metal on incendivity towards dust clouds was studied by Dahn and Reyes[117]. They found that several types of steel rods contacting a stainless steel surface at high speeds could ignite dust clouds, but that, at the same test conditions, aluminum rods could not. The melting points of carbon steel and stainless steel are not too different, yet stainless steel has less of a propensity to produce incendive sparks. This is held to be due to lower rates of oxidation possible with stainless steel[118]. Brass is also a substance which does not oxidize rapidly; thus, the lack of incendive behavior here is due a combination of low T_{mp} and low oxidation propensity.

Using the same apparatus as described above for gases, Cutler and Brearley[90] conducted rubbing experiments to determine the load necessary to apply to a rubbing block for ignition of several dust clouds (Table 15). St1 and St2 refer to the German classification system for explosion pressures of dust explosions, with St2 being more energetic than St1. The rubbing speed was 20 m s^{-1} for all tests, with a test duration of 90 s. The test specimens differed widely in their particle-size distributions, so it is not clear if chemical or physical factors were dominant.

Table 15 Minimum load needed to ignite dust clouds with a frictional rubbing machine

Dust	Particle size range (μm)	Min. load (N)
sulfur	38 – 180	500
non-dairy creamer powder	38 – 250	700
corn flour (St2)	<38 – 75	750
corn flour (St1)	38 – 75	900
powdered coffee	75 – 500	> 1000
calcium stearate	<38 – 75	< 1125

Most studies have only examined the effect of controlling the velocity. In one study[75], both the velocity and the impact energy were characterized separately. It was found that the incendivity towards corn dust clouds was greater when, for a fixed impact energy, the velocity was *lower*. This was attributed to the fact that higher tool velocities cause greater turbulence, and higher turbulence increases the MIE of dust clouds.

In a study[75] on the incendivity of impact sparks towards corn dust clouds (corn was chosen as having among the lowest MIE values for common dusts), the results shown in Table 16 were found.

Table 16 Incendivity of impact sparks to corn dust clouds

Tool	Ignitions occurred for these targets	Ignitions did not occur for these targets
mild steel	--	mild steel, rusty steel, concrete, all types of rocks
titanium	rusty mild steel, concrete, sandstone	granite, gneiss, quartz, grinding wheel
aluminum	--	rusty steel

Morse[82] found that sparks created by rubbing steel files against an emery grinding wheel would not ignite a wheat dust cloud. Ignitions were also not obtained by striking quartzitic rocks against a steel file, however striking a cerium/iron-alloy flint against a steel file did cause ignitions. In another series of tests, quartzitic rocks of up to 0.91 kg were dropped from various distance up to 26 m onto steel files. During 1824 drops, intense sparks and sometimes local burning was observed, but no propagating explosions occurred. The tests were repeated with magnesium and aluminum alloy items of up to 2.3 kg dropped onto rusted, roughened steel boiler plate. Again, some localized burning was observed, but no propagating explosions.

Ritter[119] conducted extensive tests where grinding sparks of various materials were presented to dust clouds. From these studies, he evolved the generalized boundaries shown in Figure 8—any dust with values of MIE and AIT that fall below the specified line will be ignited by grinding sparks from the given tool-material held against a grindstone. It is seen that flintstone sparks are most incendive, while steel sparks are least, of the materials examined. Similar trends were also obtained for flammable gas atmospheres, but for those, unlike for the dust clouds, an effect of fuel/air ratio was also present. The boundary lines refer only to momentary-contact (0.1 s) events. If a piece of material is forcibly held down to a grindstone, then bulk heating occurs and more incendive sparks are produced. Ritter also examined some of those 'friction' sparks and produced the results of Figure 9. Not shown are Ritter's results on aluminum/rusted steel impact sparks. These were less incendive than any of the combinations portrayed in Figure 8 or Figure 9. Unlike steel, flintstone and titanium showed little difference between the incendivity of grinding and friction sparks.

Allen and Calcote[120] found out that the type of steel used greatly affects the ignitability of dust clouds of corn starch, when pressing steel against a grinding wheel. Iron nails showed a 10% probability of ignition, medium tool steel 30%, and high-carbon steel 70%. They also collected dust from a grain elevator and found that this 'natural' dust had a 15% probability of ignition from the high-carbon steel. The authors also found that the velocity of the sparks produced was 10 m s^{-1} when the peripheral speed of the grinding wheel was 30 m s^{-1}.

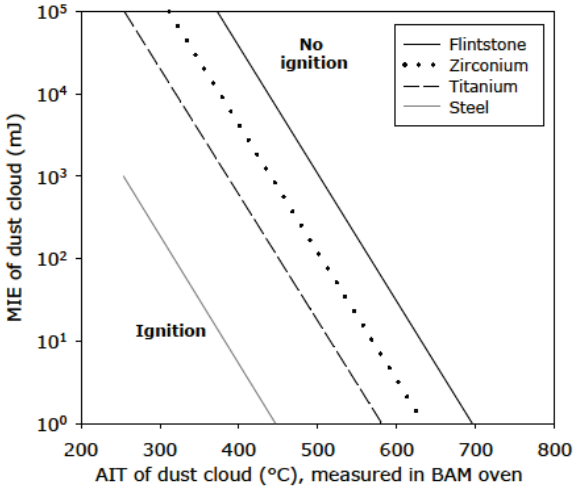

Figure 8 Ignitability of dust clouds by grinding sparks: regions of ignition and non-ignition for brief contact of material (no heating)

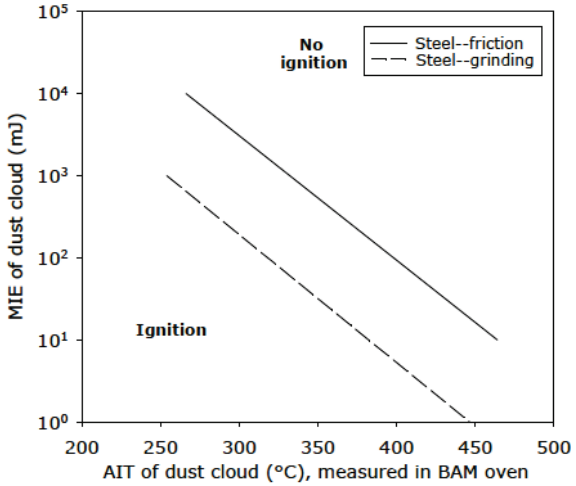

Figure 9 Ignitability of dust clouds by steel sparks: comparison of grinding (momentary) and friction (sustained heating) sparks

In addition to igniting gases and susceptible dust clouds, mechanical sparks can also ignite *dust layers* or other porous materials. Such ignitions are often smoldering rather than flaming, due to the limited amount of energy being delivered to the combustible. A case where grinding sparks flew up through a ceiling vent, and caused a fire by igniting an accumulation of dust in the void space has been reported[121]. In another case, a grinding wheel spark ignited hardwood dust, causing a flaming ignition due to the presence of an air blower[122].

Coal dust can be ignited by friction alone, if speed and force are sufficient, although the phenomenon has received only limited study[123].

Shock, impact, pressure, vibration

Kinetic energy or mechanical work (e.g., rapid compression) are ways in which external energy can be delivered to a substance and which, under some circumstances, may result in ignition.

SHOCK AND IMPACT

Shock waves can ignite gas mixtures and certain solids and liquids. Most solids and liquids are not reactive if shocked. The exceptions include explosives, pyrotechnics and other substances which are liable to decomposition. A number of theories have been developed for the shock and impact sensitivity of explosives, and these are considered in Chapter 10.

The ability of flammable gas mixture to be ignited by compression from a shock wave was first documented by Bradshaw[124] in 1907. Earlier yet work had shown that a rarefaction associated with a shock can also be the cause of ignition.

DROPPED OBJECTS

Broadly speaking, flammable atmospheres may be ignited by dropping forcibly enough one object onto another, if that same pair is also prone to frictional ignitions, but the probability of ignition is generally much lower than for frictional ignition. Bowden and Tabor[125] showed that when two bodies collide in 'normal' impact (no frictional sliding at contact) a temperature rise of only ca. 10ºC occurs for a closing velocity of 1 m s^{-1}. Yet, if the same bodies collide so that frictional sliding does take place upon contact, the temperature at the highest points along the interface will typically reach the melting point of the lower-melting solid.

Many explosives are sensitive to being initiated if dropped. In such an event, the potential energy is converted to kinetic energy and the kinetic energy, in turn, is converted into heat at the interface between the colliding objects. The drop height clearly is an important variable, as is the impact geometry, which governs deformation and, consequently, the effective surface along which the object and the target are tangent. What may not be obvious is that thermal diffusivity of the target is a dominant factor. In a study with an HMX-based explosive[126], three targets were used: quartz, aluminum oxide, and gold. The drop height necessary to initiate the explosive onto a gold surface was found to be about 400× that for the quartz surface, despite the fact that both these materials were prepared with nearly identical coefficients of frictions. The crucial factor was that the thermal diffusivity of gold is about 150× that of quartz.

HIGH-VELOCITY IMPACTING PARTICLES (UNHEATED)

A small particle can have significant kinetic energy if it is flying at high velocities, especially at or above the speed of sound. In an inelastic collision with a fixed object, significant energy can be imparted for the particle to ignite and, in some cases, to also ignite the target. NASA has studied the ignition potential of supersonic 2 mm aluminum spheres colliding into aluminum thimble-shaped targets in a pure-oxygen atmosphere at 28 MPa pressure[127]. The targets were all of the alloy 6061-T6, with a Type III, Class I hard anodization. The test variables were anodized layer thickness and the temperature of the target. A 50% ignition probability for a 3 μm anodized layer occurred for a 200°C target temperature. Specimens with a 20 μm anodized layer did not ignite until 360°C, while a 50 μm layer offered protection which was not exceeded by the maximum test temperature of 400°C. A target with no anodized layer was ignitable at room temperature. In another study[128] using large, 800 μm particles, it was found that stainless steel particles needed about 1/3 lower velocities to achieve the same probability of ignition as aluminum particles. However, steel targets were less ignitable than aluminum and Monel targets less yet.

PRESSURE (COMPRESSION IGNITION)

High temperatures can be created by the compression of gases, and, consequently, ignition can be achieved. This was first described[129] in 1802 by Prof. Joseph Mollet, in Lyon, France. Mollet had learned that a workman in a small-arms factory had accidentally discovered that tinder could be ignited by the hot-air discharge of an air-compression pump. A device to do this became commercially produced in 1806, and it was a hand pump, roughly similar to a bicycle pump. At a compression ratio of 18:1, a temperature of around 674ºC could be achieved, and this was enough to ignite tinder. The principle of compression ignition was put to more important use in 1893, when Rudolf Diesel invented the compression-ignition internal combustion engine. By 1922, Tizard and Pye[130] were presenting a theoretical study of the phenomenon.

During rapid compression, it can be assumed that no heat is lost from a system, that is, the process is adiabatic. If also no work is lost in the process, then the process is reversible and it is termed *isentropic*. For an ideal gas undergoing an isentropic compression, it is demonstrated in elementary thermodynamics that:

$$\frac{T_f}{T_o} = \left(\frac{P_f}{P_o}\right)^{(\gamma-1)/\gamma} = \left(\frac{v_o}{v_f}\right)^{\gamma-1}$$

where the subscripts on the temperature T, pressure P, and volume v are denoted as f for final state and o for initial. The dimensionless constant γ is defined as the ratio of the heat capacities, $\gamma = C_p/C_v$. For air $\gamma = 1.4$. The above equation will not always be quantitatively applicable, since at high temperatures and pressures, the gas may show non-ideal behavior. Bowden and Yoffe[131] treated the case of the non-ideal gas. Using the above equation, the highest final temperature will always be obtained using the lowest initial pressure. But for some forms of ignition, it is important to consider the total energy available in the compressed gas mass, not just its temperature. When starting from a low pressure, the mass is also low, thus it turns out that the peak

nominal energy available to be delivered to heating a specimen[132] does not correspond to $P_o \rightarrow 0$, but rather to $P_o = 0.308\ P_f$.

Ignition can also be obtained if gas compression energy is converted to a sizable pressure by means acoustic resonance. In such a scheme, a gas is introduced at high pressure into a resonant cavity, but is not compressed by piston motion. Some details have been published[73,133] on this ignition mode (sometimes termed *fluidic*, or *flueric*), but it is very rare, although a rifle based on this principle was once briefly marketed.

In addition to gaseous systems, compression ignition can occur if a liquid is compressed which has gas bubbles. Because the volume of the bubbles is more readily reduced than that of the liquid, hot spots develop at the bubbles, and these can serve as a local ignition source, if the substance is susceptible. This topic is discussed further in Chapter 10.

VIBRATION

Sensitive substances may be ignited by vibration. This may be direct mechanical vibration or shaking. But it can also take the form of acoustic energy or ultrasonic energy, both of which are pressure waves created in the air. Normally, objects in the air are highly inefficient in receiving acoustic energy. However, if *resonance* occurs, the efficiency increases many-fold. Resonance can occur when one or more dimensions of the physical object are equal to an integral multiple of the wavelength of the wave.

Vibration of rubber items in a compressed air system has led to cases where the rubber ignited from the heat induced by vibration; the sequence of events was also reproducible in the laboratory[134]. An additional example is given in Chapter 14 under *Fire hoses*. Evidently, the heating is such cases is highly localized, otherwise a gross mechanical failure would occur prior to the ignition temperature being reached.

Flames or remote objects

In some cases, the heat fluxes incident on the target are already known. For instance, they may come from the computations of a room fire model. If the heat source is an overheating object, the heat flux may often be computable by knowing the temperature, size, and emissivity of the object, along with the aid of view factors; these are discussed and tabulated in any textbook on radiant heat transfer.

A somewhat different effort is needed when the heat flux originates from a flame. The heat transfer from a flaming source will depend on numerous parameters. The most important ones include:

- fuel type (gas, liquid, solid; of various chemical compositions)
- heat output of the source
- the direction of the flow of flames (parallel to the target surface, or perpendicular [this is termed 'impinging'] or at various angles)
- distance from source to target
- type of oxidant (typically air, occasionally pure oxygen, as in an oxy-acetylene torch).

While these variables have all been studied in fundamental fluid mechanics or combustion science investigations, practical advice is somewhat scant.

SMALL BURNER FLAMES AND SMALL BURNING OBJECTS

A series of measurements on two Bunsen burner flames have been reported[135]. Natural gas was the fuel, and the burner was operated in two ways—with an inner blue cone, and without. The heights of the inner blue cones were: 25 mm (for the 100 mm flame), and 55 mm (for the 150 mm flame). Flame temperature measurements on these flames are shown in Figure 10.

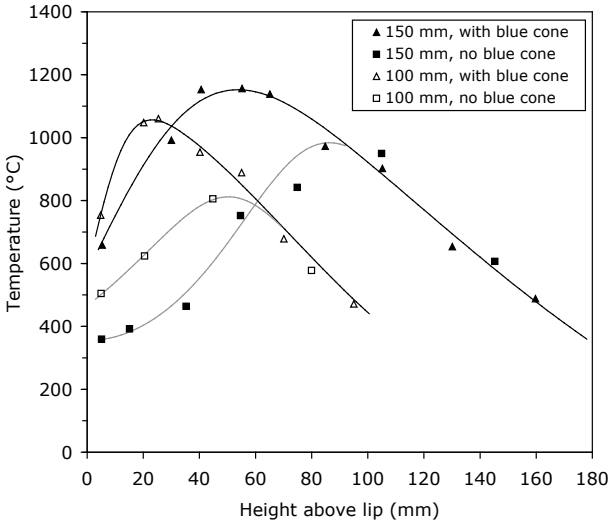

Figure 10 Temperatures in natural gas Bunsen burner flames

For most purposes, however, the heat flux, rather than the temperature, is a more useful measure of an ignition source. A NIST study examined various ignition sources, ranging from 5 W to over 300 kW[136]. The sources included both realistic igniting objects (cigarettes, matches, burning paper lunch bags, etc.) and laboratory sources (small gas burners and wood cribs). It was found that as the HRR of the ignition source increased, the peak heat flux generally did not increase. Instead, only the area covered by the peak heat flux progressively increased. For flames ranging from a 0.3 kW Bunsen-type burner to a 50 kW wastebasket, the peak fluxes were remarkably constant at 30 – 40 kW m^{-2}. Only a methenamine pill was significantly outside this range, a peak heat flux of 4 kW m^{-2} being seen for it. Quintiere[137] examined another set of experimental data and found a range of 20 – 50 kW m^{-2}. Similar conclusions can be seen from the compilation of Paul and Christian[138]. To illustrate

this constancy, Table 17 compiles data from several sources[139-141] on small burner ignition sources. Despite a wide variation in burner power levels, peak irradiance values are all clustered around 35 kW m^{-2}.

Table 17 Relation between HRR and heat flux for small burners

Burner type	Fuel	HRR[b] (kW)	Location	Peak heat flux (kW m^{-2})
needle flame	propane	0.035	45° upward	34 – 38
Kleinbrenner	propane	0.035	impinging	35
gas flame 1[a]	butane	0.081	[c]	35 – 40
gas flame 2[a]	butane	0.289	[c]	31 – 39
gas flame 3[a]	butane	0.633	[c]	20 – 40
tube burner	propane	2.8	45° upward	34
tube burner	propane	14.	45° upward	36
tube burner	propane	21.	45° upward	38
tube burner	butane	3.6	45° upward	36
tube burner	butane	18	45° upward	36
tube burner	butane	27	45° upward	36
tube burner	butane	18	70° downward	40 – 44
tube burner	butane	27	70° downward	50 – 52

[a] As defined according to BS 5852.
[b] Based on the net heat of combustion.
[c] Similar results seen for horizontal and 45° upward orientations.

LARGER FLAMING SOURCES AND BURNERS

KITCHEN SOURCES

Heat fluxes to potentially ignitable objects such as wooden cabinets located above a cooking pan holding burning vegetable oil have been mapped[142]. A 229 mm diameter cast iron pan was used to contain 0.5 L of burning oil. The heat fluxes are shown in Figure 11. Note that even at the highest distance measured, 0.76 m, the heat was 17 kW m^{-2}. The authors found that, at that height, 4 mm thick lauan plywood ignited in 2-3 min. A heat flux of 17 kW m^{-2} is enough to ignite even much thicker wood. For instance, at that heat flux, a 19 mm thick particleboard could be ignited in about 5 min. In the same investigation, it was determined that two gas burners set on maximum output would provide only 9.7 kW m^{-2} heat flux at a 0.23 m height and 1.1 kW m^{-2} at 0.76 m height. Thus, wood construction materials are unlikely to be ignited from gas burners alone, even if located at an unreasonably low height of 0.23 m above the burner.

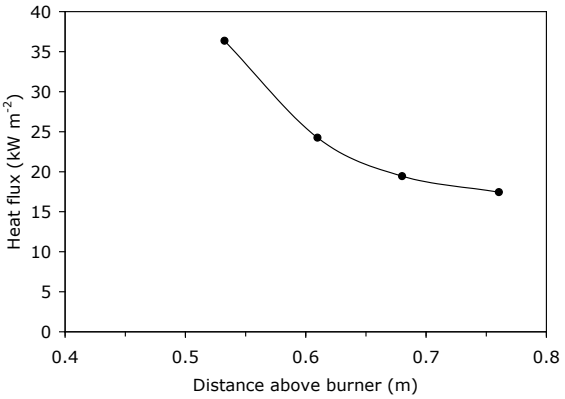

Figure 11 The heat fluxes measured from a pan of burning vegetable oil

LARGE LABORATORY BURNERS

A study done at VTT[143] examined gas burners with HRR values of 40, 100, 160, 230, and 300 kW placed against a wall. The burners released a stream of propane gas upward from a square face, which was filled with sand to diffuse the velocity of the entering fuel gas. Three different face sizes, ranging from 0.17 × 0.17 m to 0.50 × 0.50 m were explored. The peak heat flux to the wall adjacent to the burner was found to be much more dependent on the face size than on the burner HRR. A peak value of around 40 kW m^{-2} was seen with the 0.17 × 0.17 m size and 65 – 80 kW m^{-2} with the 0.30 × 0.30 m size. For the very large face size of 0.50 × 0.50 m, the peak heat fluxes were related to the burner HRR, and the original report should be consulted for those results. Published details are also available for a 50 kW porous-face burner[144] used at NIST for furniture testing.

An examination of the results for small and large burners (except for burners with unusually large face dimensions) shows that the peak flux is almost independent of burner power output, but the wall area adjacent to the burner subjected to a given flux level is nearly linearly proportional to the burner HRR. The latter point is illustrated in Figure 12. For the large-burner data, flame area contours were taken as corresponding to a 20 kW m^{-2} flux level; as a result there is a slight systematic mismatch between the large and small burner data sets. The correlation shown indicates a HRR/area ratio of 100 kW m^{-2}.

JETS AND HIGH VELOCITY BURNERS

A flame which impinges at 90º against a solid object can generate much higher heat fluxes than flames where streamlines flow generally parallel to the surface. The heat fluxes from burners in such orientation can vary from modest to exceptionally severe. On the mild end, a 'T-head' burner is used in some fire tests for upholstered furniture. It consists of a tube with numerous small holes, thus discharging at a higher velocity than is the case of Bunsen-type burners. Ohlemiller and Villa[145] measured heat fluxes as high as 70 kW m^{-2} in the impinging region of this burner's flame. In a parallel study using several different configurations of impinging flames from multi-hole propane and butane burners[140] more typical fluxes of 50 kW m^{-2} were seen. In another study on various commercial burners and plumbers'

blow torches, a maximum impinging-zone heat flux of 140 – 150 kW m^{-2} was seen[146].

For flames from large, premixed, turbulent methane/air burners, impingement region heat fluxes in the vicinity of 200 to 400 kW m^{-2} can be found[147,148]. Heat fluxes from high velocity, non-premixed jet flames[149] of fuel in air can reach around 300 kW m^{-2}. These are extreme cases corresponding to the hottest zone and for gas mixtures which are fairly close to stoichiometric. Moving the target away from the hot zone, or increasing dilution of the combustion stream will, of course, show progressively lower heat fluxes. More typical cases[149] may show values of only 100 kW m^{-2}. Flames with premixed oxygen show very high heat fluxes—for methane/oxygen or propane/oxygen flames, fluxes around 2500 kW m^{-2} have been measured[150]. Away from the center of the impingement, the heat fluxes will fall off. You[151] attempted to provide some scaling relationships for describing the fall-off in flux as radial or axial distances increase between the burner exit and the measuring point. These can give some guidance, but must be used with care, since they were developed using only very small fire sources and not verified against larger ones.

SOLID-FUEL IGNITION SOURCES

The heat flux to adjacent objects from a small wood crib or other solid-fuel ignition source is in the same 30 – 40 kW m^{-2} range as for gas burners. The picture is more complicated, however, for the heat flux from these sources to the object underneath. Data from wood crib sources[152] show small regions where heat fluxes in the vicinity of 90 kW m^{-2} can be found underneath the burning crib. Unlike other sources, where only radiative and convective heating from flames need to be considered, in this case the high heat fluxes originate due to direct conductive heating from a hot, glowing body. Such high values are, in fact, consistent with the temperature of the glowing char. The actual ignition process from such a source has not been characterized, however, since the heat transfer is definitely not 1-dimensional.

For most other solid-fuel ignition sources, localized very high heat fluxes are not found. For instance, Paul and Christian[138] examined the peak heat fluxes found underneath burning balls of crumpled newspaper and underneath wire baskets holding various amounts of shredded paper. The peak heat flux seen in this series of tests was 24 kW m^{-2}, with most experiments indicating substantially lower peaks, down to 7 kW m^{-2}. Another type of solid-fuel source is the 100 g paper cushion stuffed with newspaper used by the German railroads[153]. Döring and co-workers[154] found a maximum of 35 kW m^{-2} underneath the standard paper cushion. Variants of differing types showed flux peaks of 28 to 47 kW m^{-2}. There are some findings contrary to the above, however. Ohlemiller and Villa[145] found substantially higher heat fluxes associated with the newspaper-filled wire basket formerly used as a furniture ignition source by the State of California.

BURNING FABRICS

Miles et al.[155] measured the heat flux from burning clothing textiles. Values of only 5 – 17 kW m^{-2} were reported. These are not likely to be reliable measurements, since flame contact to the heat flux meter appears to have been erratic.

BURNING FURNITURE

One of the few larger-size commodities that have been studied as ignition sources is furniture. The earliest study[156] of burning furniture was relatively non-quantitative—heat fluxes were not measured, but ignitable targets were placed at varied distances. The results are given in Table 18.

To make quantitative heat flux measurements is not simple, since the heat flux varies with time and with the distance away from the object. In addition, the measured heat flux will also vary with the angle of the heat flux meter, but the data which are of primary interest are for vertically-oriented targets. Such measurements were made by Babrauskas[157]. A plot of irradiance values obtained at peak burning time for a 19.9 kg upholstered wicker couch is shown in Figure 13.

If the furniture item presented very small flames, or if the measurement was taken very far away, then radiation scaling would indicate that the heat flux would vary as r^{-2}. However, if either of those two conditions, held, then heat fluxes would be small and there would not be an interest in ignition aspects. Mizuno and Kawagoe[158], correlating measurements at distances of 1.35 – 3.0 m, concluded that scaling according to $r^{-1.8}$ gave better results. The scaling law of $r^{-1.8}$ applied to NIST data[144] gives an approximate predictive formula for the maximum distance at which target ignitions can be expected to occur. Figure 14 shows plots of the relation:

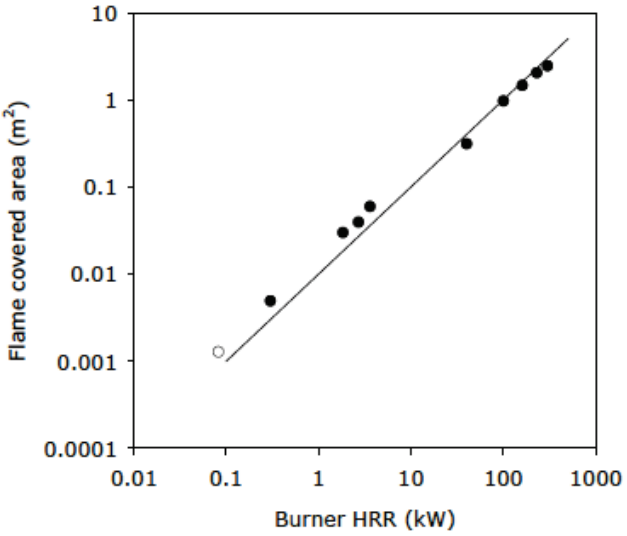

Figure 12 The relation between burner HRR and flame-covered area

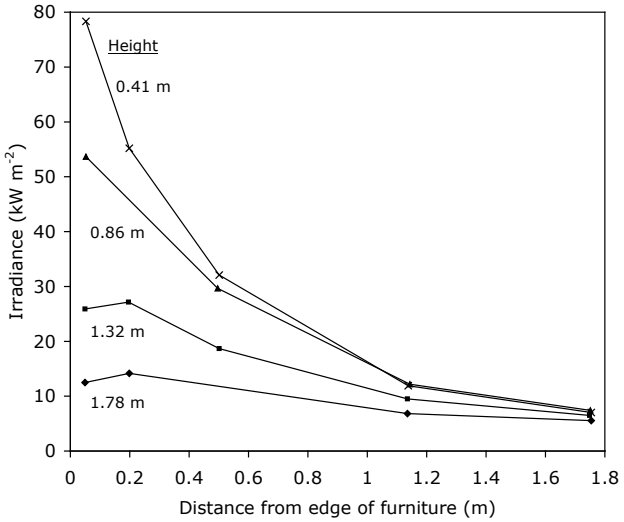

Figure 13 The irradiance to a vertically oriented target measured at the peak burning time of a 19.9 kg couch

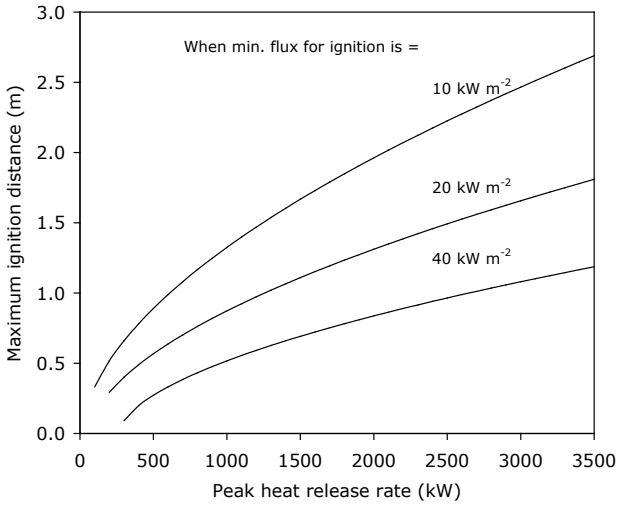

Figure 14 An approximation for the maximum distance at which target ignition is possible, as a function of the HRR of the burning furniture item

$$r = \left(0.0168 \frac{\dot{Q}}{\dot{q}''_{\min}} - 0.0028\, \dot{q}''_{\min} \right)^{0.56}$$

where r = maximum distance from edge of furniture item to target at which ignition is possible (m), $\dot{Q}$ = heat release rate (kW), and $\dot{q}''_{\min}$ = minimum flux for ignition (kW m^{-2}). A heat flux of 10 kW m^{-2} represents an approximate minimum flux for the piloted ignition of easily ignitable targets, such as other items of upholstered furniture. The heat flux of 40 kW m^{-2} represents an upper limit for the autoignition of most building materials and occupant goods. Thus, in most building fires these two values are expected to encompass the range of practical interest.

It is important to realize that burning furniture items, if placed very close to other combustibles, can readily cause ignition by direct flame contact. For instance, if a combustible wall surface is located a short distance behind a burning sofa, flames can directly ignite the wall and radiant flux calculations are not appropriate.

LARGE BURNING OBJECTS

LIQUID POOLS , WOOD CRIBS

The heat fluxes from burning pools or tanks of petrochemicals can be a severe ignition hazard. There are two basic cases to consider: (1) the object is engulfed in the flames; or (2) the object is remote from the flames. Peak temperatures[159] inside large pool fires of hydrocarbon liquids are typically on the order of 1000ºC. Thus, unless the material in question is combustible, yet very highly resistant to ignition, the ignition problem is trivial—ignition can be assumed to occur in a few seconds. Neill et al.[160] examined the heat fluxes to objects submersed in flames from small pool fires. Their measurements did not lead to predictive equations, but it is worth noting their observation that soot deposition occurred in hydrocarbon pool fires, although not in methanol fires. For fires where soot was being deposited, the heat transfer to the target diminished progressively, but slowly, so that at the end of 1 h, the heat flux was typically reduced by 50%. The most useful data on large pool fires come from several studies at Sandia National Laboratories. Net heat flux peaks[161,162] of 120 – 140 kW m^{-2} were found inside the flame volume (i.e., fluxes to objects submersed in

Table 18 Ignition of targets by burning furniture

Burning item	Maximum distance for ignition (m)		
	Cotton cloth	Plywood	Wood blocks

the flames) in a series of tests using 9 × 18 m pools of JP-4. Unlike most other heat flux measurements, the values reported were net fluxes, that is the heat flux actually entering the specimen. The net heat flux is lower than the incident heat flux due to non-unity radiant absorptivity, re-radiation, and the progressive diminution in convection as the specimen warms up. The net heat fluxes decreased during the tests to around 50 kW m^{-2} after a ½ hour. Similar studies in large (20 m diameter) JP-8 pool fires[163] using heat flux meters positioned slightly above the pool and oriented so as to view upwards, showed that the highest heat fluxes (ca. 100 kW m^{-2}) were at the edge; heat fluxes at the center were quite small (15 – 20 kW m^{-2}) due to oxygen starvation.

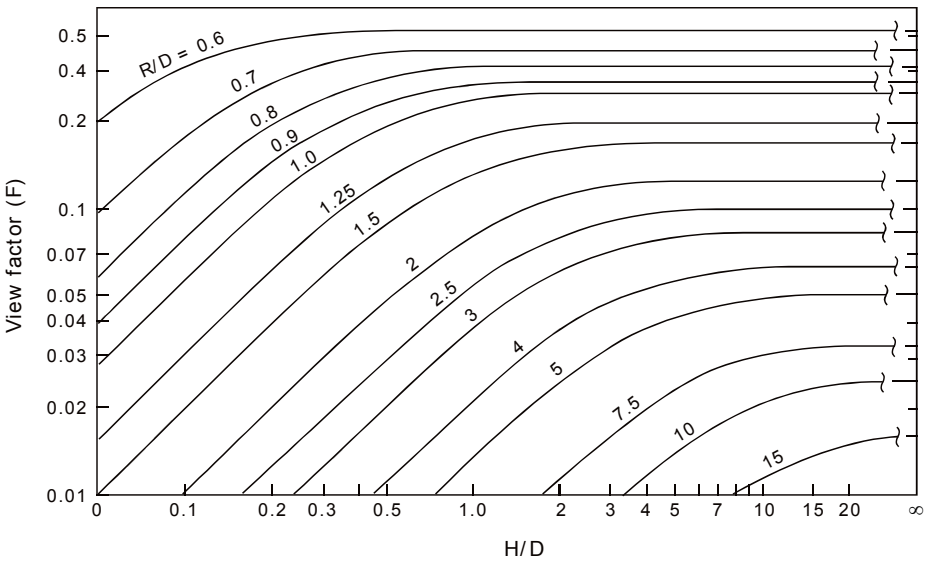

Figure 16 View factor F for a vertical target at ground level
(Copyright NFPA, used by permission)

For the case of objects remote from the flames, the simplest method for estimating the radiant heat flux to a target is that of Shokri and Beyler[164], which was derived from a data correlation and is applicable only to the configuration of a vertical target at ground level (Figure 15):

$$\dot{q}''_{rad} = 15.4 \times \left(\frac{R}{D} \right)^{-1.59}$$

where R = distance from center of pool to target (m), and D = pool diameter (m). This model is very simple indeed, since no chemical characteristics of the pool fire are considered, merely its size.

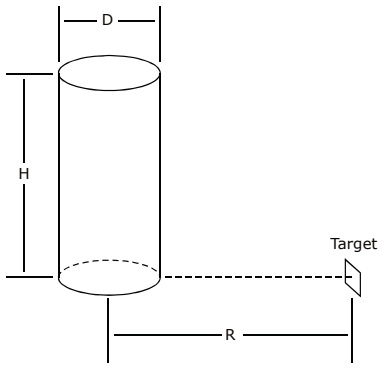

Figure 15 Geometry for vertical target at ground level, exposed to radiant heating from cylindrical-shaped flame body above a liquid pool of diameter D

As the next step in complexity, it can be recognized that the chemical nature of the fuel does play a role in determining the heat flux to a target. The simplest model which takes this into account is the *point source radiation model*. If the size of the burning object is very much smaller than the distance from the fire to the target, and if the fire is radiating equally in all directions, then[165]:

$$\dot{q}''_{rad} = \frac{\chi_r \dot{Q}}{4\pi R^2}$$

where $\dot{q}''_{rad}$ = radiant heat flux (kW m^{-2}), χ_r = fraction of the HRR which shows up as radiant energy (--), $\dot{Q}$ = HRR of the pool (kW), and R = distance from center of pool to target (m). The radiant fraction depends both on the chemistry of the fuel, especially its propensity to produce soot, and on the scale of the problem. Values of χ_r between 0.1 and 0.4 are common, but in the absence of more specific information, χ_r = 0.25 to 0.30 is often taken. A study has been reported on burning pallet loads of organic peroxides[166]. Liquids were packaged in plastic containers within cardboard boxes, while solids were packaged in cardboard drums. Radiation measurements indicated that values of χ_r spanned the small range of 0.20 to 0.28. An SFPE Guide[167] points out that the radiant fraction decreases with pool diameter and suggests a general relation:

$$\chi_r = 0.21 - 0.0034D$$

where D = pool diameter (m). Since the value of χ_r depends on the chemical nature of the fuel and this equation ignores it, obviously it is a simplification.

To improve the accuracy of the estimate, the flame can be treated as a finite geometric area, instead of a point source. The simplest such representation is as a grey-body cylinder, however, this requires additional input data, since the diameter and the height must both be known. The diameter is commonly assumed to be equal to that of the pool, but the flame height must be estimated by some supplemental formula. A number of formulas are available for this purpose, but the simplest is Blinov and Khudiakov's experimental finding[168,169] that, for pools of diameter greater than about 2

m, $H \approx 1.5\ D$. With cylinder diameter and height known, it is possible to perform a radiant-exchange calculation. The radiation from a grey body is:

$$\dot{q}_2 = F_{12} A_1 \varepsilon \sigma T_f^4$$

where $\dot{q}_2$ = radiation leaving source 1 that is intercepted by target 2 (kW), A_1 = area of the source (m^2), ε = flame emissivity (--) and T_f = source temperature (K). The *view factor* F_{12} is a dimensionless number which can range from 0 to 1 and which denotes the fraction of radiation leaving object 1 that is intercepted by object 2. View factors are simply geometric constants which can be calculated (albeit often with difficulty) from the sizes, shapes, and orientations of the objects involved. Next, the identity is used:

$$F_{12} A_1 = F_{21} A_2$$

where F_{21} refers to radiation leaving object 2 that arrives at object 1 and A_2 is the area of the target 2 (m^2). Combining the above two equations gives the desired result for the radiant flux $\dot{q}''_{rad}$ being received by the target:

$$\dot{q}''_{rad} = \frac{\dot{q}_2}{A_2} = F_{21} \varepsilon \sigma T_f^4$$

For practical problem solving, it turns out that there is no need to separately evaluate ε and T_f, but the quantity $\varepsilon \sigma T_f^4$ can be used. It has the units of kW m^{-2} and is termed the *emissive power*. Expressed this way, the basic relation is simply:

$$\dot{q}''_{rad} = FE$$

where we have simplified the F_{21} notation to F. To compute F requires knowing the flame height H and the distance R from the center of the fire to the target. Values of F for a cylindrical flame geometry to vertical target at sitting at the same height as the base of the pool[168] are shown in Figure 16. The width of the cylinder is taken as the pool diameter D and the height of the cylinder H is the flame height, as determined by one of various flame height correlation formulas. The latter assumption has some systematic bias, since the top portion of a flame has very little radiating power, and the effective radiating height is less, but in view of experimental uncertainties in determining flame heights, high precision would scarcely be warranted. The most common flame height equation is Heskestad's[170]:

$$H = 0.224 \dot{Q}^{2/5} - 1.02 D$$

If the approximation that $H \approx 1.5\ D$ is used, then the view factor can be suitably estimated as:

$$F \approx 0.272 \frac{D}{R} - 0.0347$$

The SFPE Handbook[165] and Lees[181] provide equations for computing more view factors from complex flame shapes, while Rew and Hulbert[171] describe a much more elaborate model for all aspects of pool fire radiation, but in view of the various problem uncertainties, it can be questioned whether more elaborate calculations lead to appreciable improvements in accuracy of prediction.

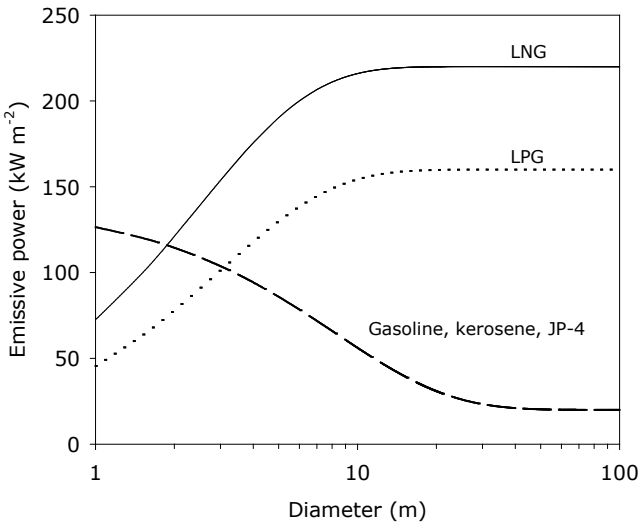

Figure 17 The effect of diameter on emissive power of liquid pool fires

The emissive power E depends on the substance that is burning and on the scale of the fire. Experimental data for the emissive power of several liquid fuels are provided in the SFPE Handbook[165]. Curves expressing these results (Figure 17) are:

LNG: $E = 220 \left(1 - e^{-0.4D}\right)$

LPG: $E = 160 \left(1 - e^{-0.335D}\right)$

gasoline, kerosene, JP-4: $E = 20 + 120\, e^{-0.12D}$

The curves for LNG and LPG are very similar and show that the emissivity increases with increasing size, as is usually found for flames of various types. The results for gasoline/kerosene/JP-4, however, seem anomalous—increasing the size of the fire causes the emissive power to drop. The reason is that these fuels generate a very large amount of black smoke, a certain fraction of which forms a 'cold smoke mantle' around the exterior of the fire. Flames periodically break through this mantle and higher radiation then falls on the surrounding objects. The experimentally reported emissive power for these fuels is a value that averages out these fluctuations. Shokri and Beyler[164] have pointed out that, at least for gasoline/kerosene/JP-4, the SFPE Handbook relations overestimate the peak emissive power that is attainable in practice.

The emissive power of large-size flames has also been studied for square-array cross-piles of wood sticks, which are termed *cribs*. The data of Hägglund and Persson[172] are shown in Figure 18. The equation that represents the data is:

$$E = 190 \left(1 - e^{-0.8D}\right)$$

The curve fit would suggest that $E \rightarrow 190$ kW m^{-2} as $D \rightarrow \infty$, but this is hard to confirm since the emissive power has not reached a plateau for the largest experimental flame depth, which was 2.0 m. Buildings or portions thereof will,

of course, show much greater flame depths. The predictive equation (and those given above for liquid pools) should not be used for $D < 0.3$ m, since convective effects are strong in fires of smaller diameter[173].

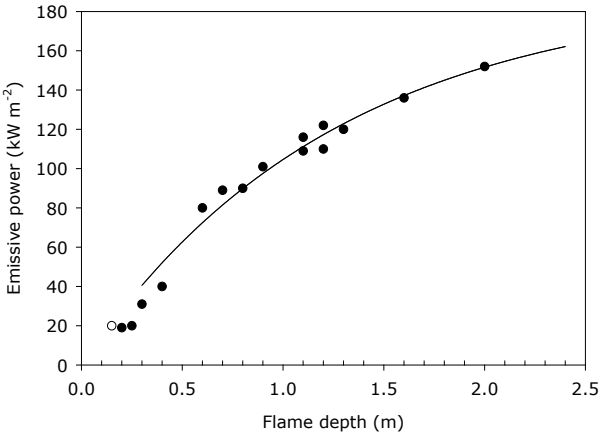

Figure 18 The effect of diameter on emissive power of wood crib flames

FIREBALLS AND JET FLAMES

In a fire safety context, the term *fireball* is generally understood to be the combustion in air of a fixed amount of fuel that is burned up quickly (typically[174] in less than 20 s). A typical fireball is illustrated in Color Plate 15. By contrast, a pool fire is one which is supported by evaporation of a body of liquid and continues to burn for a substantial length of time. If the amount of gas discharged is large, then ignition from a fireball can occur at large distances from the fuel source. A fireball can originate from a BLEVE or some other event that delivers rapidly a large amount of fuel into the air. A large fireball will typically go through three stages[179]:

1. Growth. The diameter of the fireball steadily increases during this stage, but the fireball remains located at ground level.
2. Steady burning. The diameter no longer increases, and at some time during this stage the fireball begins to lift off the ground.
3. Decay. The fireball remains roughly at its maximum size, but radiation from it progressively diminishes.

Methane fireballs were studied by Hardee et al.[174] and their results are summarized in Table 19. On the basis of their own measurements and a review of the literature, including larger-scale data, they offered two estimating equations:

$$d_b = 6.36 W^{0.325}$$

$$t_b = 2.57 W^{1/6}$$

where d_b = maximum fireball diameter (m), t_b = burning time (s), and W = mass of methane (kg).

Johnson and Pritchard[175] conducted large-scale BLEVE tests on railcar-size vessels containing 1000 – 2000 kg butane or propane. They obtained emissive power readings of 250 – 350 kW m^{-2} from the lower part of the fireballs of either fuel. The top of the fireballs registered 500 kW m^{-2} peak values, but combustible targets are unlikely to be situated above one of these fireballs. The duration of a fireball was ca. 4 s. The high heat flux values reported in these tests appear questionable. All available evidence[179] is that flame temperatures in fireballs do not exceed 1200 – 1300ºC. If so, then the emissive power evidently cannot be greater than 347 kW m^{-2} at any time, not just for the average value. Deriving design values from experiments on fireballs is difficult, since actual fireballs vary in effective radiating area with time and their emissive power varies with direction of wind. It is also clear that peak values are not themselves related to hazard and that some credible averaging technique must be used. The peak radiant power of a fireball (E times effective radiating area) is typically reached at the time of lift-off.

Table 19 Small-scale experimental measurements on methane fireballs by Hardee et al.

Mass of methane (kg)	Burning time (s)	Max. dia. (m)	Heat flux at edge (kW m^{-2})	Total energy fluence (kJ m^{-2})
0.15	1.8	3.0		
1.5	2.4	4.4	123	102 – 193
10				251 – 325

Prugh[176] suggested that the following relations can be used to calculate the characteristics of fireballs of any fuel gas:

$$d_b = 6.48 W^{0.325}$$

$$t_b = 0.825 W^{0.26}$$

$$H = 0.75 d_b$$

$$E = 0.0092 \chi_R \Delta h_c W^{0.09}$$

where W = fuel mass (kg), H = center height (m) of fire ball, E = emissive power (kW m^{-2}), χ_R = radiant fraction of heat release rate (--), and Δh_c = heat of combustion (kJ kg^{-1}). The expression for height is a design value that takes into account that fireballs become buoyant early in their combustion stage, and that the peak heat fluxes are seen when they are substantially higher than ground elevation. Suggested values[177,181] of χ_R for a number of common fuels are shown in Table 20, but it must be understood that the values are not completely independent of scale. Scale data are not available in general, but for crude oils, some scale-dependent values for pools[178] are shown in Table 21; comparable values for jets, etc., are not available. If the target is not directly adjacent to the fireball, then the incident heat flux is not E, but is diminished by a view factor. Prugh suggests that the simplest equation for estimating the view factor for radiation from a fireball is:

$$F = \left[\frac{d_b}{2R_f} \right]^2$$

where R_f (m), the distance from the center of the fireball to the target, is given by the hypotenuse:

$$R_f = \sqrt{X^2 + H^2}$$

where X (m) is the lateral distance between the target and the center of the fireball.

Table 20 Radiant fraction of HRR for several gases

Fuel	Radiant fraction χ_R (--)
methane	0.16 – 0.23
hydrogen	0.17 – 0.25
methanol	0.20
natural gas	0.23
butane	0.30
propane	0.33
benzene	0.38
ethylene	0.38
hexane	0.40

Table 21 Effect of pool diameter on radiant fraction of crude-oil fires

Pool diameter (m)	Radiant fraction χ_R (--)
5	0.26
10	0.22
20	0.16

Crawley[179] examined a film from an 80,000 kg actual BLEVE incident which indicated that the duration of burning was 17 s, of which 10 s had a steady state character. Based on this and two other very large-scale incidents, plus various small-scale tests he noted that equations not having an explicit molar mass term gave poor agreement for hydrogen fireballs. Including this molar mass effect, his proposed correlation is:

$$d_b = 10.5\left(\frac{W}{M}\right)^{1/3}$$

where M = molar mass of fuel (g mol^{-1}).

The most authoritative and extensive study has been that of Roberts[180], who correlated data on a number of different combustibles from several studies and concluded that a reasonable representation of fireball diameter is:

$$d_b = 5.8 W^{1/3}$$

The experimental data covered fuel quantities of approximately 10 – 1000 kg. Lees[181] recommended that the above correlation be considered the one of most general applicability. Roberts concluded that the burning time cannot be estimated by a single equation, rather that there is a dependence on the amount of fuel:

$$t_b = 1.1 W^{0.097} \qquad \text{W} < 5 \text{ kg}$$

$$t_b = 0.45 W^{1/3} \qquad \text{W} > 5 \text{ kg}$$

Further, Roberts concluded that for actual estimating of radiant fluxes, an effective radiation duration time, t_r, should be used:

$$t_r = 1.07 W^{0.181}$$

The heat flux found at a distance R_f from the center of the fireball could be estimated as:

$$\dot{q}'' = \frac{8.28 \times 10^5 W^{0.771}}{R_f^2}$$

The relation breaks down for large fireballs, since it would indicate an indefinitely-increasing heat flux, whereas actual experimental data[174] indicate that emissive power does not keep increasing once the fuel mass surpasses about 30 kg.

For very large fireballs, buoyancy effects become stronger, and a British expert panel[181] recommended the following relation:

$$t_b = 2.6 W^{1/6} \qquad \text{W} > 30{,}000 \text{ kg}$$

The same panel recommended that the vapor pressure of the fuel at the moment of release, P (MPa), can be taken into account by the following equation:

$$E = 235 P^{0.39} \qquad P \le 2.$$

More recent data were presented by a Russian group[182], who exploded large steel cylinders filled with gasoline, diesel fuel and kerosene. These conditions create fireballs of maximum compactness, since ignition occurs before diffusion or mixing have taken place. They obtained:

$$d_b = 5.3 W^{1/3} \qquad \text{diesel fuel, kerosene}$$

$$d_b = 4.3 W^{1/3} \qquad \text{gasoline}$$

These diameters are slightly lower than in previous studies, due to the compactness of their fireballs. The authors also reported measurements of E for small diesel-fuel fireballs of 3 – 110 kg and correlated these results as:

$$E = 110\left[1 - \exp\left(-2.6 d_b\right)\right]$$

If $d_b > 1.0$ m, then this equation gives $E \approx 110$ kW m^{-2}. Use of this equation should be limited to fuel amounts no greater than 110 kg, since higher values of E have been measured by researchers who studied larger fireballs. For fireballs within the range of validity, the authors also suggested that, if a time-dependent expression for fireball diameter is available, the above equation can be evaluated for E on a time-dependent basis. Several theories for fireball characteristics have also been developed by Russian researchers[183].

A time-dependent model for fireballs was presented by Martinsen and Marx[184]. Their maximum diameter is the same as given by Roberts,

$$d_{b(Max)} = 5.8 W^{1/3},$$

but during the initial time period, the fireball sits tangent to the grade, and expands in diameter according to:

$$d_b = 8.67 W^{1/4} t^{1/3}$$

Table 22 Emissive power measured from dust explosion fireballs

Dust	Fireball diameter (m)	Max. emissive power[a] (kW m^{-2})	Avg. max. emissive power (kW m^{-2})
aluminum powder	2.5 – 9.2	145 – 2417	858
anthraquinone	7.2 – 11.2	222 – 297	262
coal dust	7.4 – 11.4	107 – 227	162
corn flour	5.4 – 7.9	25 – 57	33
polyethylene	1.8 – 8.4	25 – 87	63
toner dust	9.7 – 15.4	125 – 294	209

[a] – peak with respect to time, average with respect to fireball perimeter

When d_b reaches $d_{b(Max)}$ the fireball stops growing and begins to rise in the air. In their scheme, the fireball duration is:

$$t_b = 0.9 W^{1/4}$$

Williamson and Mann[185] studied propane fireballs and concluded that the lift-off time t_o (s) is:

$$t_o = 1.09 W^{1/6}$$

For other fuels, they suggest the more general expression:

$$t_o = 0.68 r^{1/6} W^{1/6}$$

where r = stoichiometric air/fuel mass ratio for the fuel.

A limited amount of data suggests that the center of the fireball rises to a maximum height of 1.5× $d_{b(Max)}$. Martinsen and Marx approximate the velocity of its rise by assuming that it goes from lift-off to maximum height at a constant velocity, and that this process starts at t = t_b/3 and ends at $t = t_b$.

A plot of the heat flux versus time is quite similar to a triangle[184], thus Jones[186] proposed that it be simplified as an isosceles triangle. In this method, time is scaled according to a dimensionless time t', which is defined as $t' = \frac{\sqrt{g}}{V^{1/3}} t$, where g = acceleration of gravity (9.81 m s^{-2}) and V = volume of vapor leaked, evaluated at ambient temperature and pressure. The triangular plot then has its zero at the time of ignition (t' = 0), peaks at t' = 6, and drops down to zero again at t' = 12.

For fireballs from *dust explosions*, the emissive power has only recently been studied. Holbrow and Hawskworth[187] conducted explosions in 18.3 and 20 m^3 large-scale vessels. Dust concentrations were varied, but generally were at levels designed to elicit peak explosion pressures. Their results are shown in Table 22. A wide range of emissive powers was found, with some organic fuels, e.g., corn flour, showing very low values. The emissive power from aluminum powder was much higher since the adiabatic flame temperature of aluminum burning is air is substantially higher than for organic fuels.

Since *explosives and propellants* have adiabatic flame temperatures which are much higher than normal liquid or solid combustibles, while their heats of combustion are typically low, the fireballs produced by propellants would also be expected to show correlations different than for normal fuels. Figure 19 shows the emissive power measured from a fireball from 1 kg of gunpowder[188]. Unfortunately, 'pyrotechnics,' have diverse characteristics and can only loosely be considered a single family. Data for a number of compositions[189] are shown in Table 23, where the constants a and b pertain to the equation for estimating fireball diameter:

$$d_b = a W^b$$

Peak emissive power was generally 230 – 1000 kW m^{-2}, but no predictive relation was found. The emissive power was mostly dependent on the chemical constitution of the substance, but in most cases there was a small increase with mass of charge. Fireballs from explosives and pyrotechnics are shown in Color Plate 16 and Color Plate 17.

Merrifield and Wharton[190] studied the fireball characteristics for a series of propellants and found that the exponent was generally close to 1/3, but that the scaling factor varied:

$$d_b = (1.5 \text{ to } 3.8) W^{1/3}$$

Matters were also complicated by the fact that the fireballs produced from propellants were often more cylindrical than spherical in shape. Fireball duration was difficult to correlate on a substance-independent basis. A power-law expression for t_b:

$$t_b \propto W^n$$

Table 23 Fireballs from various pyrotechnic compositions: diameter from 1 kg charge and predictive constants for other charge masses

Pyrotechnic composition*	Fireball dia. (m)	a	b
flash (magnesium, potassium perchlorate, graphite)	5.0		
star (magnesium, potassium perchlorate, barium nitrate, PVC)	3.4	3.3	0.40
gunpowder (potassium nitrate, carbon sulfur)	3.2	3.1	0.28
priming (gunpowder, potassium nitrate, silicon)	2.4	2.5	0.29
flare (magnesium, sodium nitrate, calcium oxalate)	2.0	1.9	0.32
star (gunpowder, potassium nitrate, aluminum)	1.6	1.5	0.33
flare (sodium nitrate, magnesium, calcium oxalate, PVC)	1.2	1.1	0.21
priming (potassium nitrate, silicon, sulfurless gunpowder)	0.8	0.74	0.17

* minor ingredients not shown

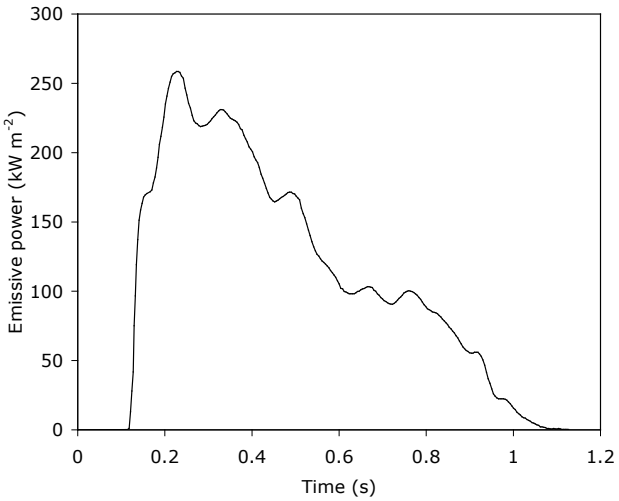

Figure 19 Emissive power from a fireball of 1 kg of gunpowder

required values for n of 0.1 to 0.33, depending on the substance. The emissive power of most of the fireballs measured was roughly 1000 kW m^{-2}, which is consistent with their high flame temperatures.

Jet flames occur when a combustible gas is discharged from a pipe or other opening and burns in the air. These can be intentional (flares at refineries) or accidental. The modeling of their heat flux can be non-trivial since (1) the flame shape is long and narrow and does not lend itself to being approximated as a spherical shape, except for the crudest of estimations; and (2) wind effects may change the lateral location of the higher portions of the flame to a sizable extent. Despite the crudeness of the assumption, the point source radiation model, discussed above, is commonly used in the petrochemical industry[181]. Some experimental data, along with suggestions for extrapolation, have been provided by Brzustowski et al.[191] A large variety of elaborate computational models have been put forth, and these were compiled (but not assessed as to validity) by Lees[181].

See also Chapter 13 for information on heat fluxes and ignition associated with gas explosions in rooms.

BURNING BUILDINGS

When a serious room fire occurs and there are windows in the façade, high heat fluxes can exist. Ignition may possibly occur of: (1) the façade itself, if it is combustible; (2) combustibles such as curtains in rooms on higher stories, if there are windows directly above the fire; or (3) combustibles on or in a building which faces the burning building, thereby creating an *exposure fire*. The ignition of items #1 and #2 will tend to occur only if the room fire is sufficiently advanced so that the window glass breaks and a fire plume is projected above the opening. Distant targets (#3) will be affected by radiation both from the window opening itself and from the fire plume above it. Thus, it is convenient to consider #1 and #2 together, and to relate these potential target locations to the fire plume that emerges from the window opening. The methodology for #3 can then be considered separately.

Heat fluxes to the façade of the burning building

A large fire usually breaks out windows of the building and there comes to be a fire plume (a nearly-vertical column of flame) that rises from the opening. If the façade is combustible, flames lapping directly at it are likely to cause ignition. But additionally, if the plume is tall enough so that the region of high heat fluxes extends to the next storey, its windows may break and fire may directly enter the storey above. Both of these possibilities are sometimes referred to as *autoexposure*. Wade and Clampett[192] have reviewed some case incidents.

The oldest studies on characterizing the fire plume above a window opening mostly only measured temperature distributions, from which some workers tried to compute heat fluxes[214]. An early series of heat flux measurements was conducted by the Fire Research Station in England[193], where for a variety of wood crib fires, the heat flux to the façade above the opening of the burn room window was found to range from about 12 to 40 kW m^{-2}. These values were very low, presumably because the window opening was sufficient to burn most of the pyrolyzed fuel inside the room. Similar experiments using wood cribs were recently reported by Hakkarainen[194]. In her tests, the heat flux was measured at 2.2 m above the top of the window and showed values around 80 – 120 kW m^{-2} after the fire had fully built up, which required around 20 min. With the popularization of the use of plastics in furniture and building materials during the 1970s, it became less likely that burning of the fuel pyrolysates would be confined to the room itself. Two studies using modern furniture fires were performed at Lund University. In the first study[195] values measured for the total heat flux were ca. 145 kW m^{-2} at 0.8 m above the top of the window, dropping to 40 kW m^{-2} at a height of 3.3 m. In a follow-on study[196], primarily the radiant heat flux component was examined, but comparison was made between wood and plastic-fueled fires. Figure 20 indicates the very large increase that plastic fuels give over wood fuels. The authors estimated that this was because the fraction of the fuel mass loss rate showing up as excess pyrolysates was 25% for wood fuel and 65% for plastic fuel. For the plastic fuels, instrumentation for measuring the total heat flux was also used, but only close to the top of the window opening. Values of total heat flux in excess of 200 kW m^{-2} were found at that location. Data obtained by Kotthoff[197] from realistically furnished rooms, mostly with wood materials, are also shown in Figure 20.

Similar magnitudes of results were also found in studies conducted at NRC in Canada[198]. When wood cribs were used, peak heat fluxes of 80 kW m^{-2} at 0.25 m above the top of a square-shaped window were measured, while 115 kW

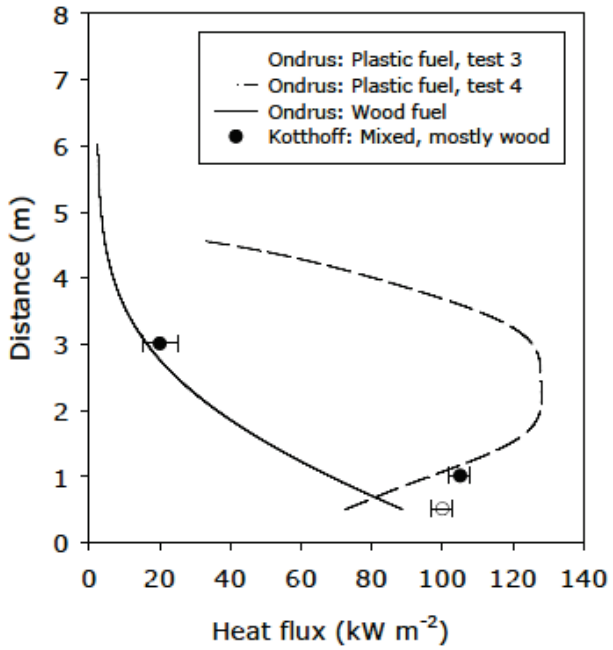

Figure 20 The heat flux to the façade, measured as a function of distance above the top of the window of the fire test room. Ondrus' values are for radiant heat flux, while Kotthoff's are for total heat flux.

m^{-2} was recorded with a tall, narrow window. In the same NRC study, propane burner fires were able to cause heat fluxes of over 200 kW m^{-2}; such extreme heat fluxes, however, require both very large fires (over 10 MW) and very large window openings. Fires under 6 MW did not create façade heat fluxes over 50 kW m^{-2} at a height of 0.5 m above window top.

The effect of combustible façade materials was studied by VTT researchers[199], who used wood boards to cover some, but not all, portions of a test building façade. Heat fluxes were measured at the center of second-storey and third-storey windows, the windows being directly in line above the window of the test room. For a non-combustible façade, a peak heat flux of 70 kW m^{-2} was found at the second-storey window; a peak heat flux of only 14 kW m^{-2} was found at the third storey. For wood board-lined façades, the second-storey heat fluxes were 100 – 112 kW m^{-2}, while 13 – 37 kW m^{-2} was found at the third storey.

The information about heat fluxes to facades presently available does not seem entirely adequate for design purposes. Nonetheless, for design purposes it would be appropriate to assume that heat fluxes of around 100 kW m^{-2} are likely to exist for the first 1 m height above the opening. This means that most combustible materials, if placed on the façade, would quickly ignite. Furthermore, much more than a single-story height (ca. 2.5 – 3 m) would be required for heat fluxes to drop below, say 12 kW m^{-2}. Even if the façade material themselves are non-combustible, the bottom of the window glass of the next higher storey may be only 0.5 – 1.5 m above the window top in the storey below. Some building codes require a non-combustible spandrel panel to separate vertically the windows of one storey from the next. But the typical requirement for a spandrel panel height is 0.6 – 0.9 m, and a 1966 FRS study[200], using a modest cellulosic-materials fuel load, showed that an 0.9 m spandrel is insufficient. Instead, the authors concluded that either fire-resistive glazing or an entire storey's-height of blank wall would be needed. The hazard with fuels having a substantial plastics content, as pointed out above, is higher.

The heat fluxes window glazing that may be permissible for design purposes can be considered in the context of the breakage of window glass. The flux of interest is not the one which will lead to initial cracking but, rather, one that will result in gross fall-out of portions of the glass. If glass both cracks and falls out, then evidently a nontrivial potential exists for ingress of either flames or firebrands from the fire taking place just outside the window. Research on this point is scattered, but it has been documented that 9 kW m^{-2} sufficed for gross fall-out of a single-glazed window[201], while 29.2 kW m^{-2} has led to failure of double-glazed plate glass windows, with gross fall-out of both panes[202]. However, both the details of the window installation and the probabilistic nature of the problem need to be considered, and research is not existent on either point.

Heat fluxes to other buildings

Massive exposure fires have been recorded, especially in earlier years when congested city centers were mainly of wood construction. Even in the 20th century, serious exposure fires have been recorded, and a survey[203] shows that ignitions across 24 m street-widths do take place. Some statistical data were collected in Japan[204] for wood-framed buildings (Figure 21). While their construction practices have not been similar to those in Western countries, nonetheless the general trend of the statistics is revealing. Even at 13 m separation, there is about a 20% probability of ignition of a neighboring façade.

The ignitable materials on the neighboring building may be its façade, such wood siding; but it may also be interior combustibles, which may become ignited once glass breaks out, or may ignite even prior to that, for high heat flux conditions.

The radiation source will vary depending upon the actual conditions. In general, the following may need to be considered:

- radiation from window openings (glazing assumed to be broken early during a serious fire);
- radiation from a fire plume of gases burning outside/above the window opening;
- radiation from a burning combustible façade;
- radiation from the entire structure, if the façade falls off but the remaining structure does not collapse.

In addition, it must be kept in mind that fires are not limited to still conditions, and strong winds may substantially affect most of the governing variables.

The radiant flux incident on a target can be computed as:

$$\dot{q}_r'' = F\varepsilon\sigma T^4$$

where ε = emissivity (--), σ = Stefan-Boltzmann constant (5.67×10^{-11} kW m^{-2} K^{-4}), T = temperature (K), and F = view factor (--). The latter variable depends solely on the geometry of the problem; if a target receives 100% of the radiation of the source, then $F = 1$. The remaining factors in the problem depend only on the combustion characteristics of the source and do not depend on the geometry. The group of factors $\varepsilon\sigma T^4$ is defined as the *emissive power* (kW m^{-2}) and represents the radiant heat flux falling on a target when the view factor $F = 1.0$. Thus, the incident radiant flux is conveniently taken as the product of the view factor and the emissive power of the source.

A fully-involved room fire may register temperatures in the vicinity of 900ºC. Viewed from the outside, if it represents 'cavity radiation' and thus the emissivity is taken as ≈ 1, an emissive power of 107 kW m^{-2} is obtained. The earliest study[205] on the subject, conducted at FRS in 1950, concluded that an effective temperature of 1000ºC should be used for determining the radiation from the window opening. This is somewhat high, and a more recent Swedish study documented values in the range of 800 – 1000ºC for a series of experimental, post-flashover fires[206]. Thus, a range of 75 – 150 kW m^{-2} for the emissive power was found. Window radiation values up to 222 kW m^{-2} were reported in tests by Law[207], but it appears that these were erroneous since the corresponding gas temperatures were measured as only 1060ºC.

There will also be a fire plume extending above the window if the fire is of any appreciable magnitude. The temperatures drop rapidly in the plume and the emissivity is much less than 1. The high radiation temperature value adopted in the FRS study stems partly from the fact that plume radiation was ignored and all of the experimentally-measured radiation was assigned to the window opening, thus creating an 'effective' value higher than the actual value from window radiation alone. In extreme cases, if an adjoining building is placed very close, not only could the external flame impinge on the adjoining structure, but even the convective gas stream emerging from a window opening could suffice for ignition. However, the radiation would be enormous at such a close spacing, so it can be assumed that the adjoining structure is far enough away that there is no direct gas/flame contact. Under those conditions, in one study[208] it was estimated that 12 – 18% of the total radiation received at the façade of a nearby building will come from the radiation of the external flames. Since the problem uncertainty is undoubtedly greater than 20%, this gives some justification to ignoring the contribution of the external flames.

Some experimental data on heat fluxes to adjoining buildings was obtained in Sweden[209]. A small, non-combustible test house having two windows and wood-crib fuel was used. Exposure heat fluxes were measured to an adjoining building located a variable distance away. Except for fires that produced only small heat fluxes, it was found that radiation was invariably higher at the eaves level than at the window level. Peak values found were 40 kW m^{-2} at a 4 m distance and 11 kW m^{-2} at 6 m away. A number of other experimental studies have been made where radiation was measured to remote targets[210,211], but none of them developed data in such a way as to enable radiation calculations to be made for arbitrary target distances. If the fire compartment has a high fuel load of plastics, rather than cellulosic fuels, higher plume emissivities and taller plume heights are expected, but full-scale research on this problem has been nil. When building façades are made of wood or other combustible material, the entire façade may become involved in fire on a burning building. Again, there is not much reliable data for design in this situation. *Wind* is a significant factor many actual exposure fires, but experimental data on its effects are scant. In general, safety factors built into design methods are expected to take into account its effects.

A different façade exposure—heat flux on a façade located adjacent to a simulated urban conflagration was measured in a Japanese full-scale test[212]. Values around 130 kW m^{-2} were recorded on a balcony against which flames were directly being blown from the flame front of the conflagration. However, because the balcony acts to shield the façade itself and to deflect flames, the heat fluxes to flat portions of the façade only registered around 50 kW m^{-2}.

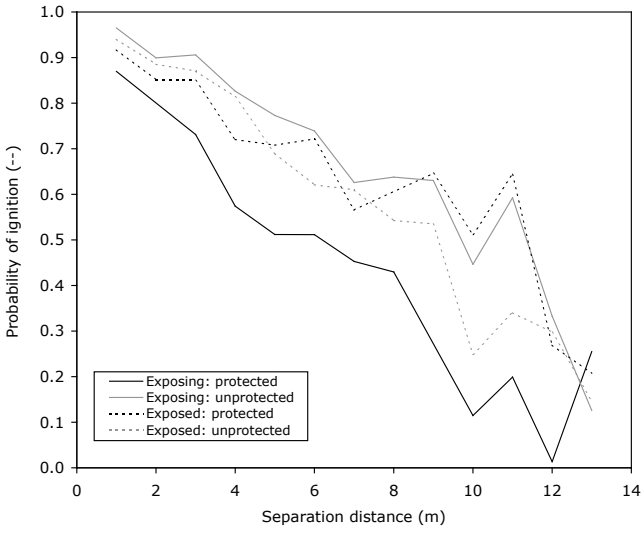

Figure 21 Probability of ignition of buildings from a nearby burning building (results from a Japanese study on wood-framed buildings with combustible and non-combustible claddings)

In an unusual study, Lynam[213] burned a small (2.4 × 5.5 m) plywood sales shack, of the type used in some locales for seasonal retail sales of fireworks. The stand was filled with 418 kg of fireworks of a wide variety, packaged in retail packages. Paper targets placed 4.6 m in front of the shack's open front windows ignited. Heat fluxes of 15 – 18 kW m^{-2} were measured at a location 4.3 m in front of the shack.; the author extrapolated that a heat flux of ca. 40 kW m^{-2} would have been found directly at the window openings. The measured flux values appear to be somewhat low, however, since a heat flux of less than 15 kW m^{-2} (taking into account 4.3 vs. 4.6 m distance) for about 160 s (duration of active burning) would not likely have sufficed to ignite paper targets. Fireworks were scattered to fairly large distances (over 35 m), but it was not determined if any of these projectiles would have been able to ignite combustible targets.

Design methods

Protection against heat fluxes from burning buildings is not normally provided by quantitative design calculations, but, rather, through code prescriptions, as discussed below. The only well-known engineering design method pertinent to the autoexposure problem comes from Law and O'Brien, who developed a method[211,214] for designing heavy-weight steel columns and beams to be used on façades exposed, without fire-protection coatings or coverings. Their method was based on experimental data where (a) the fuel was only cellulosic-based, without plastics; and (b) the ceilings were non-combustible. The second assumption is often enforced by building codes for high-rise structures, but the first assumption seems shaky, at least in today's perspective. Detailed engineering calculations for protection of nearby buildings could be done, but the rudiments thereof are incorporated into building code requirements and these are usually seen to be sufficient.

In view of the serious consequences of exposure fires, most building codes around the world have established some provisions dealing with radiant ignition of neighboring buildings. The provisions commonly require:

- that buildings not be built closer than a certain distance to the property line; or,
- that buildings, if they are built closer than a certain distance to the property line have features to avoid being (a) ignition sources (such as having no windows on that side, using only wired glass, providing steel shutters for all windows, or providing drencher sprinklers at windows); and (b) ignition targets (such as using only non-combustible or difficult to ignite façade materials); and,
- that buildings using combustible façades be separated by larger distances than ones where the façade materials themselves will not burn.

The practice for each building code or country is different, but generally fire temperatures are roughly related to some fuel load concept. Then, some radiation calculations are used to prepare tables or charts of allowable distances. These make additional assumptions about the size of the fire-source façade and the proportion of windows therein. Finally, a criterion is picked for the maximum allowable incident heat flux. Commonly, this is taken as 12.5 kW m^{-2}, which is considered as the nominal value of the minimum flux for ignition of wood products in the presence of a pilot*. Since most products have a higher minimum flux, and since an adequate pilot (e.g., a suitably large flying brand coming to the right place) is by no means assured, this value tends to be conservative, in view of the fact that autoignition fluxes are higher than those for piloted ignition. To complicate matters, the design guides often include concepts of risk management, along with fire physics. Because of this, a deterministic connection to real fire measurements cannot be established.

The earliest system presented for design purposes was developed at FRS[205]. The authors recommended that radiation view-factor arithmetic be done on the basis of radiation emerging solely from windows (and not from flames above windows). On that basis, they recommended that if a view factor is found to be less than 0.056, target ignition will not occur. For a source temperature of 1000ºC and emissivity of 1.0, this corresponds to a limit temperature of 150ºC being reached on the target. A more elaborate design system in the UK was presented in 1963 and the current UK guide[215] on the subject explains their approach. A French scheme was developed by Fackler[216,217] during 1954 – 56, whose studies were remarkably comprehensive. His second paper included a case history where fire propagated by radiation from a burning second story of one building to a parallel building 40 m away. In the US, the design methodology set out in NFPA 80A[218] is taken from McGuire's study[219]. On the basis of analyzing 3 fires (!), McGuire concluded that façades will ignite when the view factor reaches 0.07, for fires of 'normal hazard.' For 'hazardous' fires, a view factor of 0.035 was to be used, while in 'relaxed' conditions, a factor of 0.14 would be used. McGuire also proposed that 1.52 m be added to the required distance to account for the external flame, even though, based on his empirical factors, this was double-counting the flame effect. Flame temperatures did not enter into his scheme, since it was solely based on limiting the view factor. McGuire did not describe how hazard levels might be assigned, which NFPA 80A defines in a notably crude way. The emissive power for McGuire's three cases can be computed as 89, 179, and 357 kW m^{-2}. A value of 179 kW m^{-2} is somewhat higher than would be measured from a room fire, but may be reasonable if external flame contribution is ignored and the emissive power increased proportionally. The 357 kW m^{-2} value is patently unphysical, in the absence of exotic fuels.

* This value is appropriate if moderate exposure times are considered, e.g., 1 h or less. But experimental data are presented in Chapter 14 which indicate that much lower heat fluxes may suffice for ignition if the exposure lasts several hours.

Other design methodologies have tended to preserve more of the physics. Buchanan's guide[220] provides a simple computational approach. Barnett has written several papers[221,222] which form a good introduction to the designer. Collier[223] presented a design method implemented as a simple computer program. Complications arise when structures are involved where the façade is irregular or set back and some calculation schemes can become lengthy. Carlsson[208] reviewed in detail a number of the design methods and computed example cases. His results showed that: (a) the McGuire method gave the longest separation required distances; (b) the FRS method gave the shortest distances; (c) three other methods—those of Collier, Barnett, and NFPA 80A—gave results which were intermediate and were close to each other. In the absence of adequate real-scale validation, this exercise suggests the latter three methods should be preferred. The NFPA 80A method is based on McGuire's scheme and the reason that it was not found to be an outlier, but McGuire's was, is because NFPA 80A is relatively generous with use of the 'light' severity group, while McGuire discouraged its use.

Providing adequate vertical height between the top of one window and the bottom of the window above it is difficult, in view of the fact that approximately a 1-storey blank spandrel panel would need to be created to have a reasonable assurance that fire will not propagate via entry through windows[224]. Thus, in many building codes, the problem of storey-to-storey fire propagation through façade radiation is ignored. The use of checkerboard window arrangements can be made, but this does not necessarily assure safe heat flux levels in the case of wind parallel to the façade. The problem can be solved by use of fire-resistive 'eyebrows' (horizontally cantilevered panels above the windows) or balconies. Experimental evidence is available that balconies[225] or eyebrows[226] are effective as flame deflectors. Limited studies suggest that an 0.6 m projection is insufficient[200], but that a 1 m projection is adequate[224]. Harmathy[227] urged the use of drop-down eyebrows, which would be activated by a fire alarm signal. But the scheme is unlikely to be robust, since failure modes include freezing, rusting, and lack of maintenance.

BURNING FORESTS AND VEGETATION

Heat fluxes from a forest fire burning with flame-front heat release rate of 346 kW m^{-1} have been measured by Packham and Pompe[228]. They concluded that the radiant heat flux (convective heat flux was not measured) was typically 100 kW m^{-2} at the flame edge. At a distance of 7.6 m from the flame front, a radiant heat flux of 57 kW m^{-2} was estimated. The variation of heat flux over time was not studied. Telisin[229] used medium-scale test results to derive an emissivity for the flame front in burning grasslands as:

$$\varepsilon = 1 - e^{-0.16(L+0.375)}$$

where L = flame thickness (m). Measured flame temperatures were approximately 1000ºC.

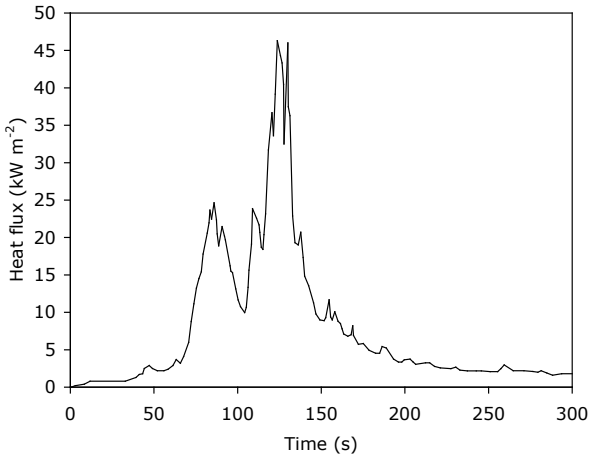

Figure 22 Heat flux measured at 10 m from the flame front of a crown fire

Grishin[230] summarized Russian research on the topic. Grishin distinguishes between a 'general crown fire' and a 'top crown fire.' The latter involves propagation of isolated fire over the crowns, without constituting a steady flame front and without an accompanying surface fire. Based on a series of experimental fires, he determined that temperatures in a 'general crown fire' were typically around 800ºC at the hottest part, although instantaneous fluctuations were some 200ºC higher. Typical heat flux distribution measured at the center of the fire was only 15 kW m^{-2} total. At some 2 m away from centerline (about midway between the center and the edge of the burning), the peak heat flux readings of 120 kW m^{-2} were found, of which about 95% was due to radiation. Peak heat fluxes of 125 kW m^{-2} were recorded in an experimental 'top crown fire,' but most (74%) of the heat was being released as convective flow, so the drop-off of heat flux with distance was apparently precipitous, although unspecified. A fire of this type is very brief: after 15 s, heat flux was no more than 60 kW m^{-2}, while after 40 s, it was no more than 30 kW m^{-2}. By 60 s, combustion had ceased. None of the test fires, of either type, lasted more than 80 s in duration. Grishin's experimental fires did not quite have the fuel load of a mature forest, so his measurements presumably somewhat underestimate severe fires in natural forests.

More recently, Cohen[231] measured the total heat flux at a distance of 10 m from an experimental crown fire that had flame heights of ca. 20 m (Figure 22). A peak of 46 kW m^{-2} was recorded, but this lasted only a few seconds. The tests also included mockup wood building facades placed at several distances away from the flame front. Walls 10 m away scorched, but did not ignite; ignition, however, did occur on a wall that had direct contact with the flame front.

BURNING VEHICLES

The Fire Research Station[232] characterized the radiant heat flux from a burning camper and a burning mobile home. Their results are shown in Figure 23 and Figure 24. The results were obtained at 10 min after ignition, which was close to the peak burning time.

HEAT FLUXES IN PRE-FLASHOVER ROOM FIRES

Heat fluxes occurring in pre-flashover room fires will vary widely. Away from the initial source of fire there will be essentially no heating at all. Near a small initial fire source, heat fluxes of the sort associated with small flames will be seen. With increasing fire spread and involvement, a hot gas layer will build up below the ceiling. The heat fluxes will be significantly hotter within this layer than in lower spaces. Söderbom[233] found values typically < 45 kW m^{-2} at the center of the ceiling during pre-flashover fires. The value at the floor level is, of course, always < 20 kW m^{-2} prior to flashover, since attaining 20 kW m^{-2} at floor level is one definition of flashover[234]. Combustion at floor level, however, is not generally where the attention is focused.

HEAT FLUXES ON BURNING WALLS

For burning walls, a number of studies have explored the heat fluxes from the flame to the yet-unignited portion of the surface. Hasemi studied this problem in detail[235] and provided correlations. For his experiments, peak values of ca. 25 kW m^{-2} were seen for the region downstream of the ignited area, but before the tip of the flames; beyond the flame tip, fluxes were no longer constant, but dropped off further downstream. Additional similar data have also been presented in a summary form[137]. More recent work by Kulkarni et al. has enlarged the diversity of material types examined[236]. The value of 25 kW m^{-2} is seen from these more extensive studies to be the lower bound of where data are clustered—most of the data are in the interval from 25 to 45 kW m^{-2}. Thus, a value of 35 kW m^{-2} might better capture the mean behavior. A 35 kW m^{-2} (or, alternatively, a range of 25 – 45 kW m^{-2}) heat flux, then, can be used to characterize the peak level of heating to a vertical surface element from its own upstream flame, just prior to its ignition. This value needs to be increased if the material is so situated as to be in a hot gas layer that is accumulating in the upper reaches of the room. Apart from the data of Söderbom, discussed above, this additional heating has not been studied.

HEAT FLUXES IN POST-FLASHOVER ROOM FIRES

The maximum temperatures actually seen in post-flashover room fires are ca. 1100ºC. A perfect black-body radiator at that temperature would produce heat fluxes of approximately 200 kW m^{-2}. Peak heat fluxes measured in post-flashover room fires can come close to this value, but are usually somewhat lower. Fang's results from an extensive series of room burns[237] are shown in Table 24.

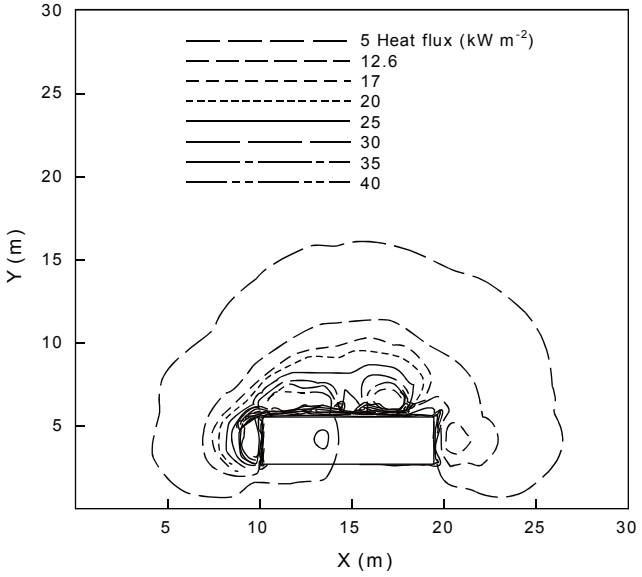

Figure 23 Radiant flux from a burning camper, measured near peak burning time, at a height of 1.8 m

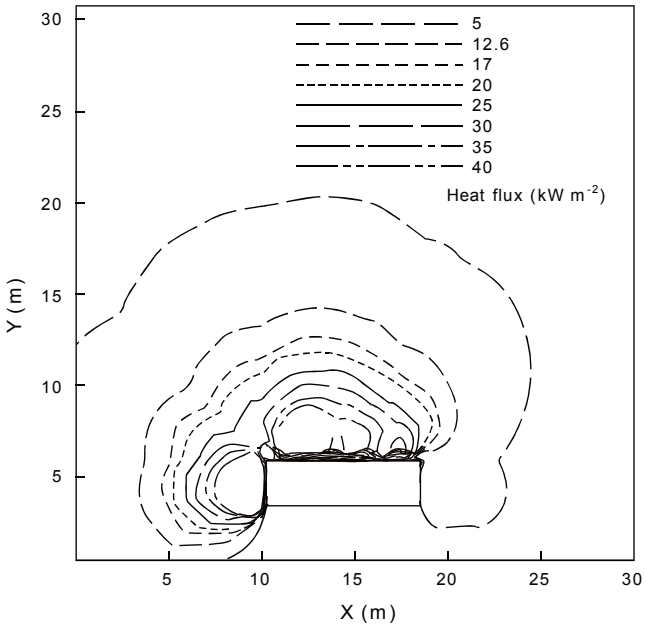

Figure 24 Radiant heat flux from a burning mobile home, measured near peak burning time, at a height of 1.8 m

	Heat flux (kW m^{-2})		
	Ceiling	Walls	Floor
Average	68 – 147	91 – 194	--
Maximum	106 – 176	116 – 229	119 – 143

ATTENUATION OF RADIATION BY WINDOW GLASS AND WINDOW SCREENS

Window glazing will attenuate radiation but only, of course, if it has not cracked and fallen out. Ordinary window glass can be expected to start falling out (not just to crack) when heat fluxes around 20 kW m^{-2} are reached[202]. The actual value depends on many factors, including the size of the pane. There is some probability of fall-out at a heat flux as low as 9 kW m^{-2}, but the probability of fallout does not become high until about 35 kW m^{-2} is reached. Double-glazed windows can resist approximately 25 kW m^{-2} without fall-out. Tempered glass is able to resist fluxes of 43 kW m^{-2}, at least under some conditions.

Thus, for ordinary window glass, ignition of objects inside a room by flames outside a window is most likely to occur only after the glass has fallen out. In some cases, however, ordinary window glass withstands high temperatures and heat fluxes and responds by slumping rather than cracking, as documented during some Australian wildfires[356]. The latter behavior is evidently somewhat rare and detailed factors have not been studied. There also exist various types of heat-resistant glass which can withstand high heat fluxes, thus the problem of attenuation of thermal radiation through glass needs to be considered.

Ordinary window glass transmits radiation at wavelengths between 0.35 and 2.7 μm very well, moderately between 2.7 and 4.25 μm, and essentially not at all for other wavelengths (Figure 25)[240]. The attenuation is very largely due to the stop-bands of the glass. Within the region of 0.35 to 2.7 μm, Bracciaventi's experimental measurements[238] showed that transmission is between 80 and 90%. Knowing the spectral transmission of the glass and the radiation temperature of the source body, the fraction of fire radiation which is transmitted through an intervening pane of glass can be estimated, as shown in Table 25[239]. Peak temperatures from a fire outside a window are unlikely to be much over 1000ºC. Under those conditions, even a single pane of the thinnest window glass in common use attenuates more than half of the incident radiation. The radiation is attenuated more if the angle of incidence is not perpendicular, but for conservativeness the perpendicular condition may be assumed.

Table 25 Transmission of thermal radiation through 3.2 mm thick window glass

Source temperature (ºC)	Transmission (%)	
	Perpendicular incidence	Diffuse radiation
900	35	31
1000	40	36
1200	49	44
2315	55	--
2727	83	--
4727	84	--
5727	85	--

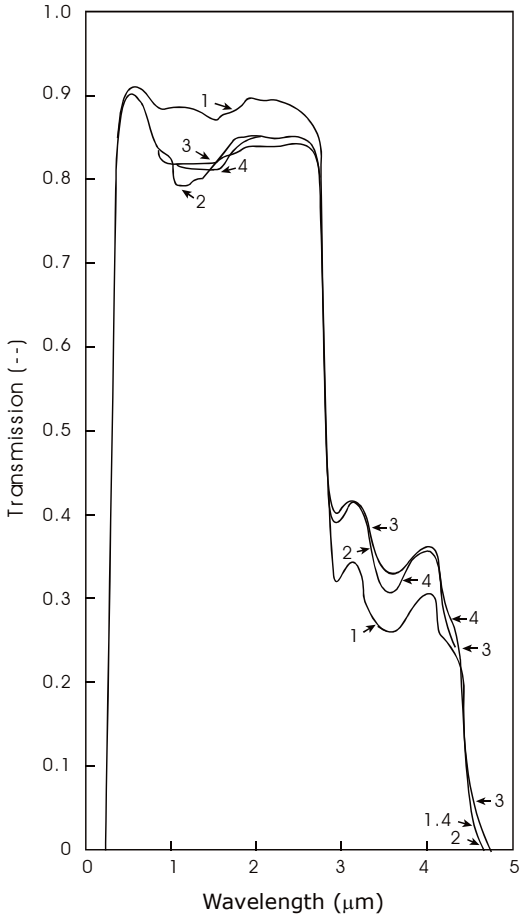

Figure 25 Spectral transmission of window glass (numbers denote four different samples)

Attenuation of radiation from a 2315ºC black-body source, taken as being representative of nuclear blast fireball radiation, was calculated by Downs and Bruce[240] while Bracciaventi[238] made calculations for higher-temperature sources; these additional results are also shown in Table 25. The angle of incidence, if not perpendicular, makes little difference until about 45º, after which point transmission falls drastically[238].

In Bracciaventi's study, the effect of soiling of the glass was also explored. After 44 days of soiling (and a visibly filthy appearance), the transmission decreased only by about 1%.

Since wired, toughened, and other forms of fire-resistive glass are able sustain high temperatures, if the thermal exposure is not of very short duration, then the glass itself will equilibrate to an elevated temperature and will provide a glass-radiated heat flux contribution to the total heat flux found on the far side, not just a transmitted portion. An experimental study where the transmitted and re-radiated heat fluxes were measured through 6 mm plate glass was performed by Moulen and Grubits[241]. Over the heat flux range

of 11.3 – 40.1 kW m^{-2}, about 40 – 45% of the incident heat flux was received on the far side, divided roughly into 60% transmitted and 40% reradiated. Wired plate glass showed slightly lower far-side heat fluxes. In these experiments, the transmitted flux percentage showed a decrease with increasing values of incident heat flux, the reason for this is unclear. Similar studies were conducted by Cowles[242], who conducted a series of 1.5 h fire-endurance furnace tests on several fire-resistive glass types, following the standard time-temperature curve[243] in the furnace. His results are shown in Table 26; the lower values were usually seen late in the test, and the higher ones earlier. The higher transmission measured at BRANZ can be attributed to the higher fluxes used in their tests.

Table 26 Effective transmission of heat flux transmitted through glass (sum of directly transmitted fraction and heat flux radiated from its surface), as determined in fire endurance furnace testing at BRANZ

Glass type	Total heat flux received (% of incident heat flux)
borosilicate glass, heat-strengthened, 6.5 mm	67 – 70
ceramic glass, 5 mm	75 – 89
wired float glass, 6 mm	55 – 62

The spectral transmittance of window screens was measured by Bracciaventi[238]. Within the region of 0.35 and 2.7 μm, transmission was about 66 – 72% for new aluminum screens, 62 – 66% for aged aluminum, 60% for plastic, and 55% for new copper screens. Transmittance was not measured outside this spectral region, so total transmission could not be characterized, but was probably no higher than the above values. In modern energy-efficient housing, it is becoming somewhat common to use double-glazed 'low-e' windows. These have coatings which transmit radiation in the visible spectrum but are reflective for the longer infrared wavelengths. Modeling has suggested that windows of this type may prove substantially more difficult to break out from fire radiation[244], and in addition there will be a much smaller transmittance of infrared energy. Actual test results on fire performance is not yet available. For specialized applications, it is possible to procure fire-resistive glass which is tested and shown to be able to resist post-flashover fire temperatures (and accompanying radiation) for substantial periods of time. At the present, however, this type of glass is costly enough that it is not in general use.

Electric phenomena

In this Section, the basic principles are examined which govern the ability of electric current or static electricity to deliver potentially incendive amounts of energy into a system. Practical aspects of failures associated with electrical wiring and devices are presented discussed in Chapter 14. Ignitions of gases, dust clouds, and solids from electrical energy sources are studied in Chapters 4, 5, and 7, respectively.

ELECTRIC DISCHARGES

Due to cosmic radiation and other factors, a small number of free electrons is always present in air. If an electric field is applied, the electrons move in the direction opposite to the electric field, i.e., to the positive electrode. If the electric field strength is increased (i.e., a sufficient voltage is applied), the electrons move faster, but still collide elastically with molecules in the air. As the field strength increases further, the collisions become inelastic and a collision of a molecule with an electron results in the fragmenting of the molecule, so that an electron is emitted and the remaining molecule becomes positively charged. This is termed *ionization*, since the molecule has become ionized (that is, it has acquired a net electrical charge). Once both positive and negative charges are present in the space, an electric current flow can occur, with electrons moving towards the positive electrode (anode) and positive ions towards the negative (cathode). The current flow that occurs when a sufficiently high voltage is applied is termed a *gas discharge*. If a sufficiently high, uniform electric field is applied, then an electric arc (sustained) or spark (not sustained) can occur. An electric arc requires that a sufficiently high current (more than ca. 0.1 A) be available. If sufficient current is not available, but the voltage is adequate (300 – 400 V), then a *glow discharge* may be sustained. A glow discharge can often be seen in the vicinity of a single pointed electrode. In a glow discharge, electrons are liberated from a cold cathode by collisions of positive ions—heating of the cathode is not involved.

For electrical breakdown of air to occur, the kinetic energy picked up by an electron due to the acceleration by the electric field must exceed the energy needed for ionization of a molecule of air. When ionized, the air molecule emits an electron, and the process accelerates. Soon there is an avalanche of electrons proceeding towards the anode. Additional electrons are emitted, as positive ions collide with the cathode. Ionizing radiation occurs when ion-electron pairs recombine, and this radiation falling on the cathode stimulates more electrons to be liberated at the cathode by photoemission. The whole process is sometimes termed the *Townsend discharge*.

The kinetic energy W gained by an electron when accelerated by an electric field E over a distance L is:

$$W = EeL$$

where e is the charge of the electron (1.6×10^{-19} C). The mean free path (average distance between two collisions) for an electron in air is 4 μm. The energy required to ionize a nitrogen molecule is 15.8 eV and for oxygen is 13.5 eV. An electron volt (eV) is a unit of energy equal to 1.6×10^{-19} J. The above relation can be solved for the minimum electric field E_{min} (V m^{-1}) which will lead to breakdown:

$$E_{\min} = \frac{13.5}{4\times10^{-6}} \approx 3\times10^{6}$$

Thus, when the electric field exceeds about 3 MV m^{-1} breakdown is estimated to occur. This is a very rough estimate, and Paschen in 1889[245] established a relation between breakdown voltage, spacing of electrodes, and gas pressure which has become known as Paschen's Law. According to Paschen's Law, the pressure × gap distance product is the controlling variable and the breakdown voltage V is given by:

$$V = \frac{c_1 pd}{c_2 + \ln(pd)}$$

where p = pressure, d = gap distance, and c_1 and c_2 are constants. Modern measurements[246] of Paschen's Law curves for air and for nitrogen are shown in Figure 26. For discharges from gaps greater than about 0.1 mm, it can be seen that the curve is essentially a straight line. For smaller gaps, however, the breakdown voltage does not go to zero and, instead, a minimum breakdown voltage is found. The Paschen curve goes up at both ends, i.e., for both small and large spacings, because of two different factors affecting the ionizing discharge process. For large gaps, the electric field is small enough that there is not a sufficient number of free electrons to initiate an arc. With a very small gap, the electric field is high and there is a high emission of electrons, but the inter-electrode spacing is very small. Consequently, the probability is low that an electron will strike and ionize a sufficient number of air molecules to start an avalanche breakdown. This minimum of the Paschen curve is approximately 340 V, and it occurs at a *Pd* product of 0.007 atm-mm. In other words, in ambient air, the minimum breakdown voltage occurs for a gap of 0.007 mm (7 μm). This is an exceedingly small distance, and two conductors this far apart would appear to be touching to the naked eye. Experimentally studying the left-hand portion of the Paschen curve requires some specialized techniques, since otherwise discharge may occur over a longer path (but lower voltage) than via the desired minimum-length path. The optimum gap size is on the order of the mean free path length of an electron; if the gap is reduced further, collisions become unlikely and emission from the cathode must primarily be relied upon to supply electrons.

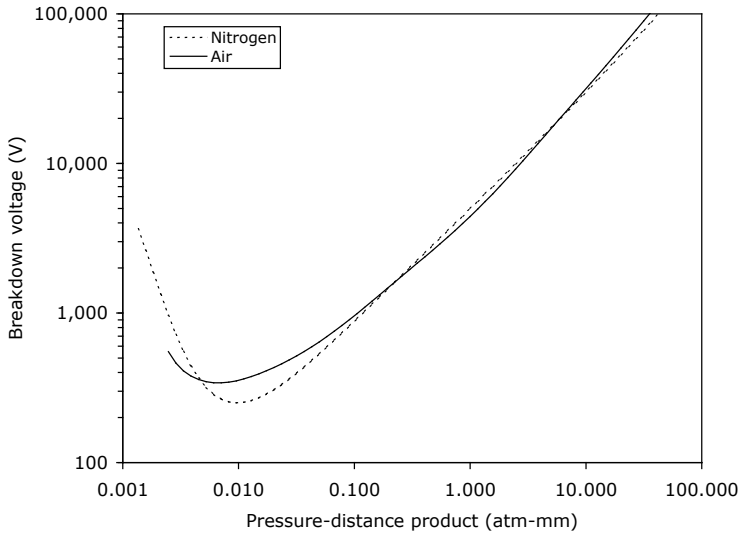

Figure 26 The breakdown voltage (Paschen's Law) between spherical electrodes in air and nitrogen

For practical applications, it can be more convenient to present results in the form of the *dielectric strength* (MV m^{-1}) which is the breakdown voltage, divided by the thickness of the insulator. This is shown in Figure 27 and indicates that for larger distances, the dielectric strength of air is approximately 3.0 MV m^{-1}; the value for nitrogen is quite similar.

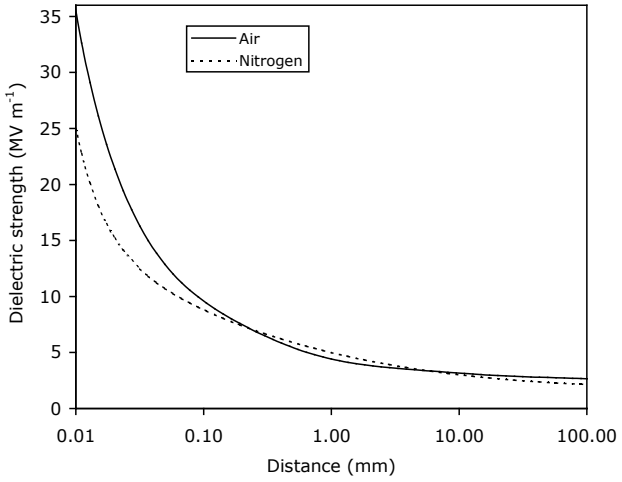

Figure 27 The dielectric strength at 1 atm, as a function of distance

The effect of *humidity* is not large, but humidity can either raise or lower the effective dielectric strength of air. This effect is governed by the voltage/time characteristic of the applied voltage, the polarity, and the details of the electrodes[247]. A fog lowers the breakdown strength to a modest extent[248], but the effect becomes large with a salt fog. At moderate *temperatures*, the dielectric strength of air is directly proportional to density[249], thus it varies also directly with pressure and inversely with temperature. But if the temperature is raised beyond about 450 K, the dielectric strength drops by more than a $1/T$ factor; beyond 2000 K the proportional reduction becomes even greater and at 3500 K the strength has dropped to about ½ that which is accounted for by the $1/T$ factor[250]. At high *elevations*, the decrease in atmospheric pressure becomes significant and the breakdown strength is lower; this affects electric installations in high-elevation locales. *Dust* will lower the breakdown voltage, but quantitatively the effect is small[251]. For atmospheres involving *gases other than air*, the

nature of the molecule involved affects the breakdown characteristics. Molecules differ in their ionization potential (energy needed to lose an electron) and their electron affinity (tendency to capture an electron). Molecules having a higher ionization potential and a higher electron affinity require a higher electric field in order to cause a discharge. When a *fire* is present, the dielectric strength is greatly reduced, as discussed in Chapter 14. Introducing *unignited fuel* into an atmosphere was studied by PTB[252]. Using an 0.6 mm gap where the breakdown voltage in air was 3.3 kV, in pure methane it was 2.0 kV, in pure hydrogen 2.9 kV, and in pure propane 3.7 kV. The effect was not linear with respect to fuel gas concentration, and small amounts of hydrogen actually raised the breakdown strength, with a value of 3.6 kV found for a 10% H_2/air mixture. Breakdown can also occur in a *vacuum*, since field emission of electrons from the cathode is possible. The breakdown strength of vacuum[253] is on the order of 500 MV m^{-1} for short gaps, but the actual value depends quite a bit both on the metal of the electrodes and on whether they are clean or contaminated. Breakdown of air and even traveling fireballs can be created by radiation from extremely powerful *lasers*, but enormous energy fluxes of $10^{11} – 10^{15}$ kW m^{-2} or greater are required[253].

Other variables that can affect the breakdown strength include electrode shape, electrode surface contamination, and the polarity (if electrodes are not identical). The standard Paschen's Law curves assume that the impressed electric field is uniform, which it rarely will be, except in controlled laboratory experiments. Deviations occur if the field has non-uniformities. Field non-uniformities act to raise the breakdown voltage, so they can conservatively be ignored[254]. A higher breakdown voltage is required for steel electrodes than for copper. For nitrogen, the minimum breakdown voltage is ca. 255 V with copper electrodes and 350 V with steel. Even at 1 atm in air, there are deviations from Paschen's Law. For instance, breakdown between two highly polished silver spheres at a gap of 0.25×10^{-3} mm (0.25 μm) was observed at only 50 V by Germer[255]. However, this was the lowest voltage found in a long series of tests—the outcome was highly variable and the average breakdown under these conditions required 200 V. Germer also produced a gap vs. voltage curve showing that the Paschen curve was violated everywhere to the left of its minimum. In the region between 0.001 and 0.008 mm, the breakdown voltage was a constant 340 V, instead of rising with decreasing gap size. Below 0.001 mm, the results showed a constantly falling breakdown voltage, going from 340 V at 0.001 mm to very low values as the zero limit was approached. Unfortunately, it is not clear from these studies under what conditions it can be expected that the Paschen curve will be obeyed—or not. Despite the fact that anomalous characteristics of such very short arcs have been documented, their electrical-safety implications have not been explored, primarily because the design of electrical equipment is based on minimum spacings being much greater.

Paschen's Law curves are identical for both AC and DC voltages. But since AC voltages are normally described by their root-mean-square (rms) values and not the peak values, this means that if results are to be applied to AC voltages, then the values indicated in Figure 26 need to be divided by $\sqrt{2}$. Thus, on an rms basis, the minimum AC breakdown voltage is = 340/1.414 = 240 V(rms). The dielectric strength of liquids and solids can also be characterized by similar graphs, but there are more extensive complications with condensed-phase insulators and specialized references should be consulted[256].

It must be emphasized that Paschen's Law is *not* used in the design of low-voltage equipment. Figure 28 compares the breakdown gap according to Paschen Law to values mandated by IEC 60079[257] for the design of electrical equipment. There are many standards worldwide that govern gap sizes (clearances) required for low or medium-voltage equipment, but they all mandate values much larger than the minimum that would suffice to prevent breakdown. Using the IEC 60079 example, at 10,000 V the safety factor is 41×, increasing to 78× at 1000 V and 700× at 240 V. At 120 VAC, of course, Paschen's Law would predict that breakdown is impossible, but the clearance mandated is 2.5 mm. According to Paschen's Law, to obtain breakdown for a 2.5 mm gap requires 6500 V.

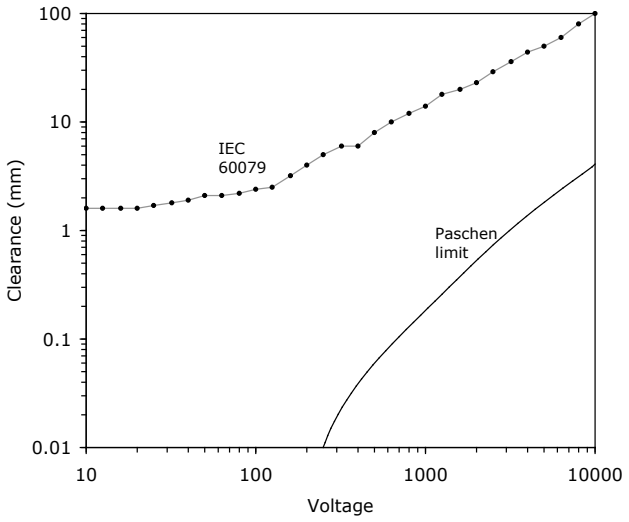

Figure 28 Comparison of Paschen values for an air gap at a given voltage (rms) to clearances required by IEC 60079

Electric 'sparks' and 'arcs' are terms that are basically similar and are sometimes used interchangeably. Thus, the loosest definition is "Electrical arc or spark: The transfer of electrons across a gap." In most cases, however, it is useful to observe differences between the two terms. Both refers to a discharge which occurs in a medium—commonly air—when the impressed voltage exceeds the dielectric strength of the medium. In one set of definitions, the differences are expressed thus:

- An electric *spark* is a dielectric breakdown of a gas between two electrodes in which the liberation of secondary electrons from one of the electrodes is the major feedback mechanism to sustain the discharge.
- An *arc* is a stable discharge between two electrodes in which thermionic emission is the feedback mechanism responsible for sustaining the discharge.

The primary difference is that *spark* denotes a transient phenomenon, while *arc* denotes a sustained event. If a discharge is sustained for prolonged time, eventually the cathode heats up sufficiently so that thermionic emission from the cathode becomes an important mechanism of liberating electrons.

THE ELECTRIC SPARK

The details of spark ignition are complex and involve an interaction of physics and chemistry effects. Much of the process is now understood, because of its importance to wanted ignitions, specifically, towards improvements in internal combustion engines. However, mathematical theories of all forms of electric discharges are highly complex and specialized, and only the simplest results will be reviewed here.

Maly and Vogel[259] have provided a detailed explanation of the process as it occurs in lean mixtures. The ignition process occurs in three basic phases. When a high voltage (typ. 15 kV) is presented across a small gap, for about 10^{-9} s there is no current flow. After that time, the *breakdown* phase begins. An extremely large current of about 200 A flows for 1–10 ns (1 ns = 10^{-9} s). A cylindrical plasma channel of about 40 μm diameter develops. The plasma rises to a temperature of ca. 60,000 K. Such enormously high temperatures which are localized to a small area are difficult to measure experimentally, and earlier literature had generally given lower values.

The electrical energy supplied is converted into the energy of dissociating and ionizing the molecules in the plasma channel. The dissociated species are typically radicals such as the atoms C, H, O, and N. The pressure in the channel jumps to about 200 atm and is accompanied by the formation of a shock wave. The shock wave causes expansion of the plasma channel, which then causes the temperature to drop. This leads into the *stationary arc* phase. This phase is much longer and lasts for about 1 μs (10^{-6} s). During this phase, the voltage across the gap drops to about 50 V. The current is highly dependent on the impedances of the external circuit, but is several orders of magnitude lower than the current during the breakdown phase. Only about 1% of the molecules remain ionized during the stationary arc phase, but the degree of dissociation remains high. The arc expands to a width of a couple mm, due to a combination of heat conduction and mass diffusion. The temperature during this phase is on the order of 6,000 K, but heat release is negligible. The current continues to fall during this phase. When it drops below about 200 mA, the final phase occurs. This is the *glow discharge*, and it lasts for more than 1 ms (10^{-3} s). During this final phase, the gap voltage rises to 200–500 V, while the current continues falling below the 200 mA level. The temperature is now ca. 3000 K, with less dissociation and only about 0.01% ionized molecules.

For some purposes, it can be useful to characterize the resistance of the spark channel. Eckhoff [260] analyzed a number of studies and concluded that all of the results can be collapsed into a single relation for R (Ω):

$$R = 40 L_s I^{-1.46}$$

where L_s = spark gap (mm), and I = current (A). The studies were all based on capacitive discharge, so the equation should not be applied to other conditions. The relation is

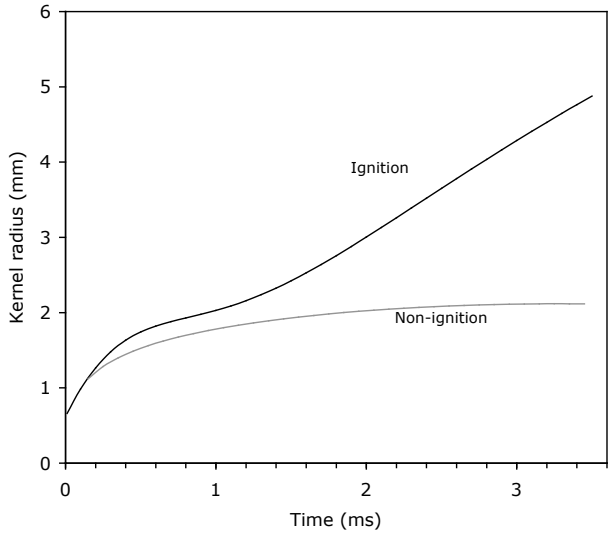

Figure 30 Growth of spark kernel in methane/air mixtures ($\varphi = 0.9$)

valid for discharge currents of 1 mA to 10 A. Chapter 4 contains further information on electric circuit parameters and their effects on spark discharge characteristics.

The spark kernel always dies out if spark discharge is in a non-flammable atmosphere. But if the atmosphere is flammable, the spark kernel, once created, may propagate or die out and not propagate (Figure 29). Conceptually, the problem is that of self-heating, as discussed in Chapter 4. The generation of heat from chemical reactions is proportional to the volume of the kernel, while the heat losses are proportional to its surface area. Thus, if the kernel becomes sufficiently large, it has a chance of surviving, i.e., propagating. Up until it reaches that size, however, it is dependent on there being sufficient electrical energy put into it to sustain its growth.

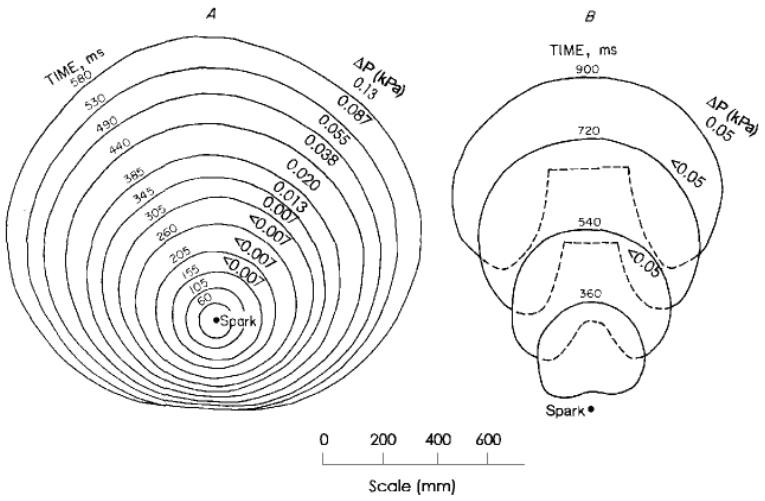

Figure 32 Flame development after spark ignition in methane/oxygen/nitrogen mixtures[270]

If the spark is of short duration, then the flame kernel initially starts out ellipsoidal shaped, then changes into a toroid (doughnut shape), centered on the spark gap. Some illustrative examples photographed by Kono and coworkers are shown in Figure 31, while Figure 33 shows the computed temperature field in the early stages of spark kernel development[261]. At about 200 μs, the kernel either starts decaying or expanding, leading to sustained ignition in the latter case[262,263]. This is taken to suggest that a value of around 200 μs is the minimum time required for ignition. At about 1 ms, the toroid shape becomes spherical.

Lintin and Wooding[264] reported on results of spark kernel growth in methane/air mixtures. Figure 30 shows that up to about 200 μs (0.2 ms) the growth curves of sparks leading to ignition and to non-ignition are identical. After that point, they diverge and after this time, in the non-ignition case, the kernel slows its growth and shortly thereafter stops growing. As a rough criterion, it has been suggested that the spark kernel must grow to a certain size radius by 200 μs if ignition is to occur. The value depends both on the nature of the gas and on its equivalence ratio; for hydrocarbon gases at $\varphi \approx 1$, radii of 2 – 3 mm are needed[262]. The initial volume of the kernel is proportional to the spark energy. Once formed, the size of the flame kernel in the early stages grows with its diameter increasing proportionately to ln (t), as demonstrated experimentally by Chomiak[265]. This growth rate is generally independent of any local flow velocity and is also independent of the exact fuel fraction in an ignitable mixture. These results pertain to still-air conditions; a similar study on turbulent methane/air mixtures was reported by Akindele et al.[266] The time scale discussed above is the one pertinent to normal capacitive discharge sparks. In the case of inductive sparks which are intentionally of long duration (e.g., for internal combustion engines), the time scale is different and the critical radius is much larger[267]. Similarly, the time and distance scales become large for flames at sub-atmospheric pressures[268]. Once kernel growth is established, Xiong et al.[269] documented that the radius continues to grow at a rate which is very close to linear: in methane/air and propane/air mixtures, they saw a linear growth up to the maximum size studied, 35 – 40 mm.

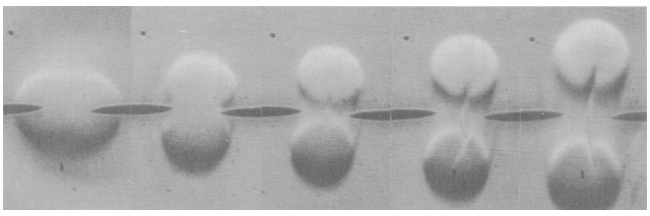

Figure 31 Development of a toroidal kernel (times: 4, 14, 24, 40, and 70 μs)
(Copyright The Combustion Institute, used by permission)

The further development of the flame front from a spark ignition has been studied by the Bureau of Mines[270]. Figure 32 shows flame development for two methane flames, developing in a 3.65 m diameter sphere. The first flame (A) is in a mixture which is well within the flammability limits, with the second one (B) being a near-limit mixture. The near-limit flame shows only vertical flame propagation, while flame A shows also substantial downward propagation, although, because of buoyancy, upward propagation is always greater.

In many practical cases, the flame development is much less uniform and symmetrical than in this example. Figure 34 shows flame kernel development photographed by Dobashi[271] under several conditions. Only when the mixture is uniform and quiescent is there a spherical pattern. Otherwise, even at the early stages the flame shape is already highly irregular.

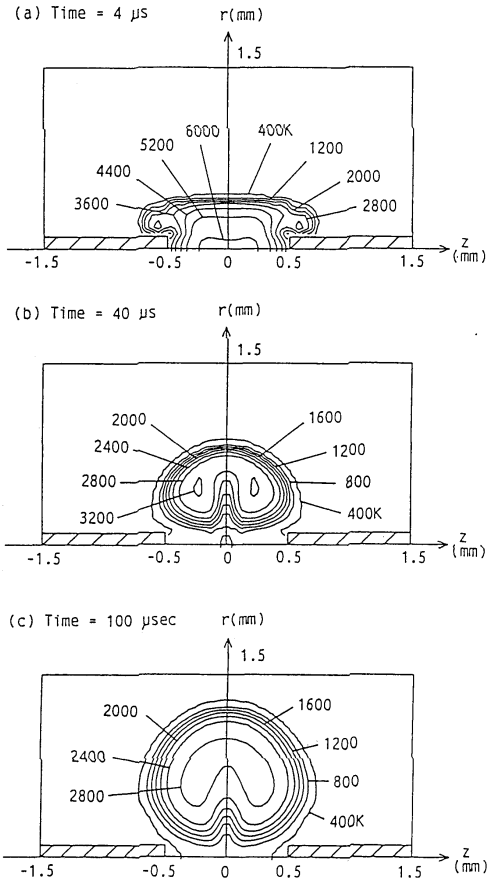

Figure 33 Computed temperature field in the early development of a spark kernel
(Copyright The Combustion Institute, used by permission)

Using their 3.65 m sphere, the Bureau of Mines ignited a mixture of 13% CO in air[272]. The flame development (Color Plate 18) shows strong irregularities, despite the ideal test conditions.

Thiele et al.[273] reported the results of an ambitious numerical modeling effort in representing the growth of a spark, even though their study was restricted to a 2-dimensional, cylindrical representation. This captures most of the important features, but not buoyancy effects. The model includes detailed chemical kinetics, radiative transport, and an electrodynamic model, but not the very earliest stage of breakdown channel development. Using the model, they made detailed calculations of spark development in air, hydrogen/air, and methane/air mixtures, although details of the latter were not given. The model gives realistic predictions of the development of the toroidal shape of the flame kernel. An interesting result from the simulation is that the growth of the flame kernel (radius vs. time) is affected by the shape and size of the electrodes. In a hydrogen/air mixture, flame kernel growth is much faster than in methane/air. By 0.2 ms, the kernel reaches about 4 – 5 mm, whereas in methane/air, the radius is only about 1.3 mm, as shown in Figure 30. In methane/air mixtures at normal gravity[274], a spark kernel initially rises at a speed of about 0.3 – 0.6 m s^{-1}.

In a computational study, Sloane and Schoene[275] examined the optimum fraction of total ignition source energy in the form of energy of dissociation. For stoichiometric methane-air mixtures, about 10% of total energy in the form of dissociation was found to be 'optimum,' i.e., leading to the lowest total ignition energy requirement. The effect was very mild, however. The optimum dissociation fraction lowered the minimum ignition energy only by about 6%. The effect was much greater on the ignition delay time. Under one set of conditions, providing 10% of the energy in the form of dissociation lowered the time from 250 μs to 100 μs.

Spark development has also been studied within the automobile industry using extremely rapid discharge circuits of ca. 50 ns during which time a peak power of 1 MW is reached; however, the characteristics of such ultra-rapid discharge sparks are not identical to those created in normal test circuits, nor to those of accidental electrostatic discharges[276].

The *net energy* available from the spark for ignition purposes excludes those portions developed in the cathode-fall and anode-fall portions of the spark channel[277] (see Figure 36). This concept would have a practical utility if an equation were available relating the fraction of energy that is available to physical details of the electrode arrangement, but such a partitioning rule has not yet been offered.

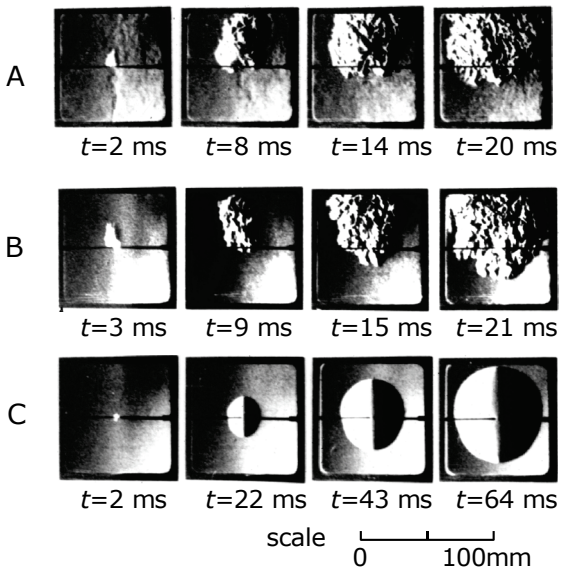

Figure 34 Flame kernels studied by Dobashi. **A**. non-uniform mixture, turbulent; **B**. uniform mixture, turbulent; **C**. uniform mixture, quiescent
(Copyright Elsevier Science, used by permission)

For extremely small gaps on the order of 0.2 μm, a category of spark known as *contact discharge* can occur. In a contact discharge, the bulk of the energy is dissipated at the anode surface, raising it to its boiling point and vaporizing it. A shower of molten metal is sometimes visible in the discharge. Eventually, the vapor condenses on the cathode. The process can ignite certain very sensitive solid explosives[278] and has mostly been studied in the context of susceptibility to electrostatic discharge.

Ignition of various substances by electric sparks is considered in Chapters 4, 5, 6, 7, and 14.

THE ELECTRIC ARC

As discussed above, a spark is, by definition, a non-steady phenomenon. In addition, there are several types of steady-state gas discharges, as shown in Figure 35. Only the arc is important of those from a safety viewpoint, and it corresponds to discharges of the highest current and the lowest voltage.

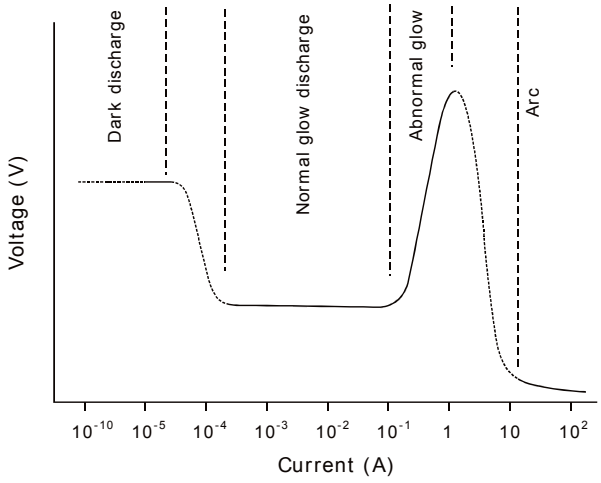

Figure 35 Schematic representation of steady-state voltage and current for several discharge types

Electric arcs have certain general characteristics, but they may be created in some dissimilar ways:

(1) By imposing across an electrode gap a high enough voltage to cause breakdown of the medium, i.e., an electric spark, and arranging that sufficient voltage and current are available from the power source to sustain a steady arc. In other words, the discharge starts as a spark and becomes an arc. The medium of most interest is air, although breakdown of other gases, and also of liquids or solids can be of interest. This form of discharge is normally important only in high-voltage (> 600 V) circuits.

(2) By moving a pair of electrodes (electric contacts) towards each other until they touch, then pulling them away. 'Striking' an arc is a procedure well-known to welders, but it also occurs at the contacts of electric switches. High voltages are not required.

(3) Arcing across a carbonized path.

(4) Glow to arc transition.

An electric arc may often be accompanied by ejection of small incandescent airborne particles. These have been treated earlier in this Chapter under *Hot solids or liquids*; additional information is presented in Chapter 14 under *Forest materials, vegetation and hay*.

Arcs are commonly subdivided into long arcs and short arcs. In a short arc, electrons emitted from the cathode move nearly directly to the anode. In a long arc, however, a region develops in between the electrodes where electrons sustain multiple collisions. Considering first the *long arc*, in steady state, the distance between the two electrodes can be divided into three regions: a *cathode fall* region, a linear region called the *long column*, and an *anode fall* region (Figure 36). In the long column region, the voltage/distance relation is a straight line. But in the spaces close to the two electrodes, voltage changes rapidly and non-linearly with distance. The cathode fall distance is typically 10^{-3} to 10^{-2} mm, over which a drop on the order of 8 – 20 V (typically, 8 – 9 V when using a copper electrode[279]) occurs. Electrodes of other materials give a slightly different voltage drop. The anode fall region is typically 10^{-3} mm and has a voltage drop of 2 – 6 V with a copper electrode. Both the cathode and the anode fall regions are separated from the long column by transition zones (boundary layers) which are significantly longer than the fall regions themselves. Since the temperatures in the long column are at least an order of magnitude greater than the anode and cathode surfaces, the boundary layers serve to change the temperature from that of the metal to that of the plasma. For distances shorter than the combined sum of the cathode fall and the anode fall regions, no linear region exists; these are *short arcs*. The total voltage drop across a short arc is typically 20 – 30 V, but may be as low as a few volts in some cases[253].

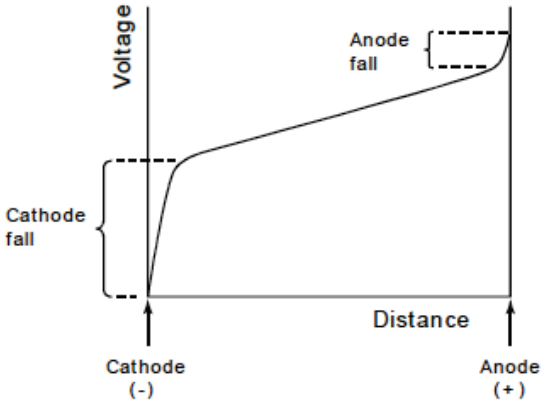

Figure 36 Regions of the long arc (not to scale)

The plasma is chemically reacting and a number of mathematical models have been proposed for its characterization. Due to its extremely high temperature, the plasma radiates very strongly, primarily in the ultra-violet (UV). However, most of the radiation is re-absorbed in the colder regions at the periphery of the plasma channel. The boiling point of the material forming the cathode of an arc has an important effect on the details of the arc. The temperature of the cathode cannot exceed its boiling point. For metals common in accidental arcs, even copper has a low enough boiling point (2562ºC) that it functions as a *cold-cathode arc*. High-temperature arcs include ones where the cathode is made of tungsten, molybdenum, zirconium, or other high T_b metals.

The temperature of an arc can vary widely. Under ambient pressure conditions, it is commonly 6000 – 12,000 K, but can reach 50,000 K. The primary factor governing arc temperature is the arc current. In a theoretical study, Lowke[280] concluded that there are two different regimes of arc operation—below about 30 A, the arc is stabilized primarily by natural convection. Above about 100 A, self-induced magnetic forces predominate. The predictions of his theory, along with data from Pflanz[281], Matsumoto[282], and Lowke, are shown in Figure 37. Also shown is the empirical data fit:

$$T = 6500 \qquad I_a \le 4.5 \text{ A}$$
$$T = 4010 + 1658 \ln I_a \qquad I_a > 4.5 \text{ A}$$

The theoretical predictions are only loosely obeyed, so the empirical data fit should be sufficient for calculational purposes. A temperature is meaningful only for a system whose constituents are in thermal equilibrium and an arc is not necessarily in thermal equilibrium—free electrons, ions, and neutral atoms can be at different temperatures. Arcs at atmospheric pressure, however, tend to be fairly close to thermal equilibrium. Lowke also provided a theory for arc radius. For low-current arcs (< 200 A), there is a complex relationship, but radii are typically between 2.5 to 10 mm. For high-current arcs (> 200 A), the radius can be obtained from the relation that arc current density[280,283] (current per cross-section area) is roughly a constant at 90 – 150 A mm^{-2}.

Once established, an arc does not necessarily last forever. In AC circuits, current goes to zero twice each cycle, and the arc may fail to get re-established once current flow restarts. An arc will also stop if the power source is disconnected so that no more voltage is supplied to the arc. In the design of circuit breakers, it is important to make provisions that the arc which results upon opening the contacts becomes quickly extinguished. Various stratagems are employed, the most universal of which is a scheme whereby the arc progressively lengthens until it can no longer be sustained. Other techniques include using an air blast to blow the arc away and directing the arc into chutes where its path is broken up and heat losses are introduced through baffles.

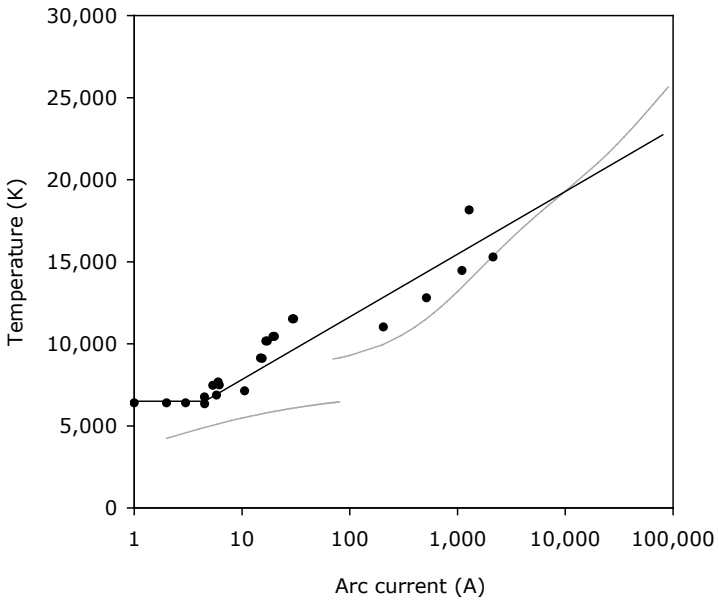

Figure 37 Temperature of arcs in ambient-pressure air, along with predictions from the theory of Lowke (gray lines) and an experimental data fit (black line).

Once a gas breakdown has occurred, the current flow is determined largely by the available voltage and the circuit resistance of the external circuit. In low-voltage circuits, the minimum length of an arc is about 0.1 mm. If electrodes are brought together to a closer distance, the arc jumps out of the gap, so as to maintain a minimum length. As an arc continues to operate, the electrode materials are eroded. Eventually, the arc will be extinguished if the electrodes are not moved closer together. The distances attained before extinction can be surprisingly large. In one series of tests using a 300 VDC supply providing up to 2400 A[284], when two copper electrodes were used, the gap length at extinguishment was 38 mm; with one copper and one steel electrode, it was 51 mm; while with two steel electrodes it was 76 mm. For applications where it is *desired* to create a stable arc (e.g., arc lights) carbon electrodes are commonly used; since carbon does not melt and only oxidizes or gasifies slowly, carbon electrodes provide an arc gap which only slowly changes its dimension.

The effect of buoyancy can act to substantially affect the shape of an arc. Color Plate 19 shows a horizontal arc[285] across a 500 mm gap of a 160,000 VAC power supply and with a measured arc current of 400 A. The arc starts to meander during the 10 ms time frame, but does not yet distend upwards. The latter behavior was examined by Drouet and Nadeau[286], who conducted experiments using currents up to 80 kA and observed that for free-burning arcs in air that lasted up to 0.5 s, the length grew in time according to:

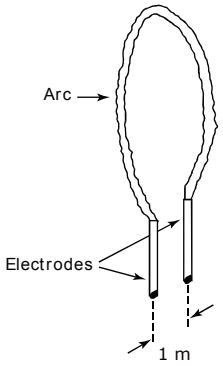

Figure 38 Geometry of electrodes and shape of arc

$$L = 30t$$

where L = length of arc (m) and t = time (s). The minimum length was 1 m, the distance between the electrodes, and the arcs grew up to 15 m long in the space of 0.5 s. As the arc grew, the shape bulged upwards, shown in Figure 38.

In another study, using a 6000 VAC circuit, actual arc lengths up to 2000 mm were observed between electrodes spaced 100 mm apart[287].

It is often of interest to know the voltage/current characteristics of an electric arc. Representing an arc as a circuit element is complicated, since its effective impedance changes dynamically with time. In addition, an arc shows two different current regimes—a low-current, convectively-dominated regime and a high-current regime dominated by self-magnetic effects. Actual voltage/current characteristics are governed by a number of factors, including:

- the gas in which breakdown is occurring (e.g., hydrogen requires a higher voltage than air);
- the pressure of the gas (higher pressure requires a higher voltage);
- gas flow velocity and turbulence (a higher flow velocity requires a higher arc voltage due to convective losses);
- magnetic fields (generally increase the arc voltage due do increased power dissipation);
- electrode material entrainment into the arc (normally reduces the arc voltage);
- ablation of insulating materials (this causes power absorption).

In this Section, characteristics will be considered only for the simplest case of an arc between copper electrodes, in air at 1 atm and without imposed convective flow, magnetic fields, etc. Stokes and Oppenlander[287] found that, for electrode gap in the range $5 \le L \le 500$ mm, the current defining the transition between the low-current and the high-current regimes is:

$$I_t = 10 + 0.2L$$

where I_t = current (A) and L = gap length (mm).

For $I > I_t$, the minimum power dissipated is:

$$P = (20 + 0.534L)I^{1.12} \qquad \text{horizontal or vertical arcs}$$

For $I < I_t$, they found the relations:

$$P = P(I_t) \qquad \text{horizontal arcs}$$

$$P = P(I_t)\left(\frac{I}{I_t}\right)^{0.4} \qquad \text{vertical arcs}$$

In the latter two equations, $P(I_t)$ is to be evaluated by inserting I_t into the large-current P expression. These equations give a good estimate of the *minimum* power dissipated, and the authors validated them over the range 50 W – 30 MW. But the *actual* power dissipated is highly variable and does not lend itself to a systematic representation. Some experimental results are shown in Figure 39. These results indicate that the arc represents a circuit element with a positive conductance for $I > I_t$, but acts as a negative-conductance device at low currents. The arc voltage in their model is obtained by using the relation $V = P/I$. For $I > I_t$, it becomes:

$$V = (20 + 0.534L)I^{0.12}$$

Similarly, since $R = P/I^2$, the arc resistance in the large-current regime is obtained as:

$$R = (20 + 0.534L)I^{-0.88}$$

In the low-current regime, the expressions become:

$$V = (20 + 0.534L)(10 + 0.2L)^{1.12} / I \qquad \text{horizontal arcs}$$

$$V = (20 + 0.534L)(10 + 0.2L)^{0.72} / I^{0.6} \qquad \text{vertical arcs}$$

Quite similar trends were observed by Conrad and Dalasta[288]. They used a 470 VAC power supply and very small electrode gap distances—6.35 to 25.4 mm. Over the current range 270 – 23,000 A, they also got a straight line when plotting the results on a log-log scale, and their lines show the same 0.12 slope as do Stokes'. There is a systematic difference in the constants describing their line, however,

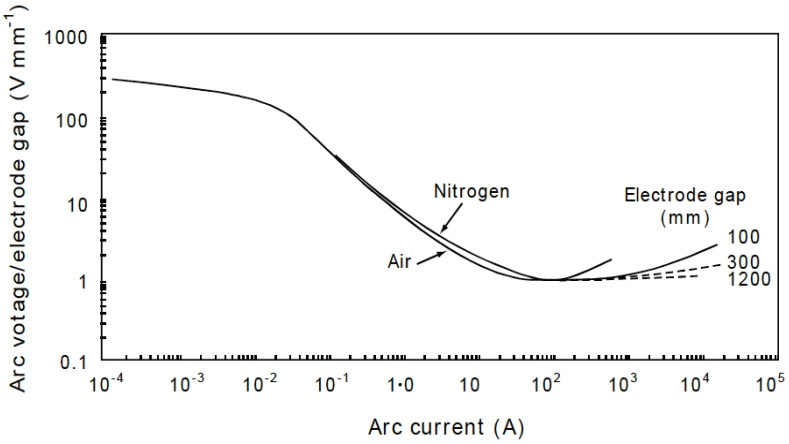

Figure 41 Simplified representation of V-I relation for AC arcs in air and nitrogen as developed by King

with the equation that can be fitted to their results being:

$$V = (16 + 1.0L)I^{0.12}$$

For most purposes, a somewhat simpler representation is adequate, and King[289] showed that in the convectively dominated regime (I < 100 A), it is adequate to assume that the overall voltage gradient (that is, the arc voltage divided by the electrode gap distance) is independent of the gap distance (Figure 40). The following equation represents well enough his results for air in this regime:

$$\frac{V}{L} = 0.961 + \frac{4.04}{0.0156 + I}$$

King's results did extend far enough into the high-current regime to establish firm trends there, however, the fact that the voltage gradient is near-horizontal for large gap distances in that regimes suggests that a limiting value is $V/L \approx 1.0$ V mm^{-1}. Strom[290] conducted experiments with arc currents ranging from 70 A to 22,000 A and electrode gaps of 300 – 1200 mm. In this range, he found a nearly-constant V/L ratio of 1.2 – 1.5 V mm^{-1}, with the lower value being typical for I < 7000 A and the higher for I > 7000 A. Since his range corresponds to the right-hand portion of King's graph, where the V/L values rise above the 1.0 V mm^{-1} minimum, Strom's results can be considered to be quite similar to King's. Strom did not find an electrode-gap effect *per se*.

A number of other workers developed other expressions for arc voltage, current, or resistance. Browne[291] considered the current regime $1.5 \le I \le 15{,}000$ A and gave the expression:

$$V = 30 + 1.18L + \frac{11.8L}{I}$$

The form of this equation is sometimes identified as Ayrton's equation, since Hertha Ayrton[292] first proposed it in 1903. In that same low-current regime, old studies indicate that the dependence on current is not necessarily of the –1 power, but that the power depends on the material from which the anode is made[293]:

$$V \propto A + \frac{BL}{I^n}$$

where $n = 2.62 \times 10^{-4} T_b$, where T_b = boiling point of the anode material (K). Since T_b for copper = 2835 K, according to this relation n = 0.74. Modern data do not exist to determine whether such a power law is useful.

For high-current (7,000 – 80,000 A) long arcs, Goda et al.[294] proposed the following expression:

$$V = 0.95L + \frac{5.0L}{I}$$

This equation shows an extremely tiny drop in voltage with increasing current but it is actually not a good fit to Goda's data, which indicate that a better fit is given by:

$$V = 0.98L + \frac{400L}{I}$$

In the high-current regime, Browne's relation and Goda's (both original and corrected) show a voltage that falls very slightly with current, while King's and Stokes' data give a voltage that increases with current. The four expressions are compared in Figure 41. Sizable differences have always been seen in comparing studies on arc voltages—in the words of Browne[291]: "Actual arc voltages are so sensitive to particular conditions that departures from the equation by 100% or more are to be expected." However, since two equations show an upward trend with increasing current, and two downward, the conclusion that emerges is that current dependence is evidently very small. On that basis,

$$V = 1.2L$$

may best capture the available results. The lack of a universal dependence of voltage on current was confirmed in

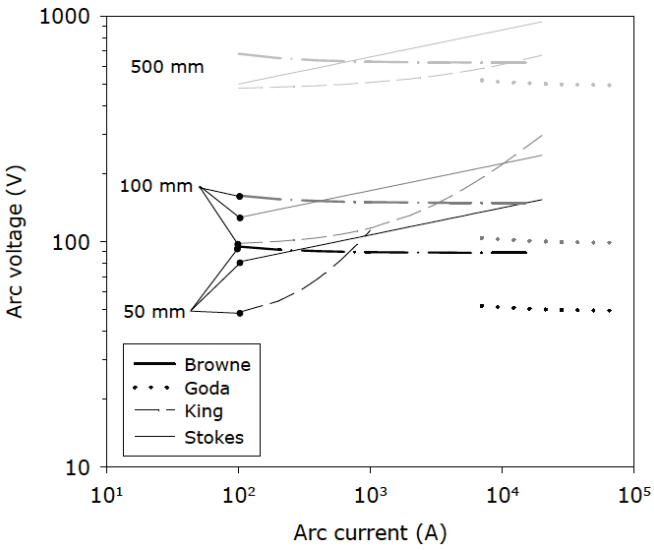

Figure 40 Comparison of three different expressions for arc voltage, applicable to the high-current regime (Goda's expression shown is the corrected equation). Expressions are shown for three different electrode spacings.

studies of Koch and Christophe[296], who created arc faults at splices of underground power cables and found *V–I* characteristics that ranged from (a) voltage decreasing with current, to (b) voltage independent of current, to (c) voltage increasing with current.

When a value of arc resistance are needed, knowing arc voltage and current, it can be computed simply as $R = V/I$. In addition, Fisher[295] recommends the following expression for arc resistance, applicable only to circuits carrying 600 VAC or less:

$$R = 4.96 \frac{\sqrt{L}}{I^{0.85}}$$

In line with the V – *I* relationships studied above, this indicates a dependence on current that is slightly less than unity power. However, while the other researchers typically obtained a linear dependence on *L*, Fisher's expression has a square-root dependence.

To use any of the above relations, it is necessary to estimate the arc current. This topic involves consideration of the details of the circuit and is treated in Chapter 14.

In practical AC circuits, the arc voltage waveforms are strongly non-sinusoidal and generally are non-repetitive as well[296]; that is to say, the waveform looks substantially different in each new current cycle. The latter effect arises because the arc creates a self-modifying environment, since arcing affects both the condition of the electrodes and of the atmosphere in which the discharge is taking place. Thus, a dynamic expression would be needed to model the circuit's time response. Dynamic models for predicting arc voltages and currents have been described by various researchers for low-voltage[291,297] (≤ 600 VAC) circuits, and high age[298-300] systems. In any case, steady-state arc circuit representations cannot be used to estimate whether an arc will burn stably or will self-extinguish, not only because physical meandering of the arc is important, but also because extinguishing criteria are intrinsically based on waveform details.

The voltage across an arc occurring in transformer oil has been represented as[301]:

$$V_a = 8.8 L_a$$

The *enthalpy density*[281,285] of an arc in air at 1 atm is approximately 0.8 – 0.9 MJ m^{-3}.

According to Lee[302], the *power* of an arc, *P*, can be conservatively estimated* as being:

$$P = 0.5 VA_{sc}$$

where VA_{sc} = bolted-short volt-amperes. This relation comes from assuming that the load (arc) impedance is equal to the source impedance, which is the condition at which the maximum power can be transferred to a load. For distribution transformers rated 750 kVA or higher, Lee also recommends that the fault current be estimated as:

$$VA_{sc} = 10 VA_{\text{tranformer nameplate rating}}$$

while for smaller transformers the multiplying factor is 12.5, instead of 10. Using the same assumptions, it can also be shown[308] that for a 3-phase arc,

$$P = 0.5\sqrt{3}\, V I_{3PH}$$

where *V* = rms voltage, and I_{3PH} = phase current during a 3-phase bolted short, while for a phase-to-phase arc the corresponding power is:

$$P = 0.5 V I_{P-P}$$

where $I_{P-P} = I_{3PH} \times \sqrt{3}/2$ or 86.6% of the corresponding 3-phase bolted short current. Thus, the arc power for a phase-to-phase arc becomes:

$$P = 0.25\sqrt{3}\, V I_{3PH}$$

Lee assumed that the entire arc power is dissipated by thermal radiation, which conservatively ignores the portion of the energy dissipated as conduction and as a pressure or shock wave. Convective losses do not enter into the problem since for short time periods buoyancy flows do not get started. However, the entire arc power is not delivered in the form of thermal radiation, and the fraction which is delivered is governed by a number of variables, including:

- the gas in which the discharge is taking place
- the pressure
- entrained contact material.

Latham[303] developed an arc model which also ignores the energy delivered as a pressure wave or a shock wave but does include heat conduction losses. Using this model, he computed the thermal radiation fraction for various arcs currents. Figure 42 shows that, in Latham's model, the radiant fraction becomes high for currents over about 1000 A, but is in the vicinity of only 20% for low arc currents.

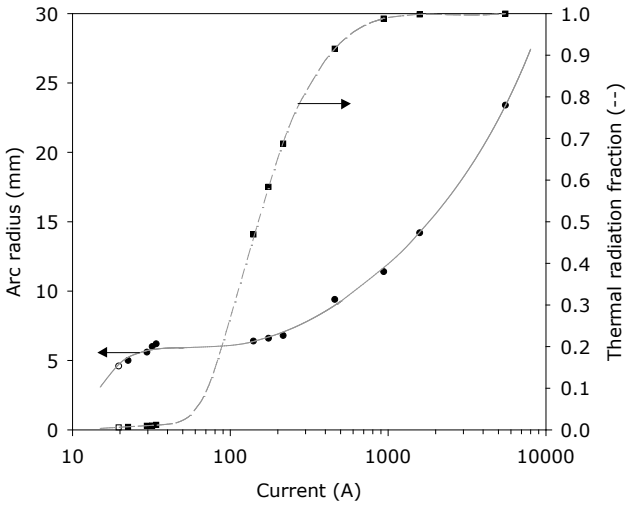

Figure 42 Radius and thermal radiation fraction for long arcs, calculated from Latham's model

* His equations are based on a very simplified view of short-circuit currents. Chapter 14 discusses the topic in more detail.

Lee's assumption of 100% radiant efficiency has been criticized by Stokes[287] as being so overconservative as to be impractical. Stokes points to the studies by Ernst and Strachan as being more realistic. Ernst et al.[304] concluded that assuming 10% of the arc power to be delivered in the form of radiation is more consistent with experimental measurements. Strachan[305] showed data for arcs in an orifice flow geometry, indicating that less than 25% of the arc power is radiated if copper electrodes are used. For other electrode materials, the radiated fraction will differ; for carbon electrodes he found only around 11%. He also studied arcs between fixed, copper electrodes[306] and found that 40 – 50% of the arc power was radiated. Fievet and Maftoul[307] studied high-current moving and motionless arcs. For motionless arcs between copper electrodes, they found that about 25% of the arc power was delivered in the form of radiation. For moving arcs, the value was much lower, ranging from 20% at 1000 A to 7% at 7000 A. In an experimental study[308] on 3-phase arcs in a 600 VAC system, Doughty et al. found that actual arc power was 77% of Lee's assumed value. The value is lower than 100% since Lee's theory assumes that the impedance of the load (i.e., the arc) is identical to the impedance of the source, whereas real arcs establish an impedance governed by actual circuit characteristics. The authors also measured heat fluxes and found a value of 450 kW m^{-2} at a distance of 0.61 m from the center of a 13.5 MW arc, using a 3-phase arc in open air. When the arc was enclosed by a 5-sided metal box, the heat flux at the front face increased by about 3×. For the open-air case, if the arc is assumed to be roughly spherical (which is a reasonable assumption in this case due to the small electrode gaps used), then a radiant power of 2.1 MW is found, which means that 16% of the arc power showed up in the form of thermal radiation. The arc current in these tests averaged around 22,000 A per phase, which according to Latham's theory would have entailed a radiant fraction of 100%. Taken together, the available experimental results are not particularly consistent, but the general conclusion might be that about 20 – 25% of the arc power from a high-current arc between copper electrodes will show up as thermal radiation.

The thermal radiation is commonly referred to as *arc flash*. The consequences of not wearing protective clothing in an arc flash are illustrated[309] in Color Plate 20.

A DC arc will extinguish only if the power supply is removed or if enough material erodes to make the gap too large. In an AC circuit an arc will self-extinguish 2×60 times (2×50 times with 50 Hz power) per second, each time the current goes to zero. But it may re-ignite thereafter, if conditions are right. Whether or not the arc re-ignites afterwards depends whether the arc channel can recover so that it will not break down again with the new imposed voltage. For a recovery to be possible, temperature has to drop and ionized species have to have time to diffuse, encounter reaction partners, and recombine. If that occurs, then the breakdown strength can rise to a sufficient value to avoid a subsequent breakdown. The temperature can drop because heat losses are occurring through conduction, convection and radiation. If wire insulation was incinerated in the process of arcing, an additional factor comes in: the pyrolyzed polymer material may help to promote recombination but it may also lead to arcing across a carbonized path.

Arcs in circuits of less than 150 V tend to extinguish and not re-ignite when the waveform goes through the zero crossing. Arcs in circuits of over 600 V tend to draw very high currents and consequently may be relatively safer since a circuit protection device is likely to open. Voltages between 150 and 600 V are considered the most hazardous in regards to fires being ignited from arcing[310]. This is because the arcs tend to not be extinguished, yet the current flows are small enough that circuit protection devices operate slowly. Typical waveforms[311] for arcing in 120 VAC circuits are shown in Figure 43. Note the intermittent nature of the arc as it extinguishes and reignites. *Restrike voltage* in distribution busbars is considered in Chapter 14.

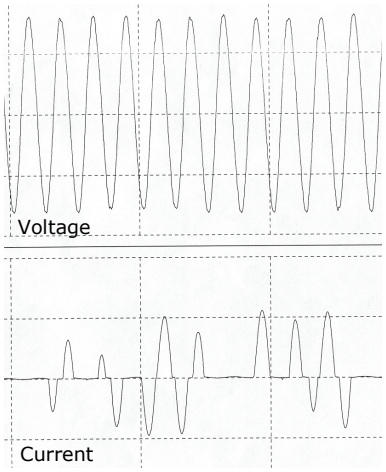

Figure 43 Typical waveforms during a branch-circuit arcing event

Arcing in a 120 VAC branch circuit was experimentally studied by Blades[312]. He found that a stable arc was difficult to create without the presence of polymeric insulation materials that might lead to arcing-through-char. The reason was because metal erosion would quickly increase the arc gap to the point where arcing could no longer be sustained. Sustained arcing was successfully demonstrated by using carbon electrodes, which do not undergo significant erosion. Even with those, for sustained arcing to occur required that the electrodes be preheated to ca. 80ºC. The preheating could be achieved by actually using a heater, or by repetitively undergoing a number of unsustained arcs, which would pre-warm the electrodes. To make the demonstration feasible, he had to construct an electrode spacing drive mechanism of high precision that permitted a very fine adjustment of the gap; without this precision control of the gap, the effect could not be demonstrated. The power dissi-

Table 27 Minimum voltage and current needed in resistive circuits to sustain an arc in air

Electrode material	Min. voltage V_m (V)	Min. current I_m (A)
aluminum	12	0.4
brass	11	NA
cadmium	8.5	0.03
carbon	20	0.01
copper	13	0.45
gold	9.5 – 15	0.38
iron	12 – 14	0.72
iron oxide	14	0.70
lead	9 – 11	0.21
nickel	8 – 14	0.5
palladium	15	0.5
platinum	13.5 – 17.5	0.9
silver	8 – 15	0.4
steel, carbon	14	NA
steel, stainless	15	0.5
tin	11.2	0.4
tungsten	10 – 16.1	1.0
zinc	9	0.03

pated in the arc was about 12.5 W. It is important to realize that arcing will often be *in series* with the load (e.g., at contacts), not in parallel with the line. There is no increased draw of current when a series arc occurs, instead, current flow will decrease, due to the series-flow of current. No overcurrent protective measures can have any effect against a series arc, but sophisticated methods have been developed that detect an arc 'signature'; these are described in Chapter 13.

An arc cannot be sustained unless there is both a minimum voltage and a minimum current available from the circuit[274,313-317], as shown in Table 27. Where available, the values of Zborovszky were preferentially cited, as hers were deemed to be measured most accurately; where not, the entire range found in the literature was cited. Surface contamination may change the V_m value slightly, but only limited results are available[274]. Values in other atmospheres are generally not too different. It must be understood that the voltage/current requirement is roughly hyperbolic, thus an arc will not be sustained if both voltage and current are at their minimum values. An arc running at near-minimum current will require a voltage much greater than the minimum voltage, and vice versa. The current needed for carbon is lower than for any other material. This has the practical implication in that a carbon coating may well be acquired on metallic contacts, and this could lead to very low currents being sufficient to sustain arcing. There are also some indirect data suggesting that hydrocarbon pollution of metallic contacts—without a visible layer of soot—may suffice to cause metallic electrodes to behave similarly to carbon electrodes[318]. Cadmium shows the distinction of having very low values both for minimum voltage and minimum current. Not surprisingly, this has led to the use of cadmium in the IEC/PTB break-flash test apparatus (Chapter 12). The values in Table 27 apply only to resistive circuits; minimum currents in inductive circuits may be substantially smaller[319], as discussed in more detail later. The minimum voltage/current values pertain to an arc of infinitesimal length. If the arc is made longer, the minimum voltage rises sharply, while the current less so. Yokomizu et al.[320] provide some illustrative data showing how the minimum arc voltage rises with increasing arc length or arc current. In a resistive circuit, an arc may be observed upon opening a contact, even if the supply voltage is less than V_m, but the discharge is so short-lived that it is usually not possible to ignite gas mixtures with them[274]. The important question, however, of the minimum voltage sufficient for a spark or arc to be incendive in a flammable atmosphere is poorly researched. Data discussed in Chapter 4 indicate that 4 – 5 V may suffice in resistive circuits and 0.5 V in inductive ones, but conditions under which such low voltages can suffice are not necessarily clear.

For situations where the two electrodes are not made of the same material, the minimum voltage can be viewed as being the sum of the cathode fall and the anode fall voltages, with voltages appropriate to the two materials being summed.

Apart from larger particles being ejected due to gross failure of the electrodes, both the anode and the cathode can generate a stream of tiny particles coming from it, with the particle formation being governed by forces of magnetic compression. The tiny particles have a velocity directed perpendicular to the surface.

Most cases of arcing require that a material such as plastic, wood, etc. be present nearby if the arcing is to lead to fire. But arcing to *aluminum electrodes* can directly lead to ignition of the aluminum metal[321].

Contact arcs regularly occur in electric switches, relays, and similar devices. They also occur inadvertently, when, for example, two bare current-carrying conductors are accidentally shorted. When considering electric switch contacts, the arc caused by closing the switch, is called a *make-arc* (or *closing arc*), while the arc caused in opening the switch is a *break-arc* (or *opening arc*, or *parting arc*). The process of creating an arc (at voltages which may be much less than the Paschen Law minimum of 340 V) is quite similar for both types of contact arcs. In the case of a break-arc the steps involved are:

(1) The electrodes that were originally touching at numerous spots start to touch at only a few very small spots.
(2) A high current density passes through the small metal diameter of contact area that is available.
(3) The 'metal bridge' joining the two contacts starts to melt.
(4) The bridge elongates and rises in temperature.

(5) The bridge reaches the metal's boiling point, becomes unstable and ruptures.
(6) Voltage rises rapidly across the gap, thermionic emission from the hot cathode starts, and eventually the gap becomes ionized and an arc forms.
(7) The diameter of the arc expands from that of the bridge to its eventual free-burning diameter.

The voltage across the gap at the moment of rupture is only ca. 1 V. The reason Paschen's Law does not apply is that is describes the characteristics of room-temperature, non-ionized gases, and the space between the contacts is ionized and at high temperature. Even though 10 – 15 V is needed for the steady-state operation of an arc, the arc is able to initiate with only a 1 V drop due to inductive effects of the two leads. If a current of at least ca. 1 A before the break has been carried and the polarity of the current remains unchanged for at least the time needed for positive ions to traverse the gap, then a stable short arc may be initiated. The circuit must also be such that before the ionization due to the initial spark has dissipated, the voltage between the electrodes rises to a value which is above the minimum. This may be prevented if a capacitor is connected directly across the electrodes, the capacitance of which is sufficient to delay the voltage buildup across the gap. Some devices with mechanical switch contacts incorporate a capacitor across the switch for exactly this purpose of preventing a continuing arc.

The voltage/current relationship for a break-arc at contacts in a low-voltage circuit depends on many physical details of the contacts, including the type of material, the separation speed, and the gap created. Figure 44 illustrates some data reported by Widginton[317]; additional examples have been given by Holm[313]. The asymptotic values (minimum voltage at high currents and the minimum current at high voltages) are higher than those given in Table 27 since the experimental conditions were not optimized so as to give minimum values.

In *closing* switch contacts (make-arc), the sequence of events is very similar. Contact is initially made at only a few high spots. These have limited current-carrying capacity and proceed to melt and rupture, at which point an arc develops. That arc in normally extinguished by heat losses when the contacts close together more tightly.

In circuits where either the minimum voltage or the minimum current requirement is not met for an arc, it might seem that arcing is simply precluded. But this is not necessarily true in real devices where 'parasitic' inductances or capacitances will invariably be present. Parasitic reactance elements are ones that are not purposely installed, but rather created by wiring, terminals, and other necessary physical arrangements. In the simplest example, even in a DC circuit, a parting arc can be created which has an repetitive waveform and higher voltage peaks than the power supply voltage. It may happen that initial vaporization of the metal

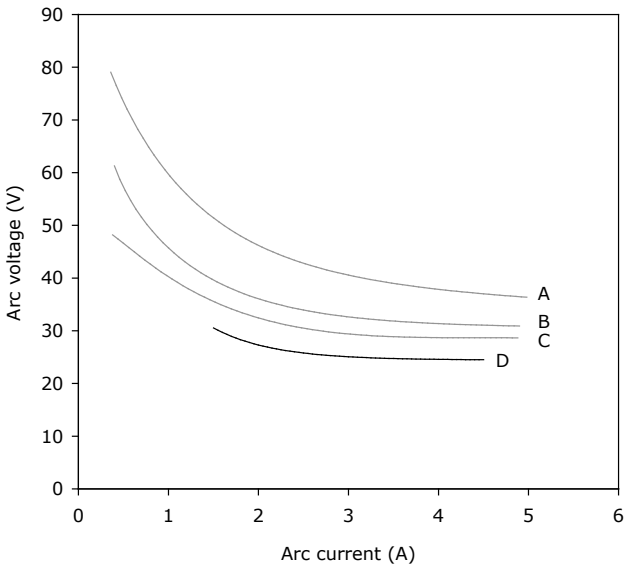

Figure 44 V-I characteristics of break-arcs caused by pulling apart 0.3 mm copper electrodes. **A** and **D** = 1.0 mm gap; **B** = 0.4 mm gap; **C** = 0.2 mm gap. Separation speed of **A**, **B**, **C**: 20 m s^{-1}; **D**: 0.01 m s^{-1}.

bridge allows for an arc to form, but as the contacts pull apart, the arc is not sustained. Current flow now abruptly drops to zero. This creates a back emf, $V = -L\frac{dI}{dt}$, where L = inductance (H) and I = current (A). Because of the abrupt drop in current, high voltages—in the kilovolt range—can be generated even with modest parasitic inductance. Thus, a circuit where power supply voltages and steady state voltages may have only been in the tens of volts can provide enough potential difference to cause a second breakdown in the gap. The process occasionally can go on for a number of cycles before final arc extinction. The discharge involved is not necessarily an arc, but may be a glow discharge or multiple spark breakdown. For example, with a very simple circuit where a copper wire was used to short-circuit a 6.3 V lead-acid battery, peak voltages of 17 – 22 V were measured across the spark gap that opened up due to melting of the wire[322]. Voltages in the vicinity of 300 V can be generated in this manner from a 24 V power supply[323]. In experiments on motor-contactor coils in a 220 VDC circuit, voltage peaks of 11,000 V (55× the supply voltage) were measured in extreme cases upon opening the circuit, although peaks of 10 to 20× were more common[324]. The authors also document an observation of a spark across fixed conductors 12.5 mm apart in a 550 V circuit; according to Paschen's Law, this would imply a discharge voltage of 37,500 V or a voltage ratio of 68×. Statistically, problems will be fewer in AC than in DC circuits, since in an AC circuit many contact openings will take place during a part of the cycle where worst-case behavior is not elicited, while opening a DC circuit is always effectively a 'worst-case' situation. In general, the duration of the spark discharge increases with in-

creasing power supply voltages, and at voltages less than V_m the duration is often only so short (a few microseconds) that the discharge is non-incendive.

A more complicated effect is *tank resonance*, which requires an inductive and a capacitive element. It is due to the formation of an RF resonant circuit between the main energy storage device (capacitor or coil) and parasitic circuit elements. Thus, for example, even if the circuit only has a single inductor as its reactive element, there will be a stray capacitance formed between the wiring. The small value of such a parasitic reactive element means that resonant frequencies are high. The resonant circuit can thus be charged to a much higher voltage than is the steady-state voltage of the connected power supply. Arcing recurs each time that the voltage reaches its breakdown value in the gap. A glow discharge can be especially effective for ignition, since the amount of energy going into a discharge in an inductive circuit is nearly the theoretical $\frac{1}{2}LI^2$ for a glow discharge, but about half that, $\frac{1}{4}LI^2$, for an arc discharge. It is hard to provide simple, general rules for circuits where both L and effects are important, since the problem then has several independent variables. In some situations capacitance in the circuit can be beneficial, since with an optimally chosen value, it can actually suppress arc formation[324].

The condition of the contacts in a break-arc geometry affect the discharge duration and, in turn, the likelihood of ignition. Inorganic surface contaminants (oxides, sulfates) generally increase the duration[274]. Very small amounts of organic contaminants can also prolong the duration of the discharge and thus increase the probability of ignition.

The characteristics of a break-arc are affected by the gases present in the atmosphere. In one study[322], it was found that the presence of methane in air shortens the discharge period and thus, makes the arc less incendive than measured in pure-air conditions.

Glow-to-arc transition has been illustrated by Attwood et al.[325], who studied arcing on 60 Hz AC powerlines. Figure 45 shows typical waveforms for current and voltage across the electrodes. Until a breakdown voltage (typ. 300 – 800 V) is reached, there is no current flow, or only a 'leakage current.' At breakdown, however, a small amount of current begins to flow. The voltage drops to a steady-state glow voltage of around 300 V, while the current continues to rise. At a certain point, depending on circuit characteristics, the voltage abruptly drops, while the current abruptly rises. After a short transient, a nearly-steady (slightly decreasing) arc voltage stabilizes, while the current continues to rise. The jump between glow and arc discharges requires a large current to be available, typically 100 A; conversely, once created, the arc is able to continue until current drops to a very small value (0.1 – 0.5 A). For recurring arcs, the breakdown voltage is called *restrike voltage* and is further discussed in Chapter 14.

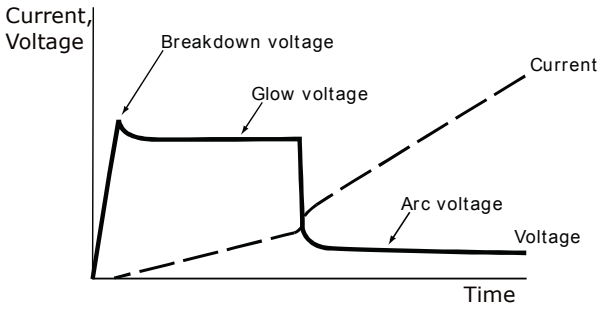

Figure 45 Glow-to-arc transition on an AC powerline (only the initial portion of a half-cycle is shown)

Arcing and vibration

In laboratory experiments, sustained arcing at contacts can be demonstrated by mildly vibrating clean, crossed copper conductors while passing a current[312]. This can create oxide bridges that lead to a glowing connection (see below). Once a glowing connection is established, it persists without needed for further vibration.

Pressures developed by an electric arc

When arcing occurs in sizable power transmission or distribution components, the arc can develop some very substantial pressures. It has been measured[326] that pressures from a 100 kA, 10 kV arc at a distance of 1 m away are about 20 kPa. This pressure is about 10× the capacity of many walls to withstand side-pressure, thus wall collapses can and have occurred. If the arc is not burning in open air, but is confined to a box, some enormous pressures can occur, documented in one case as being 7000 kPa. The pressure is developed due to expansion of metal as it is vaporized and by the heating of air to the high arc temperatures.

ELECTRIC CURRENT

Properly determining electrical causes of fires tends not to be too difficult when high-current or high-voltage circuits are concerned. But in the common scenarios of appliances of modest power or of branch circuits carrying loads of 20 A or less, investigation can be much more difficult. In either high-current or high-voltage situations, electrical failure patterns are typically associated with relatively large metallic parts and the subsequent fire will usually not alter this evidence grossly. Fire originating in small-gauge wiring or at small connection parts, on the other hand, quite often will damage the evidence more seriously, leaving much to speculation. There is a modest body of laboratory research where low-current failures have been simulated, but much is still unknown about details of scenarios leading to actual electrical fires in low-current circuits. In this Section, the basic principles are developed concerning ignitions from current-carrying devices. More detailed discussions on failure modes of wiring, lighting, appliances, etc. are taken up in Chapter 14.

Faults associated with the flow of electric current primarily involve the following phenomena, which are not mutually exclusive:

- sparking or arcing in the gas phase
- arcing across a carbonized path
- glowing, and other forms of overheating
- ejection of hot particles.

The scientific principles of electric discharges (e.g., sparks and arcs) have been covered in the preceding Sections. Arcing across a carbonized path is a phenomenon which is associated with the surface degradation of electric insulators. The ignition source and the substance being ignited, effectively, are identical in this phenomenon. As such, it is covered in Chapter 7. Thus, the rest of the present section focuses on overheating, ejection of hot particles, and some miscellaneous phenomena.

UL considers[327] that a potential risk of fire exists in appliances and devices which (a) use voltages over 30 VAC (rms) and can provide currents over 8 A; or (b) can dissipate more than 15 W. Most consumer appliances fall into one or both of these categories. These limits appear to be based solely on judgment and are unlikely to be actual true limits to ignitability, nonetheless, it is evident that if the power available is lowered, the risk is to some extent reduced.

OVERHEATING WIRES

It is rather hard to ignite the thermal insulation of wires by exceeding the current rating for the conductor, since a large excess is required. Experimental data on this point are examined in Chapter 14. Calculating accurately the temperature rise of a cable is not easy, due to dielectric losses, skin effect, and magnetic and thermal interactions of conductors (and possibly adjoining cables). In addition, many properties needed are temperature-dependent. The IEEE textbook on this topic[328] should be consulted for these details. To make an rough calculation, however, is less complex. VTT researchers[329] offer the following as a simple approximation for a single, insulated conductor:

$$T_{in} = \frac{I^2}{2\pi^2 \sigma \lambda a^2}\left[\frac{1}{Bi} + \ln\left(\frac{b}{a}\right)\right]$$

where T_{in} = temperature of insulator (K), I = current (A), σ = electric conductivity (= 5.8×10^7 S m^{-1} for copper), λ = thermal conductivity of insulation (W m^{-1} K^{-1}), b = outer radius of insulation (m), a = radius of conductor (m), and Bi is the Biot number:

$$Bi = \frac{bh}{\lambda}$$

where h = convective heat transfer coefficient (W m^{-2} K^{-1}). As an example, suppose a 14 AWG wire is considered having a wire insulation thickness = 0.4 mm. For this wire, the diameter = 1.63 mm, so a = 1.63/2 = 0.815 mm = 0.815×10^{-3} m and b = 1.015×10^{-3} m. Assume that the insulation ignites at 400ºC = 673 K , λ = 0.15 W m^{-1} K^{-1}, and h = 50 W m^{-2} K^{-1}. This gives Bi = 0.338. Now, solving for I:

$$I = \pi a \sqrt{\frac{2T_{in}\sigma\lambda}{\left(\frac{1}{Bi} + \ln\left(\frac{b}{a}\right)\right)}} = 135 \text{ A}$$

Since 14 AWG wire has a rated ampacity of 15 A, this is an overcurrent of 9×. This estimate is high, and Chapter 14 indicates that an overcurrents in the range of 3× to 7× suffice to ignite wire insulation.

OVERHEATING ELECTRICAL CONNECTIONS

Overheating at electrical connections is a common cause of fires. The physics and chemistry of electrical connections are very complex, as illustrated by the phenomenological flow chart put forth by Kuroyanagi and coworkers[330]. From Figure 46 it can be seen that numerous phenomena are involved, but not all have been studied systematically and in detail.

Aronstein[331] investigated heating at aluminum–aluminum contacts is some detail. He found that:

- Incipient failing of a connection can be defined as occurring when the contact resistance reaches a value of about 10 mΩ.
- The contact resistance is not a smooth function of contact force. Instead, there is an abrupt drop in contact resistance at a certain contact force.
- A poor connection acts as a current limiter and the current/voltage relation is nonlinear and with hysteresis. If

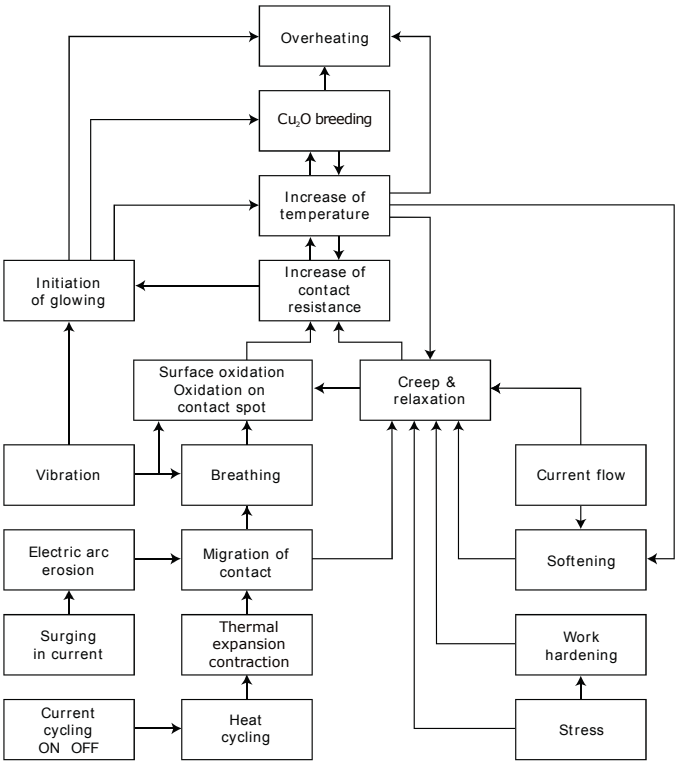

Figure 46 Mechanisms for overheating at electrical connections

current is increased beyond the limit value, unstable operation results and the connection cycles between carrying current and being an open circuit.
- Conduction through a poor connection commonly occurs at only a single spot and involves a process of periodic electric breakdown of the oxide film.

Evidence of overheating is clear when mechanical connections between two current-carrying conductors start to show glowing. Normal, good electric connections should not be subject to a temperature rise much in excess of that for the conductors themselves. This depends on the connection having a very low resistance. Most metals which are used for carrying electrical current are subject to oxidation when exposed to atmosphere. The metal oxide film formed on the surface has a very high resistivity. Thus, a connection where the mating parts are oxidized will be a high resistance connection and will overheat if significant current is passed through it. Temperatures of a glowing connection vary widely, but peak values at the hottest point have been measured from 1100ºC[346] to 1500ºC[332]. Temperatures up to ca. 300ºC have been measured on metal parts some distance away from the hot point[346].

Some metals, such as cadmium, beryllium, and nickel, do not readily form a thick oxide coating, and thus they are often used for contacts of relays and switches. Copper oxidizes slowly, and its oxide is semiconductive. Aluminum oxidizes very rapidly and its oxide has negligible electric conductivity, except for a tiny amount of current that can flow through an aluminum oxide layer due to electron tunneling. For practical purposes, the current that can be carried through an aluminum oxide in nil, and glowing would be unlikely due to insufficient current. Thus, Newbury and Greenwald suggested that the formation of intermetallic compounds (which have intermediate conductivity) is the actual mechanism occurring at the glow site[332].

One of the earliest efforts to study glowing connections was organized by the CEE[333] (now IECEE, and a part of IEC) in 1961. Tests were run in the laboratories of the Verband Deutscher Elektrotechniker in Germany and the Imperial Chemical Industries in the UK. The primary results are shown in Figure 47. The connection acts as a non-linear circuit element. For currents over 10 A, drops of around 2 V are found. But for small currents, voltage drops in the tens of volts can be found. At a maximum current of 20 A, ca. 50 W is dissipated in a copper/brass connection and around 35 W for copper/iron. The study also noted that the power dissipation depends only on the materials involved and not on the nominal size of the contacts. It was also found that to start the glowing process, a current of 4 – 6 A had to be supplied; glowing of freshly-made connections could not be started with smaller currents.

Glowing connections were later studied by Hotta, who identified a number of fire cases attributable to this

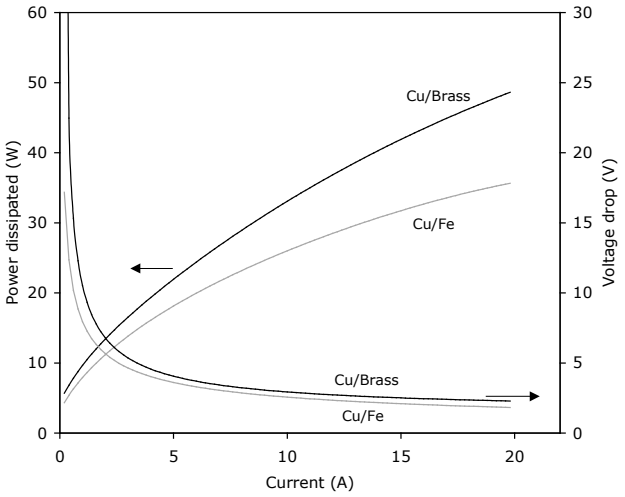

Figure 47 Power dissipation and voltage drop across glowing connections of two types

cause[334]. In laboratory studies on AC circuits, he found that approximately 15 W was dissipated in a glowing copper-copper connection drawing 1 A, and about 25 W at 2.5 A. By means of X-ray analysis, Hotta identified that the high resistance in a copper-copper connection is due to progressive formation of Cu_2O at the junction. He then conducted resistivity studies on pure Cu_2O, which material, he concluded, shows a sharp drop in resistance as temperatures exceed about 900ºC; his quantitative findings, however, have been questioned by Hagimoto[335], who was not able to reproduce the measurements. In a follow-on study, Isa[336] further examined the process and concluded that the glowing connection can be represented in terms of circuit elements as two back-to-back series-connected diodes:

The general sequence of events when the '*Cu_2O breeding process'* occurs at glowing connections has been delineated by Kuroyanagi et al.[330] (Figure 48). Kawase[337] studied the details of the Cu_2O breeding process at copper-to-copper connections. Using an AC source of less than 100 V and of 0.5 to 1.0 A, he noted the following sequence of events when an intermittent connection is made. Initially, when the contact is made and broken, blue sparks are generated. After a number of make/break cycles, the sparks become red, instead of blue. If after this time, contact is made continuously, the Cu_2O breeding process begins to take place. Layers of Cu_2O begin to grow on both contacts (Figure 49). Along the layer of Cu_2O, a single bright filament emerges. Molten metal is located along this thin filament, which meanders "like a worm." Kawase measured the voltage-current relationship of the glowing connection and found that it cycles between high- and low-conductivity states. He interpreted the cycling as a recurring breakdown of the interface between Cu and Cu_2O and confirmed the back-to-back diode circuit model. The CEE work earlier had already noted

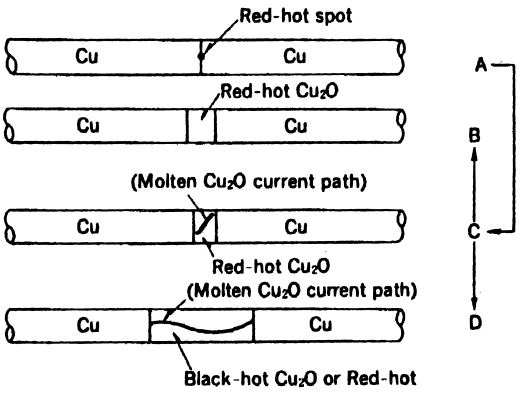

Figure 48 Sequence of events in the Cu_2O breeding process

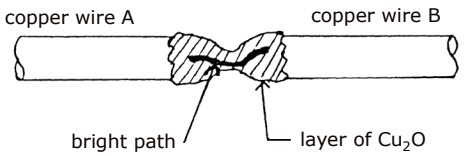

Figure 49 Detailed view of ongoing Cu_2O breeding process

that once a glowing connection is established, if it is interrupted it can resume without first needing to go through a blue spark phase.

Similar experiments were also done by Hagimoto et al.[338], who measured the breeding speed at which Cu_2O is formed in both AC and DC circuits. In AC connections, they found incandescent points occurred at both ends of a meandering, glowing path. The rest of the path was at a lower temperature. In the case of DC connections, they found that an incandescent point was formed only at the (+) electrode. They also found that:

1) The average DC power dissipated at the contacts of 1 mm wires was almost a constant 16 W for currents over 2 A.
2) The average AC power dissipated at the contacts of wires 2 mm in diameter was almost a constant 28 W for currents over 5 A.
3) For 1 mm wires, the maximum breeding speed of Cu_2O was 17 mm h^{-1} in circuits carrying 2 A AC, and 18 mm h^{-1} with 2 A DC. For 2 mm wires, the speed was 6 mm h^{-1} with 2.5 A AC, and 12 mm h^{-1} with 5 A DC.
4) For 1 mm wires, the current necessary for the glow to be sustained was 0.3 – 2 A AC and from 0.3 A to greater than 8 A DC. For 2 mm wires, they were 1 – 2.5 A AC and from 0.5 A to over 8 A DC.
5) The upper limits of these ranges of current were affected by the sputtering caused at the glowing contacts.

Photographs showing glowing connections from the experiments of Hagimoto et al. are shown in Color Plates 21 through 24. They also conducted experiments with stranded cords and found that currents "over a few amperes" were hard to sustain at a glowing connection of a stranded wire—the wire tended to break at the point of heating.

Sletbak et al.[339] studied additional details of the Cu_2O breeding process and found that the filament glows at 1200 – 1300ºC. The process is able to sustain itself, since copper continues to be oxidized underneath. The high temperatures attained can readily lead to ignition. With a current of 1 A, values of 200 – 350ºC were recorded at a 10 mm distance from the glowing point.

If a temperature of ca. 1250ºC is taken to be as typical for the hot part of a glowing Cu-Cu connection, it can be noted that it is very close to 1230ºC, the melting point of Cu_2O. Hagimoto et al.[338] explain that the pulsing waveform found for glowing connections is accounted for by spatter (mechanical sparks) that is sometimes seen to be emitted from the connection. The spatter ejects material and this causes a momentary fluctuation in current. In DC circuits this only takes place from the positive-voltage side of the glowing connection.

Kinoshita et al.[340] examined a variety of metallic contacts using both AC and DC circuits and identified the main reaction products formed at the connections. Their results are summarized in Table 28. The connections differed in their time response. In the DC studies, some connection types showed a basically steady response after a few minutes; others showed a rising drop throughout the test. These results are summarized in Table 29. Interestingly, in the DC studies, the rate of oxidation was non-linearly dependent on the current (Figure 50).

Table 28 Results of Kinoshita et al. on a variety of metals

Metals	Power supply	Outcome	Main products
Cu, Cu	AC	breeding	Cu_2O, CuO
Cu (+), brass (-)	DC	breeding	Cu_2O, CuO
Cu (+), Fe (-)	DC	breeding	Cu_2O, CuO
brass, brass	AC	slow growth	ZnO, Cu_2O, Cu
brass (+), Cu (-)	DC	slow growth	ZnO, Cu_2O, Cu
Fe, Fe	AC	slow growth	Fe_3O_4, Fe_2O_3
Fe (+), Cu (-)	DC	slow growth	Fe_3O_4, Fe_2O_3

Table 29 Voltage drops in DC circuits at a glowing connection carrying 2 A

Metals	Voltage drop
Fe(+) to brass(-) Fe(+) to Fe(-) Fe(+) to Cu(-)	steady ≈ 2 V
brass(+) to brass(-) brass(+) to Fe(-) brass(+) to Cu(-)	steady ≈ 5 V
Cu(+) to Cu(-) Cu(+) to brass (-) Cu(+) to Fe(-)	rising from 5 V at start to 9 V at 90 min

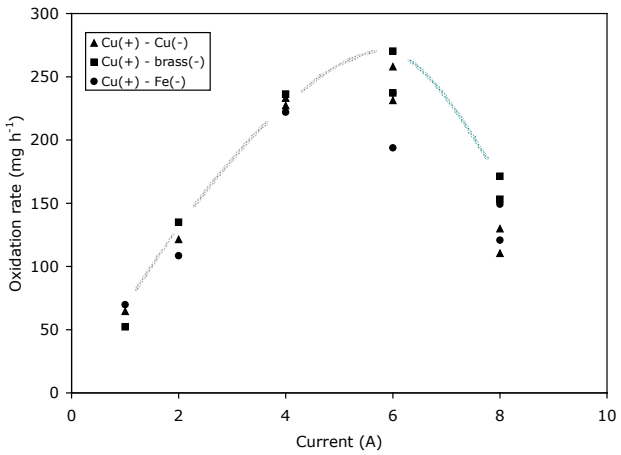

Figure 50 Oxidation rate of several connection types for DC current

In other tests using a variety of metals, Suzuki et al.[341] found that stable glowing connections could be achieved with steel against steel, aluminum, copper, and brass. In their experiments, aluminum against aluminum, copper, or brass gave unsustained glows, while copper against copper or brass could produce no glow. The voltage measured across the connection (for AC currents in the range of 1 – 10 A) was found to be the predictor of glowing performance. If a pair of metals was able to produce more than about a 2 V drop, then stable glowing was possible. Since, for some reason, Suzuki et al. were unable to produce the breeding process often seen in other investigations, their negative results point out that the phenomena are not easy to reproduce.

It has been proposed that a phenomenon identified as 'micro arcing' is involved in a glowing connection. When two metals are separated by a metal-oxide layer, conduction is essentially nil across the layer, which is a dielectric. But the applied voltage can cause a breakdown of the oxide layer. This discharge can cause a fine metal bridge to be created across the dielectric. Substantive current will flow through the metal bridge, but because of its limited current carrying capacity, it shortly overheats, melts, and breaks apart. The process then continues, but because of the high temperatures being created locally, oxide layers are further built up. This theory is not universally espoused, but UL states that their experiments have provided some substantiation[342].

The simplest theoretical model of an overheating connection is obtained by assuming that heat is produced at a constant rate in an infinitesimally-thin plane section across the wire. The wire is represented as a cylinder, without any change of geometry at the point of connection[343]. The solution for the temperature of that cross-section is:

$$\Delta T(t) = q'' \sqrt{\frac{r}{2\pi\lambda h}}\, \gamma(\tfrac{1}{2}, t/\tau)$$

where q'' = power density at the plane section (W m^{-2}), r = radius of the wire (m), λ = thermal conductivity of copper (W m^{-1} K^{-1}), h = effective heat transfer coefficient from the surface of the wire (W m^{-2} K^{-1}), γ = incomplete gamma function[344], and time constant τ(s) is given by:

$$\tau = \frac{r}{2}\frac{\rho C}{h}$$

where ρ = density (kg m^{-3}) and C = heat capacity of copper (J kg^{-1} K^{-1}). The equilibrium value of the temperature rise is:

$$\lim_{t\to\infty} \Delta T(t) = q'' \sqrt{\frac{r}{2\lambda h}}$$

As an example, for a copper wire of 14 AWG, r = 1.63/2 = 0.815 mm, ρ = 8890 kg m^{-3}, C = 385 J kg^{-1} K^{-1}, and λ = 400 W m^{-1} K^{-1}. Assuming that h = 50 W m^{-2} K^{-1}, and that 10 W is dissipated in the connection, giving $q'' = \dfrac{10}{\pi r^2} = 4.8\times10^6$ W m^{-2}. Then

$\Delta T(\infty) = 4.8\times10^6 \sqrt{\dfrac{0.815\times10^{-3}}{2\times400\times50}} = 685$. If the ambient temperature = 20ºC, then the temperature at the overheating connection will be 20 + 685 = 705ºC, which is way over the ignition temperature of most combustibles. This theoretical treatment is highly simplified, nonetheless it indicates that very high temperatures can be anticipated.

The ignition of structural components of a building can be caused by a glowing connection, but there is little data to assess this potential. Aronstein[350] demonstrated in laboratory studies that a connection producing 50 W can ignite wood studs. A minimum time of 25 min was needed for ignition to occur from a 50 W fault. He also found that a connection glowing at a 45 – 50 W level was able to melt aluminum. Electric outlet cover plates made of thermosetting plastic were able to be ignited at the 30 W level; thermoplastic ones, however, were prone to melt away rather than to ignite.

Ettling[345] examined the situation where a nail pierces a conductor in a cable buried in the wall and a resultant glowing connection occurs between the nail and the two pieces of severed conductor. He found glows similar to those studied by Meese and Beausoleil[346]. A fire has been documented[347] which was caused by a glowing connection at a computer unit where the 120 VAC supply was protected by a 1 A fuse, which did not blow. Details of research on glowing connections within electrical receptacles are considered in Chapter 14.

IEC[348] and Sandia National Laboratories[349] both developed different test methods intended to simulate a glowing connection as a means of testing the ignitability of electric wires and cables from this source, but neither method has been validated for ignition of building components. The Sandia apparatus comprises a screw-terminal strip, with a small heater inserted under one screw. The heater provides up to 200 W, although this is time-dependent, due to the negative-temperature coefficient of the heater material. The peak heater power is about 5× greater than the values measured in actual glowing connections, which would imply that the test method is highly conservative. But test results using the method indicated that at a 50 W level, ignition is not observed. Since actual fires evidently involve connection dissipation of less than 50 W, the findings imply that actual fire conditions differ in some ways from the test mockup.

EJECTION OF HOT PARTICLES

Electrical short circuits and arcs sometimes eject incandescent metal particles ('mechanical sparks'). Color Plate 25 shows that even a metal box and cover are not sufficient to retain such material. These can be propelled a modest distance in a residential wiring situation. In the case of short-circuiting in a baseboard heater (Color Plate 26), Aronstein[350] found particles propelled up to 1.5 m (5 ft).

Aronstein also considers that, in low-voltage circuits, the risk of ignition is higher from non-incandescent molten aluminum particles, which can be produced if aluminum wire or connectors are used, than from incandescent particles. While the temperature of molten aluminum is lower than the temperature during its combustion, much larger drop sizes can be attained by molten drops than is normally attained by ejected incandescent particles.

DENDRITES

It has long been known that when a film of water comes onto the surface of an insulator that separates two closely-spaced, bare electric conductors carrying current, electric failures—and possibly ignition—can occur. The details were first studied in 1965 by Elliot[351] who discovered the process of formation of dendrites*. The growth of dendrites is possible with most metals used in electric devices, except aluminum, gold, and platinum. Very little ion content is required in the water; Elliot found that less than 10 ppm NaCl was sufficient. The process does require DC current, so it does not pertain to normal power distribution systems nor AC appliances. The growth is highly voltage-sensitive, but at higher voltages can be surprisingly fast and extensive. For example, Elliot found that at 50 VDC, a gap of 12 mm could be bridged in about 8 minutes. The dendrites are not pure metal, but rather, comprise both metal and metal oxides. Conduction of current across the gap increases with increased formation of dendrites; under heavy formation, a 'sludge' results.

ADVENTITIOUS BATTERIES

A potential difference can be created by electrochemical means any time that an electrolyte is present in conjunction with two dissimilar metals. In one accident, an explosion happened when a worker lowered an aluminum dipstick into a cast-iron tank which contained an acid mixture, along with some produced hydrogen[134]. Subsequent measurements indicated that a potential difference of 1.5 V existed between the two metals.

STATIC ELECTRICITY

GENERAL PRINCIPLES

Static electricity represents electric charges which are 'static,' that is, they are collected upon a surface and are not continuously flowing in an electrical current. The steps involved in a static electricity discharge are schematically illustrated in Figure 51. For significant charge separation (sometimes loosely called *charge generation*) to occur, at least one material must be involved which is an electrical insulator. An electrical insulator is considered to be a substance that has a resistivity above about 10^8 Ω-m, which unfortunately includes most organic substances.

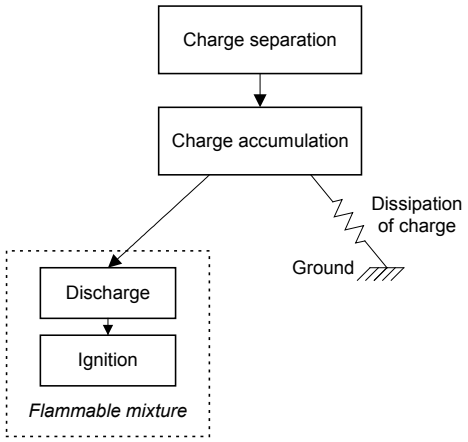

Figure 51 Static electricity fundamentals

Electric charge may be separated by the following means:

1. contact and separation or friction between solids
2. relative motion at a phase interface (liquid-solid; liquid-gas; or between two liquid phases)
3. induction (whereby charge is moved due to the presence of an electric field), also sometimes termed polarization
4. ion collection from a discharge process (e.g., from corona discharge)
5. double-layer charging
6. fragmentation of solids having non-uniform surface charge densities

* These dendrites are not to be confused with dendritic crystals sometimes formed within a molten metal that has cooled. The latter are structures *within* the bulk metal, while the dendrites considered here are growths that protrude from the metal.

7. mechanical fracture (electron emission due to strained or ruptured bonds within solids), also termed piezoelectrification[352]
8. thermal cycling (e.g., charging by freezing[353]), also sometimes termed pyroelectrification.

Contact or friction between two dissimilar substances can produce a charge separation if either of the two substances is an insulator. The contact may be solid/solid, solid/liquid, or liquid/liquid. The most common modes pertinent to fire ignitions are:

a) contact and separation between dissimilar solids
b) flowing powders
c) flowing liquids.

A mild amount of charging can be created simply when two surfaces come into firm contact and are then separated. Friction merely enhances the charging by increasing the effective area of contact. Traditional wisdom is that not only must the materials be dissimilar, but that sizable charging will take place only if they are far apart on the *triboelectric series*, which is a rank-order listing of materials according to how much of a negative or positive charge they tend to pick up[374]. Later studies indicated that, for dielectric materials, the location on the triboelectric series is determined by the material's dielectric constant[361]. Current understanding, however, is that electrification is not precluded in contact between objects made of the same material. Thus, plastic chips falling down a chute made of the same plastic are known to be able to undergo electrostatic charging[354]. It is believed that this may involve both physical factors (e.g., stresses at the surface) and chemical factors (contamination). Temperature differences between the two nominally-identical surfaces increase the likelihood of charging. Electrification is possible due to friction within powders of a single substance. In that case, smaller particles may pick up one polarity of charge while larger ones the other. Gross separation of charge can subsequently occur if the powder is moved or poured in such a way that size segregation occurs[354]. Electrification due to ionized gases flowing past surfaces can arise, but if the gas is at normal temperatures (i.e., not a hot plasma), then the charging that can be achieved is trivial, amounting to less than a volt[436]. Lüttgens[361] points out that this applies only if the gases are not contaminated with solid or liquid particles. Charging to significant voltages that has been attributed to flowing gases turns out to involve small amounts of aerosols. Rapidly expanding gases released from a high-pressure reservoir will cool and this can result in charged droplets being formed. Airplanes pick up a charge by moving past charged particles. Gases which contain solid/liquid aerosols or gas streams which generate liquid or solid particulates (e.g., the discharge of a CO_2 extinguisher; the rapid evaporation of liquid propane) can pick up a charge.

A specific example of relative motion at an interface is the breaking of bubbles. One explosion has been attributed to bubbling of oxygen produced from the dissociation of hydrogen peroxide through a tank that contained an organic liquid at the surface[355]. The discharge was speculated to be a corona discharge, but it was pointed out that some surface inhomogeneities were also needed for it to occur—perhaps a floating metallic object.

Induction charging only pertains to conducting bodies. If a neutral conducting body is brought close to a positively-charged substance, a charge separation will occur in the conducting body, with negative charges flowing towards the positively-charged substance. Positive charges will then accumulate at the opposite end of the conducting body. If contact is now made with the positively-charged substance, local charges will be neutralized, but a net positive charge will remain at the far end.

For certain materials, *moisture* in the air promotes the dissipation of charge since it decreases the electrical resistivity of some materials; it never affects the separation of charge. For many other materials, however, the resistivity is not lowered due to atmospheric moisture. Adding vapor-phase moisture does not actually change the electrical conductivity of the air; adding a mist or spray raises the conductivity, since it traps ions which would otherwise be available to conduct charge[356].

DISCHARGE TYPES

Discharges of static electricity can involve the following geometries:

- discharge between two conductive electrodes
- discharge involving one conductive electrode and an diffuse insulating medium
- discharge from one mist or cloud to another.

Apart from events taking place solely in the atmosphere (which are considered under *Lightning*, below), discharges involved in accidental ignitions are classified as:

(1) spark
(2) corona discharge
(3) brush discharge
(4) powder heap discharge
(5) propagating brush discharge (Lichtenberg discharge)
(6) lightning-like discharge.

Spark

A normal electric spark discharge (Color Plate 27) occurs through the air separating two electrodes when the electric field reaches a value of approximately 3 MV m^{-1}. Thus, for a gap distance d, the voltage V required is $3d$, where V is in megavolts and d is in meters. For a spark to be incendive, the gap distance normally must be equal to or greater than the quenching distance. Considering 2 mm as a typical quenching distance, the voltage required is on the order of 6 kV. Up to about 1000 mJ can be delivered in a spark. This is a sizeable amount of energy, well beyond the MIE of most substances. The charge transferred in an incendive spark is always greater than 10^{-7} coulombs[357]. Spark discharges are distinguished from other electrostatic discharg-

es in that breakdown occurs across the *whole* gap separating two electrodes. MIE values derived from tests using uniform fields between metallic electrodes should not be assumed to apply when one or both of the electrode surfaces is non-metallic, nor when the field is non-uniform. In general, it requires much more energy to ignite a gas mixture when a non-metallic electrode is involved[358].

Corona discharge

A corona discharge (sometimes called *point discharge*) is a slow, diffuse discharge that originates at a metallic electrode and branches out in a diffuse manner into space or towards poorly conducting surfaces. Unlike a spark or an arc, a corona discharge does not create a hot, conducting plasma channel. A corona discharge requires an electrode that has a needle-like point, typically less than 5 mm diameter (Color Plate 28). Charging such an electrode results in an electric field which is distorted, being generally low, but much greater near the point. Corona discharge has the lowest energy of the electrostatic discharge types. It is visible as a violet glow in a darkened room. A corona discharge can also occur in the presence of second electrode, but is still considered a 'one-electrode' discharge since the discharge does actually reach the second electrode. A minimum voltage of about 2 – 6 kV is necessary for a corona discharge to occur, with smaller potentials needed for finer-pointed needles. Characteristics of corona discharges are different, depending on whether the point electrode is positively or negatively charged.

The maximum energy normally realizable from a corona discharge—not much over 0.01 mJ—would even theoretically suffice to ignite only the most ignitable of gases, such as CS_2 or H_2. However, actual ignition requires that the energy be delivered into a small kernel, and the diffuse nature of a corona discharge precludes that. This implies that much more than the tabulated MIE value would be needed and, consequently, that it is unlikely that a corona discharge will ignite flammable atmospheres. Under some conditions, laboratory experiments have demonstrated that combustible mixtures can be ignited, however, the conditions required have been extreme, e.g., charging up to 72 kV[429], or use of circuits that supply a continuous flow of current, rather than being a one-time static discharge[359]. It is evident that a corona discharge cannot ignite dust clouds. Corona discharges are often used in processes and machinery as a safety measure for lowering charge accumulation.

Brush discharge

When a grounded conductor is brought into an electric field that is near its dielectric breakdown strength, a gas discharge can occur in the form of a brush discharge. The discharge is able to occur because of electric field distortion introduced by the electrode, which locally raises the field above its breakdown value. The name comes from the brush-like shape of the discharge, Color Plate 29. It differs from a corona discharge, in that the latter is visually observed to be diffuse. A brush discharge is similar to corona discharge in being a low-energy, one-electrode discharge, but whereas a corona discharge requires a needlelike electrode, a brush discharge occurs when electrodes have a radius of 5 – 50 mm. A minimum potential difference of about 20 – 25 kV is needed for a brush discharge to occur; however, it is considered that discharges at less than about 60 kV are limited to certain laboratory experiments and are unlikely to occur in industrial accidents[360]. Circumstances leading to a brush discharge can include[361]:

- approaching a highly-charged insulator such as plastic films or plastic pipes with a finger or a metal tool;
- discharging of solids from plastic bags in the vicinity of metal parts;
- filling a tank at a high velocity with an insulating liquid, with the charged liquid surface approaching an internal fitting that can act as an electrode;
- lowering a conductive cup, etc., into a highly charged liquid;
- projection of metal parts into a cloud of highly charged dust or aerosol;
- pouring of insulating powders into silos when the fill surface approaches a conductive fitting;
- projection of ships' masts, flagpoles, or antennas into a powerful atmospheric electric field—this is known as St. Elmo's fire.

The incendivity of brush discharges is proportional to the radius—larger-radius conductors are more likely to lead to ignition than ones of smaller radius[361]. Commonly, the high electric field will occur due to the presence of a charged insulator. Only a limited amount of the charge built up on the insulator can be discharged through a brush discharge, due to the limited mobility of charges on the insulator. It is estimated[360] that the energy from a brush discharge will not exceed about 4 mJ. In addition, most of the energy released during a brush discharge does not contribute to incendivity, since the energy is not just localized at the place where a flame kernel is formed. Thus, only 10% of the energy released is actually effective towards ignition[413]. The necessary high electric field strengths are readily found in many powder operations, in mists, and also with movement of plastic films.

While it is most common for brush discharges to occur from a grounded conductor, this is not a fundamental prerequisite, and brush discharges can originate from electrodes at various potentials[361]. This type of brush discharge is called 'spraying' and can occur whenever the potential V (MV) of the electrode and its radius r (m) are such that:

$$\frac{V}{r} > 30 \text{ MV m}^{-1}$$

Brush discharges from a negatively charged insulator (and, therefore, positive charge on the grounded conductor) are much more incendive than from a positively charged one; indeed, there are some doubts that the latter is possible.

This phenomenon appears to be related to the fact that a bright 'root' is formed at the electrode only in the case of a positively-charged grounded conductor[413]. For a brush discharge to ignite a flammable gas mixture, it is necessary that the insulator/conductor gap over which the discharge occurs be greater than 20 – 30 mm. In addition, a minimum surface potential needs to be reached. In most cases, this is about 45 – 60 kV, but under certain extreme cases ignition took place with a potential as low as 20 kV[413]. For a brush discharge to ignite a liquid in a tank, it is necessary that[429]: (1) the liquid be charged negatively, with a surface potential of 30 kV or higher; and (2) a rounded metallic electrode be available, ideally between 10 and 50 mm diameter.

Even though about 3.6 mJ can be delivered in a brush discharge[362] and there are dust clouds that have an MIE ≥ 1 mJ, most studies have concluded that brush discharges will not ignite dust clouds[363], provided that the cloud is not a hybrid dust/gas mixture. A brush discharge has been shown to be capable of igniting dust clouds in certain highly unusual experiments[364]. Larsen et al.[365] painstakingly attempted to ignite clouds of sulfur dust and found that an oxygen concentration of 55% or greater was needed. This is understood to be because a dust cloud fundamentally alters the electric field that leads to a brush discharge.

Powder heap discharge

In some cases, when rapidly filling large containers such as silos or flexible intermediate bulk containers (FIBC) with powders, a much higher charge can build up in the settled powder than was present in the air through which the material moved and a discharge can then take place. This occurs because a growing volume of powder is aggregated, plus when the powder is compacted, its charge likewise gets compacted if the powder is insulating and charge cannot get dissipated. The powder heap discharge is also called a *cone discharge* or a *bulking discharge*. It occurs along the exposed surface of the powder (Color Plate 30). Glor[366] computed certain theoretical limits to this form of discharge. It turns out that a minimum particle size of ca. 0.1 mm is needed for powder heap discharge to occur, but the majority of the actual incidents have involved polymeric resin particles in the 1 – 10 mm range. Early recommendations used to state that up to 10 mJ can be delivered in a single discharge step. But Glor[367] found, on the basis of correlating full-scale test results, that the maximum energy W (mJ) which can be delivered is:

$$W = 5.22\, D^{3.36} d^{1.462}$$

where D = silo or diameter (m) and d = median particle diameter (mm). Thus, Glor concluded that discharges as large as 1000 mJ may be anticipated for large particles flowing into a large silo, although Britton[379] argued that Glor's test methodology may not be realistic.

A minimum product feed rate is needed for a powder heap discharge to occur. This has been estimated at 3000 – 5000 kg h^{-1} for 3 mm particles, rising to 25,000 – 30,000 kg h^{-1} for 0.8 mm particles[361]. The effect of accumulated volume has not yet been quantified. It appears that only a small fraction of the charge accumulated can be dissipated in a powder heap discharge, but this has likewise not been quantified. Powders having a resistivity of less than 10^{10} Ω-m are conservatively judged to not be susceptible to explosions from powder heap discharges[367]; powders which have caused explosions have had resistivities > 10^{12} Ω-m.

In the rapid filling of silos, a propagating brush discharge along the container walls can accompany a powder heap discharge over the surface of the product.

Propagating brush discharge

A very vigorous discharge can occur when certain conditions are met for the charging of a surface. There is a limit to the amount of surface charging that can be sustained on a surface without discharging by ionizing the air (2.65×10^{-5} C m^{-2}). This limit can be increased if a double layer of charges of opposite polarity is accumulated. A way for this to occur is when an insulating layer is directly on top of a grounded metallic layer. This allows opposite polarity charges to build on the second side of the insulating layer (Figure 52). Under those conditions, the maximum surface charge is governed by the breakdown strength of the insulator, which may be on the order of 20 – 40 MV m^{-1}, instead of the 3 MV m^{-1} for air. In addition, the dielectric constant of many common insulators is 2 – 4 times that of air. These two factors combine to give maximum surface charges of around 5×10^{-4} C m^{-2}, and it is considered that 2.5×10^{-4} C m^{-2} is the minimum surface charge needed for a propagating brush discharge. With very thin films of certain plastics, surface charge densities up to 8×10^{-3} C m^{-2} have been measured[368]. A propagating brush discharge (Color Plate 31) can ignite most flammable mixtures, including dust clouds. A discharge occurs in one of two ways: (1) a grounded electrode is brought near the charged insulator surface; or (2) a dielectric breakdown of the insulating layer, resulting in a local puncture. A propagating brush discharge is capable of discharging nearly all of the charge stored in the double layer.

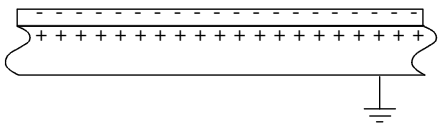

Figure 52 Double-layer charging (charge pairing) occurring when a charged insulator is adjacent to a grounded conductor

A propagating brush discharge (also called *Lichtenberg discharge*) does not occur if the thickness of the insulating layer is greater than 8 – 10 mm, but it also is less likely to occur with very thin insulating layers. For the charge buildup to be successful, the insulating layer has to have a high dielectric strength. A minimum voltage of ca. 4 kV is needed for a propagating brush discharge to occur with very thin films (10 – 20 μm) rising to 8 kV for 0.2 mm thick ones. A

propagating brush discharge will not occur if an insulator has such low dielectric strength that it breaks down prior to charging up to the necessary voltage. Up to ca. 1000 mJ can be delivered in a propagating brush discharge.

A related double-layer charging phenomenon can occur if a plastic sheet is charged with opposing polarity charges on its two surfaces. A significant discharge can then occur if two such sheets are stacked.

Circumstances leading to a propagating brush discharge can include[361,369]:

- conveying an insulating powder at high velocity through plastic pipes or bins that are grounded on their exterior;
- conveying an insulating liquid at high velocity through plastic pipes that are grounded on the outside, or metallic pipes that have an insulating interior coating;
- loading of insulating powders into large, non-conductive silos;
- operating at high velocities conveyor belts that have metallized outer surfaces and an insulating core;
- repeated collisions of dust particles on an insulating surface atop a grounded layer.

In some cases, a propagating brush discharge can occur without an overt grounded layer, for instance when rain is falling on a plastic pipe conveying an insulating powder[370].

A propagating brush discharge does *not* form simply due to the deposition of a thin layer of powder on a metal surface. This is because the breakdown strength of the porous structure is not higher than that of air. Similarly, normal solvent-based paints lead to a porous structure which likewise does not exceed the breakdown strength of air. However, certain insulating coatings on containers and storage vessels are not porous and could sustain a propagating brush discharge.

Lightning-like discharge

Lightning in the atmosphere can occur when water droplets and ice particles are charged to very high potentials. Since particles in dust clouds will also pick up an electric charge, lightning-like discharges have been observed to occur in the dust clouds formed during volcanic eruptions. What is unanswered is whether such discharges can occur on a smaller scale, to wit, in connection with storage silos. A number of accidents have been blamed on such discharges, but the details of the circumstances have never been clear. Lightning-like discharges would presumably be able to ignite almost any combustible matter, so the conditions—if any—that might lead to such lightning would be important to quantify. Boschung et al.[371] conducted experiments whereby a 60 m^3 bunker was rapidly filled with various dusts. They measured peak field strengths of 1000 to 2000 kV m^{-1} during this filling. The peaks were of short duration, but for about 15 – 20 s, the values exceeded the 300 – 500 kV m^{-1} that is needed for lightning discharge. However, no lightning discharges actually occurred. The authors believe that a scale effect was being seen, and that much larger volumes could lead to a lightning-like discharge. The events would be expected to be rare, since normal transport of dusts does not lead to high electrical charging: the experiments reported were set up to be worst-case conditions.

MEASURING OF DISCHARGES

The ignition of a flammable gas mixture or a dust cloud is measured in terms of minimum spark energy that is needed for a capacitive discharge. This is not an absolute measurement, but strongly dependent on the details of the electrical circuit, the electrodes, etc., much as has been discussed in connected with ignition of gases. In a spark discharge, as discussed in Chapter 4, the nominal energy can be determined by measuring the capacitance and the charging voltage. Other forms of discharge, such as corona or brush discharge, do not lend themselves to such measurement. For such discharges, an equivalent energy concept is used. A certain discharge is said to possess a given energy W if it is just able to ignite a mixture which has the minimum ignition energy W, as determined by capacitive discharge testing.

ELECTROSTATIC CHARGING AND DISCHARGING OF SOLIDS

In a common science-class demonstration, cat fur is used to create electrostatic sparks. A live cat, however, can also undergo charging and a subsequent spark discharge. A case is documented where an electrostatically charged cat demolished an execution tank at a pound where town gas was being used and got ignited[372]. Hailstones can occasionally be charged to very high levels, and a case is reported[373] where the discharge occurring upon such hailstones hitting a storage tank sufficed to burn paint on it.

For surfaces in contact to pick up a significant charge, at least one of the surfaces has to be of high surface resistivity. The electrostatic effects of changing the *relative humidity* do not relate to any changes in the conductivity or other properties of air. Instead, increased RH lowers the surface resistivity of some materials and thus decreases the likelihood that surfaces in contact will pick up a high charge. Other materials, however, are but little affected by increases in relative humidity. A sufficient number of materials are affected by RH so that the effect shows up in statistics. A recent study on the topic is not available, but in 1933 Guest[374] compiled data showing that fires and explosions caused by static electricity predominated in winter months, when RH is low indoors, and became several-fold less frequent during summertime. Many insulating materials show a strong drop in surface resistivity at high RH values, for example, fabrics[394] and paper[356]. Waxes are an exception since they have a hydrophobic surface[375]. Plastics show diverse behaviors.

Ranking of solids according to their propensity for picking up an electric charge is inherently misleading, since actual

charge accumulation depends on characteristics of both the surfaces in contact. Henry[376] demonstrated that nylon rubbed with brass picks up more charge than PET, but the PET picks up more charge than nylon when rubbed with wool.

The capacitance with respect to ground that objects represent increases with their size according to the equation:

$$C = 4\pi\varepsilon\varepsilon_o r$$

where C = capacitance (Farads; F), r = radius (m), ε = dielectric constant (--), ε_o = permittivity of vacuum (8.854×10^{-12} S s m^{-1}), where the abbreviation capital S denotes Siemens, the basic unit of electrical conductivity. The dielectric constant for air = 1.0. While this equation is exact only for spheres, objects which are roughly of similar sizes in the three dimensions can be estimated with it. The maximum charge which can be built up on an isolated object in air is governed by the breakdown strength of air E_{max}, which is approximately 3 MV m^{-1}.

The maximum charge density which can be built up on the isolated object is given by:

$$\sigma_{\max} = \varepsilon\varepsilon_o E_{\max}$$

or σ_{max} = 26.5 μC m^{-2}. Since the area of a sphere is = $4\pi r^2$, then the maximum charge which can accumulate on the spherical body is:

$$Q_{\max} = 4\pi r^2 \times 27 = 339\, r^2\ \mu\text{C}$$

The capacitance C is defined as = Q/V. Thus,

$$V = \frac{Q}{C} = \frac{Q}{4\pi\varepsilon\varepsilon_o r} = E_{\max} r = 3.0\times10^6 r$$

As discussed in Chapter 4, assuming that no losses occur, the energy which can be delivered from a capacitive spark is:

$$W = \frac{1}{2} CV^2$$

where we have used W for energy here, in order to avoid confusing with the electric field, designated here as E. Substituting the above, gives:

$$W = 501 r^3$$

where W = energy (J). For many hydrocarbon vapors, a value of MIE ≈ 0.25 mJ is applicable. Then, to cause an incendive discharge from a charged, isolated body, its radius must be at least:

$$r = \left(\frac{0.25\times10^{-3}}{501} \right)^{1/3} = 0.008\ \text{m}$$

Since this limit is only 8 mm, it would be very difficult to develop a safety measure on limiting the physical size of bodies that pick up a charge. In practice, somewhat higher minimum sizes will suffice, since ideally efficient conditions will not be present for discharge. For a propane/air mixture (MIE = 0.26 mJ), a minimum radius of ca. 12 mm was found necessary in order to have an incendive discharge[377]. The capacitance some common objects is given in Table 30.

Table 30 The estimated capacitance of some objects

Object	Capacitance (pF)
buckets, small drums	5
55-gallon drum	100
automobile	500
tank truck	1000
large tractor-trailer	3000

The electrostatic charging of *plastic sheets* can occur by rubbing, by passing over rollers, by rapidly separating sheets, and by various other means. Gibson and Lloyd[378] found that, at RH values less than 40%, many plastics are able to pick up a surface charge of 10 to 23 μC m^{-2}. For higher RH values, the charge densities decreased, the values dropping to about half at 75% RH. In experiments with polyethylene sheets, they found that the surface could be charged to about 75 kV. Sparks occurred when grounded objects were brought close to the charged surface. Incendive sparks could be created in atmospheres containing methane, acetone, toluene, and other vapors. In some cases, the conductivity of plastics is extremely low, and this may help prevent an incendive discharge. Magison[318] documents a case where a hydrogen/air mixture could not be ignited from a plastic case charged to 25 kV. For an incendive discharge to occur, charge must flow at a sufficient rate through the charged material. In testing, it was found that the flow of charge was so small that discharges occurred only as a series of small pulses, with none being able to ignite the gas mixture.

Industrial operations can charge substances to some high potentials[388], as shown in Table 31.

Table 31 Peak charging voltages measured in some industrial operations

Operation	Potential found (kV)
flange on steam ejector	15
conveyor belt moving at 3 – 15 m s^{-1}	80
roll of paper unwound at 10 m s^{-1}	150

A charge accumulated on a solid does not remain there permanently and eventually dissipates (undergoes 'charge relaxation'). This is defined in terms of the relaxation time, which is the time it takes for charge to decay to (1–1/e) = 63% of its initial value. It can be estimated from:

$$\tau = \varepsilon\varepsilon_o \rho$$

where τ = relaxation time (s), and ρ = volume resistivity of the material (Ω-m). Some values[379-381] for ε and ρ are given in Table 32. As an example, for dry wood the relaxation time is computed to be $3.0 \times 8.854\times10^{-12} \times 10^{10} = 0.27$ s. In view of this fast decay of charge, significant electrostatic problems would not be expected. On the other, for PTFE the relaxation time is computed to be 177,000 s, or 49 h, showing that charge decays extremely slowly on PTFE. As

a rough guideline, substances having resistivities below about 10^{10} Ω-m show little propensity for electrostatic discharge hazards. When the initial charge is known, and the constants are available for a material, the charge remaining at any time t is computed as:

$$Q = Q_o \exp(-t/\tau)$$

where Q_o = initial charge (C), and t = time (s).

Table 32 Dielectric constants and volume resistivities for some solid materials

Substance	ε (--)	ρ (Ω-m)
cellulose acetate	3.5 – 7.0	$10^8 – 10^{11}$
cellulose acetate butyrate	3.5 – 6.4	$10^8 – 10^{10}$
cellulose nitrate	6.4 – 8.4	10^9
glass, plate	7.5	2×10^{11}
glass, Pyrex (borosilicate)	5.0	10^{13}
HDPE	2.3	$10^{14} – 10^{15}$
melamine formaldehyde	6 – 9	$10^{10} – 10^{12}$
Neoprene	9.0	10^{11}
nylon	3.5	4×10^{12}
paper, dry	1.7	10^{10}
PCTFE	2.8	10^{16}
PET	3.1	10^{11}
PMMA	3.4	$> 10^{13}$
polycarbonate	3.2	10^{14}
polyester, glass reinforced	4.0 – 5.5	10^9
polypropylene	2.2	$10^{13} – 10^{15}$
polystyrene	2.5	$10^{15} – 10^{17}$
polyurethane	5 – 8	$10^9 – 10^{12}$
PTFE	2.0	10^{16}
PVC	6 – 7	$10^9 – 10^{14}$
rubber, chlorinated	3.0	1.5×10^{11}
rubber, hard	3.0	3×10^{11}
sulfur	3.8 – 4.4	$10^{14} – 10^{15}$
TNT	5.2	9×10^8
wood, dry	3.0	$10^8 – 10^{11}$

Pyrotechnic compositions typically show $\rho = 10^{11} – 10^{12}$ Ω-m when measured at 20% RH, but these mixtures are hygroscopic and values drop greatly at higher humidity[388].

High values of humidity (60 – 70%RH) lead to a microscopic layer of moisture to be accumulated on surfaces. The conductivity of the moisture layer can be higher than for the substrate, allowing a more rapid leaking down of built up charge. In industries where electrostatic discharges can have serious consequences (e.g., explosives manufacturing), it is sometimes recommended[382] that RH be set at ≥ 65%, for an ambient temperature of 20ºC. For other ambient temperatures, a study on the electrostatic charging of 6 fabrics and 3 primary explosives as a function of temperature and RH showed[383] that the same charging voltage would be produced if the RH versus temperature relation is:

$$RH = 80.7 - 0.79\,T$$

where T = temperature (ºC).

Conveyor belts made of high-resistivity materials can build up very high surface potentials due to passing over rollers. Up to 120 kV was measured in one study during periods of extremely low humidity[357]. It was found that charging depended on low values of *absolute* moisture in air, and that RH was not the proper variable for describing the charging tendency. Static eliminators were found to be impractical, since electrostatic charge is re-applied by each roller, so an eliminator would be needed in conjunction with every roller.

ELECTROSTATIC CHARGING AND DISCHARGING OF PERSONS AND APPAREL

A mild shock due to electrostatic discharge is common for human beings. Such discharges can also be incendive. In the early part of the 20th century when gas lighting was used, a parlor trick was common[373] whereby a person would shuffle his feet across a carpeted floor, then light a gas jet by causing an electrostatic spark discharge between his fingers and the metal fixture. Shoes charge the wearer because each time the foot is raised, the capacitance to ground is decreased and charge accumulates on the person.

Charging readily occurs when apparel is worn which is highly insulating and the apparel contacts and separates from external objects. The charge picked up on the apparel then induces a similar charge in the body. A strong spark discharge can be created when one layer of clothing is removed from atop a second one. Or, a discharge may occur from the body to an external object.

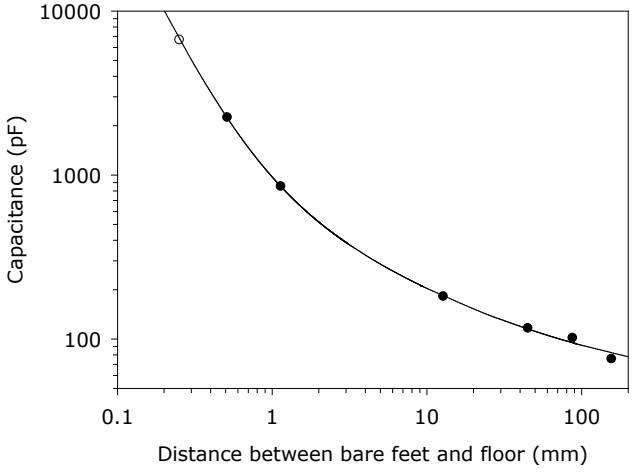

Figure 53 Effect of footwear thickness on the capacitance of a person (assumed standing on a floor of moderate conductivity)

It is generally considered that a human being[384] represents a capacitance to earth of about 120 – 300 pF, with typical values being 150 – 250 pF, and 220 pF sometimes proposed as a 'standard' value[393]. Actual capacitance[385] varies with the thickness of the footwear, as shown in Figure 53. The 'standard' capacitance of 220 pF can be seen to correspond to a footwear thickness of 8.3 mm. An extreme value of 1100 pF has been reported for a male subject wearing leather-sole shoes[386], but its meaningfulness is unclear—the latest experimental study[387] on this subject showed values only within the range 60 – 165 pF. The position of the person affects the capacitance. If the capacitance of a standing person is 250 pF, a sitting individuals may show 280 – 300 pF. An individual infinitely far away from the ground plane[388] would register a capacitance of 30 – 40 pF.

In dry air, the body can charge up to 5 – 25 kV, although voltages towards the high end of this range are uncommon and are limited by corona discharge. Thus, under the worst circumstances, the energy that is stored and is available for release in a spark is:

$$W = \frac{1}{2}CV^2 = \frac{1}{2}\cdot 300\times 10^{-12}\cdot\left(25\times 10^3\right)^2 = 94 \text{ mJ}$$

If this much energy could be effectively applied, it would be enough to ignite all common ignitable vapors and also many dusts. However, more typical values of stored energy due to friction of apparel would be 5 – 20 mJ. A value of 25 mJ has been adopted by a British standard[389] as the maximum practical value needing to be considered. Fisher developed an electrical circuit which creates a rather complex discharge waveform, intended to simulate human discharge under worst-case conditions[384]. At an RH of 50%, a person walking on a carpet will generate no more than about 3 kV, and for RH of 60% or higher it appears to be impossible to create any significant voltage[386]. Thus, the problem is limited to dry atmospheric conditions.

In tests at 20% RH where an individual was doffing laboratory coats of cotton or polyester/cotton blend and the undergarments were of various fibers, charging voltages of 1.8 – 3.6 kV were measured[390]. The charge accumulated by a person repeatedly sliding around on a painted-plywood chair has been measured[391] to be 1.8 μC. At 30 – 35% RH, a person getting up from sitting on a doctor's stool[385] can be charged to 1.0 – 3.0 kV. A person sitting down, then rising from a plastic-covered chair can get charged to about 4 kV under the worst-case conditions (nylon clothing, low RH); but if the RH is raised to 80%, then charging only up to a few hundred volts is possible[392].

The electrostatic charge associated with the changing of linens on hospital beds was studied by Holdstock and Wilson[393]. The metal bedframe (with a measured capacitance of 185 pF), was found to be charged up to 32 kV. The person doing the task was reported as being charged up to 60 kV, although it is not clear why corona discharge did not occur to limit this. When laundry antistatic agents were used, reductions of ¼ to ½ were found. The highest charging voltages all involved modacrylic blankets. In bedding sets that used polyester instead of modacrylic blankets, both the person and the bedframe were charged only to peaks of 17 kV. If a flammable gas atmosphere were present, these values would be much more than sufficient for ignition of even high-MIE gases. If the bed linens are removed by progressively folding them (a common hospital procedure) instead of pulling off, peaks are much reduced. For the best case—cotton bed linens—incendive sparks might be avoided, since peak charging voltages were only ca. 1.5 kV. In extreme circumstances, values up to 2 – 5 kV were found with cotton bed linens by Guest et al. [385]. The reductions achieved by use of laundry antistatic agents would not be sufficient to avoid incendive sparks for the worst case of modacrylic blankets and removal by pulling method.

In an early study, Wilson found that an energy of 18.6 mJ was needed to ignite a CH_4/air mixture from a person forming a capacitance of 220 pF[394]. This is vastly greater than the 0.2 mJ normally considered to be the MIE of methane and gave cause to various speculations concerning resistive losses through the body time effects because not all the energy is released in a single spark. However, a study by Tolson identified the pivotal role of capacitance[395]. For 86 pF, 1.1 mJ was needed; for 150 pF, 4.4 mJ was needed; while for 500 pF, the minimum was 20.2 mJ. A more extensive study by Movilliat and Giltaire[396] gave the results shown in Table 33. Discharges through points give anomalous results (see Chapter 4), but the remaining data show that human capacitor is nearly as effective as the electrical one, provided other circuit parameters are not changed at the same time. Thus, 9 kV is necessary to cause ignition of a CH_4/air mixture from a human being, even though 1 kV has been found sufficient (the lower limit was not explored) to cause non-incendive discharges from a human[397].

Table 33 Incendivity of human body and capacitor discharges

Gas	Electrodes	Human body		Capacitor
		Volts	Energy (mJ)	Energy (mJ)
28% hydrogen /air	15 mm Ø	2800	0.60	0.53
	1.6 mm Ø	2350	0.40	0.35
	points	4900	1.75	0.26
8.5% methane /air	15 mm Ø	9000	5.9	4.7
	points	9600	6.7	0.8

Wilson[398] conducted experiments similar to the above using natural gas/air mixtures. In these experiments, the exact capacitance that the body formed appeared unimportant, but the shape of the electrode did influence the results. A minimum voltage of ca. 6 kV was found to be needed, and a minimum energy of 1.7 mJ. As the size of the electrode was increased from 1 to 12 mm, both the voltage and the energy needed increased. In a continuation of the work[399], 5.5 kV was found needed for mixtures of 8.5% methane in air, while 1.3 kV sufficed for 29% hydrogen in air.

Johnson experimented with stoichiometric acetone/air mixtures and found that the energy required for ignition from a human spark discharge was 3.0 mJ, compared to 1.3 mJ needed for capacitive discharge from a 55 pF capacitor[400]. In Johnson's first experiment, the capacitance of the human was 136 pF. In a second test where the human created 171 pF capacitance, the energy required rose to 3.4 mJ. What proved constant for the three conditions (one capacitor, two humans) was the discharge voltage, which was always 6.7 kV.

A discharge from a person can ignite acetylene/air mixtures at a level of 1.1 mJ[401]. For a human to ignite the explosive PETN, the person would need to be charged to over 70 kV, which is impossible in most practical circumstances[401].

Guidelines are also available (Table 34) which relate the energy discharge from a person to the sensation[418, 379]. A perceptible sensation corresponds requires that the person be charged to about 2 kV[361]. In view of the above results, discharges that are perceptible but not severe are likely to lead to ignition if the person is in a space containing a gas in its flammable range. However, since people do not generally walk around in flammable atmospheres, it is found that electrostatic discharge from humans is actually a rare cause of unwanted ignition of gases[402].

Table 34 Human responses corresponding to various levels of discharge energy

Energy	Response
1 mJ	perceptible
10 mJ	prick
30 mJ	sharp prick
100 mJ	slight jerk
250 mJ	severe shock
> 1 J	possible unconsciousness
> 10 J	possible cardiac arrest

The resistance of the human body[384], measured to a fingertip is about 1300 – 2000 Ω, but if the person undergoes a discharge via a grasped metallic object, the body's effective resistance may be only 360 – 700 Ω.

ELECTROSTATIC CHARGING AND DISCHARGING OF GRANULAR MATERIALS

When granular materials—powders, dusts, grains, etc.—are in motion, they can pick up a charge. Insulating powders—those with a resistivity greater than about 10^{12} Ω-m—do not easily dissipate a surface charge they may acquire and, thus, can be prone to spark discharges. This is especially a problem if they are conveyed or stored in insulating pipes or silos. Perhaps surprisingly, even powdered metals—aluminum and magnesium—become poor enough conductors due to surface oxidation so that explosions of dust clouds of these metals have been caused by electrostatic discharges[403]. The tendency for powders to pick up a charge is roughly proportional to their surface/mass ratio (or inversely proportional to particle diameter)[404,405]. This effect appears to be related to the number of interparticle contact points that are available. There is also a material-specific factor—not all powders of the same surface/mass ratio pick up the same amount of charge under a given set of conditions. One condition which can sometimes be controlled is the nature of the processing operation—these differ substantially in their ability to charge powders. Table 35 shows the specific charge (coulombs per kilogram; note that 1 C = 1 ampere-second) which can be associated with different operations. Clearly, pneumatic transfer is the processing step where the highest ignition hazards may be expected to occur. Recommendations of this kind imply that maximum charge that can be picked up is linearly proportional to the mass of granular of material. Unfortunately, this is often not the case. In studies on granular explosives[405], it was shown that increasing the mass from 50 g to 500 g increases the charge by 1.4× to 3.0×, instead of 10×.

Table 35 Effect of processing type on electrostatic charging of powders[404]

Operation	Specific charge (C kg^{-1})
sieving	10^{-11} – 10^{-9}
pouring	10^{-9} – 10^{-7}
scroll feed transfer	10^{-8} – 10^{-6}
grinding	10^{-7} – 10^{-6}
micronizing	10^{-7} – 10^{-4}
pneumatic transfer	10^{-6} – 10^{-4}

The electrostatic charging is normally much higher if the particles flow along a plastic surface than a metal one. Dahn[406] measured agricultural grains flowing along polyethylene liners and found charging, expressed as an energy/mass ratio, on the order of 2 – 6 mJ kg^{-1}; flowing along metal chutes, the comparable values were 10^{-2} – 10^{-1} mJ kg^{-1}.

As with solids discussed in an earlier Section, charge accumulated on powders decays with time and the relaxation time can be estimated from the equation there. Streaming currents (see below) are possible with flowing powders, just as with flowing liquids. Unlike for liquids, however, little quantitative guidance is available.

Powders where the individual particles are charged and then agglomerated show a *bulking* effect. The maximum surface charge density of a small particle is 26.5 μC m^{-2}. The total charge when N of them agglomerate will be N times the surface charge on each. But the effective radius of the 'macrosphere' becomes small enough that 26 N exceeds the breakdown strength of air, i.e., becomes greater than 26 μC per m^2 of macrosphere surface. A discharge has to occur and this is known as a *bulking discharge.* These sparks that occur across the surface of the heap are known to be able to ignite sensitive gas/air mixtures[407], but have not been extensively characterized.

The resistivity of powders changes drastically with moisture. At conditions of RH > 60 – 65%, any charge formed is rapidly leaked away and hazardous conditions would not be expected[408].

Discharging of dry chemical (sodium bicarbonate or ammonium phosphate/ammonium sulfate) fire extinguishers can cause static electricity buildup. It was found experimentally that this can result in charging voltages which would correspond to discharge energies of up to 54 mJ[409]. Energies of this magnitude would be enough to ignite many dusts, not just gases; however, no actual testing of ignition potential was reported.

During loading or conveying of powders, local non-incendive discharges (corona and possibly brush discharges) may occur which are helpful, rather, than deleterious, since they serve to reduce the charge buildup. Based on this observation, to reduce the incendivity of bulking discharges, it is commonly recommended that a grounded wire be strung through the center of a container receiving insulating powders. This causes small corona-like discharges to occur to the grounding wire, instead of large sparks to the container itself. A ground wire is equally effective if the container is insulating, instead of conductive[407]. The ground wire must be thin (around 1 mm) in order to ensure a corona-like discharge.

While pure gases cannot pick up a charge due to motion, cases of mine explosions have been documented[410] where compressed air nozzles were discharged into atmospheres containing dust and methane.

Pneumatic transport systems cause a build up of charge largely due to bends in the pipeline, but within a few meters of travel distance a steady-state value of charge is reached[411]. For a given air velocity, increasing the product mass flow rate decreases the charging tendency. Charging tendency is also reduced by reducing air velocity and by increasing particle size of the granular material. Electrostatic discharges commonly occur whenever granular materials are pneumatically conveyed. These are typically non-incendive corona discharges. It is the possibility of spark discharges or other more energetic forms that forms the crux of the fire safety problem in these applications.

Silos can build up very high potentials when granular materials are conveyed into them. In one study[411], up to 150 kV was measured, with the highest readings being at the top, close to the product entry location.

Table 36 Electrical conductivity of common liquids

Hazard	Example substances	Typical electrical conductivity (S m^{-1})
Low: conductivity less than 10^{-13}	hexane	10^{-17}
	carbon disulfide	8×10^{-16}
	benzene	5×10^{-15}
	heptane	3×10^{-14}
High: conductivity of 10^{-13} to 5×10^{-11}	xylene	10^{-13}
	dioxane	10^{-13}
	toluene	10^{-12}
	cyclohexane	2×10^{-12}
	styrene	10^{-11}
	kerosene	1.5×10^{-11}
	hexamethyldisilazane	2.9×10^{-11}
	Jet-A fuel	$2 - 3\times10^{-11}$
Low: conductivity greater than 5×10^{-11}	gasoline	10^{-10}
	turpentine	4×10^{-10}
	crude oils	10^{-9} to 10^{-7}
	halogenated hydrocarbons	10^{-8}
	methyl alcohol	10^{-7}
	ethyl alcohol	1.4×10^{-7}
	cetones	10^{-5}
	water: deionized	10^{-5}
	iso-propanol	10^{-4}
	water: acid rain	10^{-2}

Note: resistivity (Ω-m) = 1/conductivity
Above data from[412-414] and other sources; for other substances, Britton's extensive compilation[379] can be consulted. Conductivities of liquids are highly variable and values given are only suggestive. In addition, increasing the purity or decreasing the temperature serves to make the liquid less conductive.

ELECTROSTATIC CHARGING AND DISCHARGING OF LIQUIDS

Many liquids are prone to undergo charge separation when they move past either a solid surface or the interface with another liquid. The charging process arises from minute concentrations of ions present in the liquid. But there is a competition between motion causing charging and innate conductivity causing a relaxation of charge. If a sufficiently high charge is accumulated, an electric discharge may occur. This discharge may cause an ignition under appropriate fuel/air ratio conditions. A negative electric charge is more incendive than the corresponding positive charge on the liquid. Charge relaxation readily occurs if the liquid has a high electric conductivity and for such liquids a high charge does not build up. Unfortunately, many organic liquids (i.e., aliphatic, aromatic, and cyclic hydrocarbons; ethers; some silicones) are good insulators (Table 36). Crude oil, alcohols, aldehydes, cetones, esters, ketones acids, epoxides, and nitriles on the other hand, are typically sufficiently

conductive. As a rough rule, most water-soluble liquids are conductive enough to not raise problems of electrostatic discharge in the course of bulk flow[415]. Liquids with conductivities < 5×10^{-11} S m^{-1} are considered to be of low enough conductivity that electrostatic hazards must be carefully guarded against. However, if the conductivity is extremely low, then ionized species that could cause charge buildup are also largely absent. Liquids with a conductivity of less than 10^{-13} S m^{-1} are considered to be in the latter category[429]. Thus, the peak hazard involves liquids with conductivities from 10^{-13} to 5×10^{-11} S m^{-1}. Low conductivity liquids do not support spark discharges to their surface, but can be subject to incendive brush discharges[379].

Liquids of high conductivity can be involved in static electrification accidents if they are within insulating vessels, or in the form of an aerosol, or in some other environment where a conductive path to ground is absent. A common form of electrification of high-conductivity liquids is spray atomization. As discussed below, water is a substance which can be electrified by atomization.

Since charging of low-conductivity liquids readily occurs, a question that has often been asked is: Why do explosions not occur more frequently in vessels holding ignitable liquids? The reason is generally understood to be because in many cases the vapor space above the liquid where discharges occur is fuel-rich[416].

A study on electrostatically-caused explosions of drums[417] identified the liquids most commonly involved:

- benzene
- toluene
- styrene
- dioxane
- hexamethyldisilazane
- toluene/heptane mix.

These chemicals all shared the traits of: (1) conductivity below $5\diamond10^{-11}$ S m^{-1}; (2) MIE < 1 mJ; and (3) wide temperature limits of flammability.

Pure hydrocarbons do not exhibit electrostatic charging; however, even impurities at the 0.001 ppm level change this situation[418]. The presence of a small amount of *water* in the product can increase the electrostatic charging effect up to 50-fold. Oxygen and sulfur compounds also promote charging in hydrocarbons[429]. Raising the *temperature* increases both the conductivity and the charging tendency, but the increase in charging tendency is usually greater[429]. For some substances, extreme changes have been noted with temperature, for example, with one test substance[419] the charging current increased by 1000× as the temperature was raised from 0ºC to 20ºC.

For insulating liquids flowing in *conducting pipes*, the charge density (C m^{-3}) picked up is linearly proportional to the liquid's flow velocity and the charge density reaches a steady-state value after a certain distance down the pipe. As early as 1913, Dolezalek[420] found that benzene and diethyl ether flowing through metal pipes can charge up to 2000 – 3000 V, with the voltage being roughly proportional to the flow velocity. The charge pickup up is less if the pipe is non-metallic. Flows which consist of two-phase liquids, liquids with suspended solids, or mixtures of immiscible liquids tend to build up higher charges than single-phase liquids. Charge buildup can especially increase if the liquid flows through a fine-pore filter. By passing through such filters, kerosene could be charged up to a voltage of –250 kV; further attempts at charging resulted in a spark breakdown within the liquid[421]. In experiments examining the effect of fill fraction on the charged potential in 100 m^3 kerosene tank[422], it was found that highest voltages were produced for a fill fraction around 50%. In experiments set up to reconstruct an industrial accident[423], it was found that pumping toluene into a metal 55-gallon (208 L) drum required that a voltage of –8500 V and a stored energy of 3.6 mJ be built up before ignition occurred via discharge to a grounded rod.

When a liquid which has picked up a charge enters a tank, at first the charge density Q''' (C m^{-3}) in the tank is identical to the charge density of the entering fluid. Gradually, however, relaxation occurs, that is, the small but finite conductivity of the liquid allows a recombination of charges. The relaxation of charge can be characterized by the fundamental time constant τ which is computed the same way for liquids as for solids (see above), although commonly expressed using the bulk conductivity:

$$\tau = \varepsilon\varepsilon_o / \kappa$$

where κ = bulk conductivity of the liquid (S m^{-1}). For most hydrocarbon liquids*, $\varepsilon \approx 2$. For kerosene, as an example, $\kappa = 15\times10^{-12}$ S m^{-1}, giving $\tau \approx 1$ s.

Bustin and coworkers[424] discovered that liquids of very low conductivity (< 1×10^{-12} S m^{-1}) behave anomalously ('non-ohmically') in that charge relaxation is faster than exponential, decaying approximately hyperbolically. For these very low conductivity liquids, Bustin discovered that the basic governing variable determining the relaxation time constant is no longer the conductivity but, rather, the charge level and the charge mobility. The ohmic theory of charge relaxation is based on the assumption that the total number of charge carriers is constant. But for low conductivity liquids, in the uncharged state the number of charge carriers is small; when a liquid of this kind is charged, charges of one sign are removed and charges of the opposite side added, but the sum greatly exceeds the number of carriers in uncharged liquid. Bustin further assumed that the low initial quantity of charge carriers in the uncharged liquid can be set to zero, and that the charged liquid will then have charg-

* Note that this is not true for oxygenated organic liquids; as an example, for alcohols $\varepsilon \approx 20$.

es of only one sign, assumed as positive. The charge decay with time then goes as:

$$q^+ = \frac{q_o^+}{1 + \mu q_o^+ t / \varepsilon\varepsilon_o}$$

where q_o^+ = initial charge density, and μ = charge mobility ($m^2\ V^{-1}\ s^{-1}$). In practice, the group of variables $\mu q_o / \varepsilon\varepsilon_o$ is taken to be an experimental constant. As an alternative to determining the value experimentally, it has been shown[413] that if the decay is assumed to be exponential, but using a fictional conductivity of 0.5×10^{-12} S m^{-1}, then reasonable relaxation time estimates can be made.

For actual vessels, the relaxation time found experimentally is not the fundamental time constant, but it is related to it. In a theoretical study[425] to characterize this actual relaxation time, it was found that the vessel geometry only matters for fill fractions greater than 90%, and that the relaxation time depends on τ and on $D_t\kappa/\lambda$, where D_t = tank diameter (m), and λ = surface conductivity (S). Thus, both the surface conductivity and the bulk conductivity affect the relaxation time. The actual relaxation times were generally found to be 2 –3 times τ, provided that $D_t\kappa/\lambda$ is greater than about 5. In a similar vein, Strawson and Lewis[426] reported on measurements with an aviation fuel where the at-rest conductivity was compared to the relaxation times for flow past filters. They found that the actual conductivity for the liquid in motion is not identical to the value measured in tests where the fluid is at rest. The values of effective conductivity were found to be between 0.04 and 7 times the at-rest values; most of the values were lower than the corresponding at-rest values, except when at-rest values were already below 1×10^{-12} S m^{-1}. They concluded that the charging process itself causes some ionization, which raises the effective conductivity, but did not delve into reasons why certain conditions lead to effective conductivities lower than the at-rest value.

In many practical arrangements, a metallic fill pipe will exist in the middle of the tank. Its presence has been shown[427] to greatly reduce the maximum potential to which the surface of the liquid charges up to, with the voltages being in some cases reduced to 1/3 those which would occur in the absence of the pipe. It is recommended that the fill pipe extend close to the bottom of the tank[379].

The small size of a flammable liquid container does not preclude ignition due to electrostatic discharge, as documented in a case involving a 2.5 gallon (9.5 L) plastic container containing an alcohol-based solvent[428]. A small explosion took place when a person used a steel knife to puncture the hermetic seal of the container. Laboratory testing suggested that the event was due a charge created by shaking the liquid, and not due to a charge on the person.

For hydrocarbon liquids that pick up some water impurity, relaxation times in tanks can be much lower than predicted, due to sedimentation (settling). The effect arises because of charges associated with the water component and its gradual movement in the tank[429]; the theory has been presented by Klinkenberg and van der Minne[418].

If a liquid is at rest, ion impurities will cause a certain amount of separation of charge, but the net charge in the pipe will be zero. But when a low-conductivity liquid is in motion in a pipe, not just separation, but an actual flow of charge occurs. This flow is called a *streaming current* and it arises because ions in the liquid tend to move with the flow, while the opposite charge on wall dissipates to earth. For it to occur, the liquid must have a conductivity in the range of about 10^{-13} to 10^{-7} S m^{-1}. Higher conductivities lead to rapid neutralization of charge, while smaller ones do not permit a double layer to be formed. It was proposed by Schön[430] for such liquids, that the streaming current is roughly independent of the liquid's exact conductivity and can be approximated as:

$$I = \frac{dQ}{dt} = 3.75\times10^{-6}(uD)^2$$

where Q = charge (Coulombs). Since the cross-sectional area of a pipe is $\pi D^2/4$, the charge density Q''' (C m^{-3}) in a liquid leaving a long pipe depends on the flow velocity u according to:

$$Q''' = \frac{4}{\pi}\frac{I}{uD^2} = 4.78\times10^{-6}u$$

Schön's equations have been used widely. However, more recent experiments[413] revealed that even for smooth-bore pipes (rough-bore pipes are much more hazardous towards accumulating charge and general results cannot be given for them) experimental data are not conservatively represented by Schön's equations. This led to the recommendations of:

$$I = 9.42\times10^{-6}(uD)^2$$

$$Q''' = 1.2\times10^{-5}u$$

But if liquids contain substances which act, effectively, as pro-static agents, then the worst-case condition must be considered:

$$I = 2.5\times10^{-5}(uD)^2$$

$$Q''' = 3.18\times10^{-5}u$$

An even more basic problem is that Schön's assumption that Q''' is independent of pipe diameter was found to be untrue[431]. Instead, the expression should be:

$$Q''' = 5\times10^{-7}u/D$$

where D = pipe diameter (m). A corresponding flow velocity can then be obtained from one of the above equations. Similar values also apply to loading of tanker trucks. It has been found[432] that incendive discharges may be expected if the charge density exceeds 20×10^{-6} C m^{-3} for top loading and 30×10^{-6} C m^{-3} for bottom loading, thus values smaller than these are usually taken as safe.

Moisture and impurities can greatly increase the charge density, but experiments have to be set up carefully to illustrate this. The effect is not found unless the liquid is pumped through filters[433]; charge generation associated with tank-loading in the absence of filtering does not show deleterious effects of impurities. Metallic trash in tanks can act as 'charge collectors' and greatly reduce the charge density necessary to cause an electrostatic discharge[433]. The effect takes place since small metallic objects can be buoyed up by turbulence or by foaming of the product. The combination of filtering + splash loading was found to be highly conducive to discharges; removing either of the two factors greatly diminished the potential for a discharge. In low-viscosity liquids, splash loading by itself produces a charged foam in the tank which can lead to discharges even when the inflowing liquid has little charge on it.

When liquids flow in *insulating pipes*, little streaming current occurs because the charge induced in the pipe walls does not get dissipated to ground. Instead, the primary hazard is of direct breakdown of the pipe material due to an electric discharge. When this occurs, cracks or pinholes may be created; if the liquid is combustible, an external fire hazard can then happen. This is illustrated in one study where kerosene which had picked up a high negative charge from being put through a filter caused an electrostatic discharge that punctured a polyethylene pipe and created a visible leak[434]. Glass pipes are not subject to pinholes, but a discharge may originate in the liquid which extends to the exterior of the pipe (Figure 54)[435]; discharges larger than the one illustrated also were documented and these typically broke the pipe.

Filters, especially micropore filters (mesh size < 150 μm), are the most significant way that very high charges can be imparted to moving liquids. In fact, in most experiments where it is desired to place a charge on a liquid, vigorous pumping through fine filters is used as the technique. *Rough-bore hoses*, such as ones containing an internal grounding helix, can be almost as effective as microfilters in charging liquids. A *grounded grid* through which a liquid passes can act similarly to a filter in causing charging. Any other arrangement where a two-phase flow is introduced (e.g., bubbles) can also have a similar charging effect.

Liquid sprays can cause intense static electrification; this was first observed near waterfalls in the 19th century and is called *spray electrification*[436]. The process occurs due to the presence of a double layer of charge at the liquid surface. Small pieces of material in the form of droplets removed from the surface can then possess an unbalanced charge. By this process, a water stream may ignite a flammable atmosphere, and this concern arises in operations, for example, where a water spray is used to clean equipment which was used to store flammable liquids. Oil tanker explosions have occurred when water streams have been used to clean 'empty' tankers which contained a flammable atmosphere; this problem came to a head in 1969, when explosions occurred in three very large crude carriers during washing[429,437]. A water mist used in such cleaning[438] may pick up a charge of ca. 30 nC m^{-3}. The solution found was to provide inerting for the tanks, typically using scrubbed flue gas. Potentially incendive charges may also be picked up simply by sloshing of liquids. A similar, but generally larger static charging effect can be produced by jets of *steam*[439]. Predicting charging details is very difficult, but incendive sparks may occur if insulated metallic objects are present in the vicinity or if grounded objects pick up an induced charge and the ground connection is subsequently removed. A small amount of an immiscible component can make a very large change in charging of sprays; in one set of experiments[440], adding 5% water to kerosene increased the charge density by about 1000×.

A laboratory study on the tanker washing problem[441] eventually identified a mechanism for incendive discharges. When a water jet impinges upon a solid surface, upon impact, the jet breaks up into fine and coarse water particles. The coarse drops acquire an electric charge of one polarity, while the fine ones a charge of the other sign. The system is unstable and coarse drops separate and fall out early. The separation of droplets then causes a separation of charge. The result is an atmosphere filled with a charged aerosol. If a tank has been charged this way and contains grounded metal protrusions, then incendive discharges were found to occur when a 'slug' of water falls through the charged aerosol. This slug acquires a charge by moving through the charged aerosol, and incendive discharges were observed in propane/air atmospheres when water slugs fell and passed at 1 – 4 mm from a grounded protrusion within the tank. The study also found that corona discharges occur when droplets fall off grounded protrusions, but no such corona discharges were incendive.

Napier and Rossell[442] studied the charging of sprays of organic liquids, as may occur during a leak or break in piping in a chemical plant. They found that in the aerosol cloud created by the spray the maximum field strength only reaches 0.2 MV m^{-1}, which is greatly below the dielectric breakdown strength of air (3 MV m^{-1}). Thus, direct ignition cannot occur by means of a discharge from the aerosol cloud. However, many joules of energy can be stored in a cloud formed in this manner. Thus, a hazard may still occur if this charge can be transferred to an isolated object, which might then sustain a discharge to ground. Opening the valve of a liquefied gas tank (e.g., butane) will cause a jet of 'gas' to be discharged, but minute droplets of liquid are also carried along. An accident is reported where a jet issued from a butane tank leak and ignited upon impacting a nearby wall[134]. Similar accidents have been reported upon opening the tank valve of a cylinder of dissolved acetylene. In the latter case, droplets of acetone are carried along with the acetylene gas.

Experimental study of discharges

While numerous studies have quantified the separation and movement of charge in liquid systems, studies where details of electric discharges was explored have been few. Wright and Ginsburgh[443] conducted experiments where ball electrodes of various diameters were charged to either a positive or a negative potential and discharges allowed to occur to a liquid surface. The authors concluded that it was very difficult to obtain constant-concentration fuel/air mixtures above liquids that are actually vaporizing, so they simulated the problem by use of a transformer oil (essentially non-vaporizing), above which was a well-mixed atmosphere of 6% propane in air. Their results (Figure 55) indicate that ignition is much harder to achieve when the electrode is negatively charged with respect to the liquid. These discharges were corona discharges, rather than the spark discharges seen when the electrode was positive with respect to the liquid surface. The authors also reported on a number of other experiments where grounded objects, partially or fully submersed in the liquid, led to incendive discharges. These showed the role of 'field concentrators,' whereby discharges occurred due to local distortions of the electric field, despite electric fields being modest when measured over larger distances. Lyle and Strawson[444] conducted similar experiments and found that 4.7 mJ spark energy was needed to ignite a propane/air mixture when the spark went between a metal electrode and the liquid surface (Figure 56). By contrast, the MIE of propane/air mixtures, when ignited by a spark discharged between two optimally-designed metal electrodes is 0.26 mJ; thus using the standard tabulated MIE value would give an unanticipated safety factor of 18. Several additional studies are described in Chapter 14 under *Aviation fuels*.

Gasoline vapors can be ignited from corona discharge if fuel is dripped onto a high-voltage transmission line[249]. For a 55 m diameter conductor, a minimum electric field of 1530 kV m^{-1} was needed; for a smaller 33 mm conductor the value rose to 1740 kV m^{-1}.

Krämer and Asano explored experimentally the minimum conditions necessary inside tanks for spark incendivity[445]. They found that a minimum charge transfer of ca. 0.1 μC (microcoulombs) was necessary. A minimum potential of 58 kV was also found to be needed. The tests were done using electrodes of various diameters, with the electrode simulating a protuberance in a tank to which a discharge would be occurring. A optimum diameter of 20 to 40 mm was found for spherical electrodes. Larger diameters led to a slight increase in the minimum needed discharge potential. A 10 mm diameter led to a significant increase in the needed potential. The minimum charge transfer needed to cause an ignition of a flammable tank atmosphere also depends on the fraction of fuel which was in vapor, versus aerosol, phase. While 0.1 μC could ignite a 100% vapor atmosphere, 1.0 μC was needed when 65% of kerosene fuel was in aerosol phase, and 2 μC when 95% of the fuel was in aerosol phase[421].

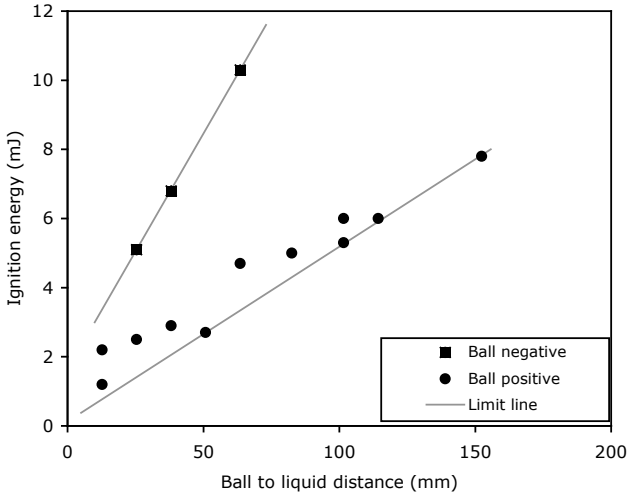

Figure 55 Energy required to ignite flammable atmospheres by electrostatic discharge between ball electrode and liquid surface

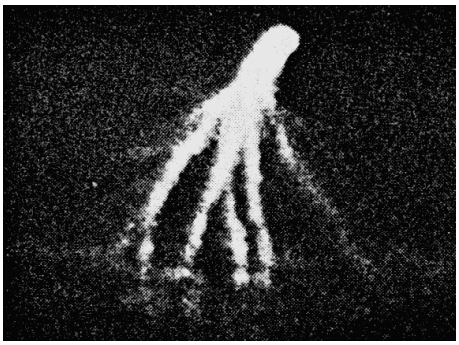

Figure 56 Spark from metal electrode to a liquid surface
(Copyright Institute of Physics, used by permission)

Discharges can also occur within the bulk liquid, although these are common only to a few fuel types[419]. But there is no danger of ignition, if the liquid is without air bubbles.

Additional experimental findings are given in Chapter 14 under *Aviation fuels*.

SAFETY MEASURES

Bonding and grounding of all metallic objects that might become electrostatically charged is the highest priority safety measure. Furthermore, safety is promoted by maximizing the use of metal, as opposed to non-conductive, tanks, pipes, etc. But even if a container is metallic and is suitably grounded, all hazards are not necessarily eliminated, as shown in Figure 57. Inerting eliminates the potential of explosions in flammable atmospheres, but is restricted to situations where it can be affordably provided.

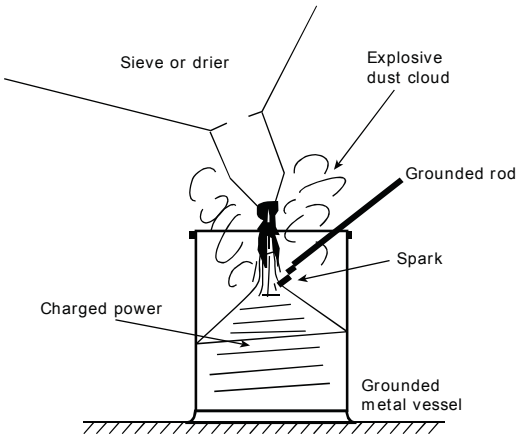

Figure 57 Example of arrangement where an incendive discharge can take place inside a grounded metal vessel

Traditionally, it used to be claimed that *splash loading* promotes electrification. Thus, a generally recommended practice is that liquids should be introduced into the bottom of a tank, not poured openly from the top. However, experimental studies suggest that this is only true in certain circumstances. Bachman's[433] study indicated that filtering is also needed for a hazard to be created, while Lyle and Strawson[444] could not find any measurable effect in their study. Britton[379] agrees that splash loading does not cause significant electrification but considers that, indirectly, splash loading may promote hazardous conditions due to:

(a) an absence of the electric field reduction that is provided when a metal dip pipe is used;
(b) accumulation of excessive charge densities at the liquid surface by stratification;
(c) turbulent mixing causing a dilution of the vapor layer near the liquid surface (which is the most likely place for an incendive brush discharge to occur, but which would normally be above the UFL) by sufficient air to bring it into the flammable region; and
(d) the creation of froth above the liquid surface, which may be more easily ignitable than the vapor from a quiescent liquid.

It has been recommended[446] that for filling tank trucks with petroleum products having a conductivity $< 5\times10^{-12}$ S m^{-1}, the filling velocities be restricted so that the velocity × pipe diameter product $uD \le 0.38$ s^{-1}, while for conductivities in the range of $5 - 10\times10^{-12}$ S m^{-1}, $uD \le 0.5$ s^{-1}. The American Petroleum Institute recommends[429] that flow velocity should:

- be below 1 m s^{-1} until the outlet of the fill pipe is submerged;
- afterwards, be the lesser of (a) 7 m s^{-1}, or (b) $0.5/D$, where D = diameter of pipe (m)

Anti-static agents should be used where needed to increase the conductivity of the liquid. A residence time of 30 s should be allowed for charge relaxation after a petroleum product passes through a filter and before it is exposed to conditions that could lead to an electrostatic ignition[429]. Introducing water into a gaseous atmospheres does *not* help to avoid static discharges. Britton's book[379] provides an extensive, detailed list of additional safety recommendations.

LIGHTNING

ORDINARY LIGHTNING

Lightning becomes possible because electric charge can become separated and accumulated in clouds. Clouds are highly complex entities. There are large temperature gradients, liquid and solid particles, convective flows, and effects due to phase changes. Even today, the physicochemical environment of clouds is by no means comprehensively understood. One recent theory by Ermakov and Stozhkov[447] is illustrated in Figure 58. Thundercloud formation begins when a cold air mass meets a warm one. Ionized, warm, moist air rises, but is then progressively cooled at higher elevations and condensation of water vapor on nucleation centers begins. In the initial phase, condensation proceeds faster on negatively charged nuclei than on positive ones, and the upward air flux produces large-scale separation of charge and a resultant electric field. The latent heat released in condensation assists the buoyancy of the upward air current. Cosmic rays produce ionized showers of particles. When the electric field exceeds 0.2 – 0.3 MV m^{-1}, electron avalanches occur, ionized tracks link with each other and form a conducting tree structure. This allows cloud-to-cloud discharges to occur. In the mature phase, droplets grow and coagulate. There are ascending and descending air flows and the cloud becomes asymmetric, with an excess of negative charge at its base. The electric field between the cloud and earth's surface increases, leading to cloud-to-ground discharges. The maturity phase may last 20 to 30 minutes and produce 50 to 100 cloud-to-ground discharges. This is accompanied by a larger number of cloud-to-cloud dis-

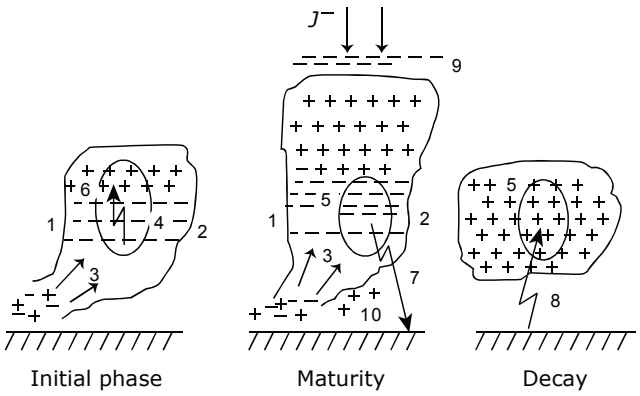

Figure 58 Formation of thunderclouds as described by Ermakov and Stozhkov. **1** warm air front; **2** cold air front; **3** ascending flux of wet ionized air; **4** and **5** extensive air showers produced by primaries with energies over 10^{14} eV or 10^{15} eV, respectively; **6** cloud-to-cloud lightning; **7** cloud-to-ground lightning; **8** ground-to-cloud lightning; **9** negative screen layer; **10** positive charge at cloud base; $\mathbf{J}^-$ current of negative ions from the ionosphere to the top of the cloud.

charges. In the decay phase, vertical air motion is damped out, precipitation occurs, and ground-to-cloud discharges may be observed.

The origins of a lightning strike are due to a separation of charges in clouds. There is most commonly a three-layer 'sandwich': positive charges on top, negative charges in the middle, and positive charges at the bottom[448]. Lightning becomes possible when a potential of 10 – 100 MV with respect to the ground has been reached. A *lightning flash* is composed of several events. The actual discharge begins with the formation of the first *stepped leader*, which is a localized gas breakdown of about 50 m length. The process continues in a stair-step fashion until a leader gets to within about 50 m of the ground (or an object on the ground). The negative charge of the stepped leader induces a positive charge in the earth below. Protruding grounded objects start to conduct heavier point-discharge currents. A streamer then arises from one of these objects or from the earth itself, connects to the leader and starts a *return stroke*. The return stroke is the brightly visible 'lightning stroke.' After the first return stroke, a *dart leader* may descend directly to the ground, without stair-stepping. This dart leader is ball-shaped. It will be followed by a second return stroke. There may be 3 or 4, but occasionally many more, strokes per the total event, which comprises the lightning flash. The total lightning flash may last from 0.01 to 2 s, with 0.2 – 0.4 s being typical, but each individual stroke only lasts about 30 μs. The interval between strokes may be around 40 ms. The current carried by the stepped leader is small, only on the order of 100 A. But each return stroke will typically carry 10 – 20 kA of current and peak currents in excess of 100 kA are occasionally recorded[449]. Somewhat different mechanics govern strokes that do not reach the earth, the cloud-to-cloud discharges. *Thunder* is an acoustic shock wave that originates in the gas breakdown region and then propagates out through the air.

In thunderstorms, a lightning flash may recur twice a minute, but in severe thunderstorms, as many as 25 per minute can be expected. A cloud-to-ground stroke may discharge about 25 coulombs per each stroke. The average length of a stroke is 3 km, and the average energy released is 10^5 J m^{-1}, making an average energy release of 3×10^8 J per stroke[450]. The pressure within a lightning column can reach about 8 atm. A cloud-to-ground flash may be as much as 14 km long; cloud-to-cloud flashed can be much longer.

In calm, sunny weather, the earth is at a slightly negative potential (0.3 to 0.45 MV) with respect to the ionosphere—the earth is continually losing electrons except during lightning events, during which the flow is rapidly reversed. The electric field is approximately 100 to 600 V m^{-1}. When turbulence arises and thundercells start to form, the polarity reverses, and the clouds assume a negative polarity with respect to the earth. The electric field builds up to 10 – 20 kV m^{-1} between the clouds and the earth. Just prior to a lightning strike, the cloud may be charged to a potential of some 30 MV with respect to earth. While the dielectric breakdown strength of normal dry air is 3 MV m^{-1}, within thunderclouds, much smaller electric fields—0.3 to 0.5 MV m^{-1} are sufficient to trigger a lightning flash. Occasionally, especially in connection with tornadoes, lightning discharges take place with the bottom of the cloud being at a positive polarity with respect to earth.

When a lightning strike occurs, nearby metallic objects can have a current induced in them. This includes not only electrical wiring, but other metallic objects such as building beams.

In electrical circuit terms, a lightning stroke can be considered a constant-current source. Therefore, the energy dissipated in object along its path is:

$$\int I^2 R\, dt$$

where I = current (A), R = resistance (Ω), and t = time (s). This accounts for the much higher damage found for objects of poor conductivity, than for metals[451]. Design values for the current of 100 – 200 kA are commonly used[452] since only about 1% of lightning strokes give currents in excess of 200 kA[450]. The current from a second or subsequent stroke is typically less than ½ that from the first one.

Ignitions from lightning

The primary damages[453] to residences from lightning are considered to be:

- brick, concrete and other solid surfaces moved or cracked

- plumbing pipes punctures
- holes burned or punctures in roofs
- arc damage to metal structures such as window frames
- arcs across wiring.

The last three of these, of course, may also be accompanied by ignition of combustible materials. Frydenlund[452] reported on a survey of lightning strikes to private residences (Table 37). Similar statistics are not available for other building types.

Because the temperature rise in an object is proportional to its resistance, a metallic object (e.g., a lightning rod) may sustain limited temperature rise, while a poor conductor such as wood may become ignited. Ignition of an apartment house roof is shown in Color Plate 32. Ignition of structural members inside walls and ceiling is shown in Color Plate 33. Lightning ignitions can assume a wide variety of geometric patterns, as illustrated in Color Plate 34. Multiple ignitions from a single strike are not rare (Color Plate 35).

Table 37 Locations of lightning strikes to private residences

Place struck	Percent
roof or projections	32
TV antenna	29
overhead power line	29
adjacent tree	10

Whether combustibles will be ignited from a lightning flash or not depends critically on whether there is a flow of *continuing current* in the channel after the stroke[463]. About 25 – 50% of lightning strikes exhibit this characteristic—these are sometimes called *hot bolts* (Figure 59). Lightning strikes which are positive (i.e., the cloud being positive with respect to the ground) are much rarer than the converse, but these are precisely the ones that are most likely to cause

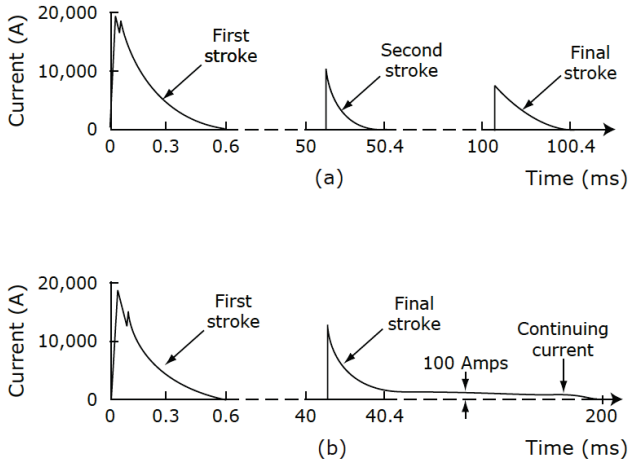

Figure 59 **(a)** Cold bolt, no continuing current; **(b)** hot bolt with a continuing current of ca. 100 A
(Copyright Dover Publications, used by permission)

ignitions, since their peak currents and total charge transfer are much larger. Positive flashes do not have the stepped-leader characteristic of the common, negative strikes, and consist of a single stroke, followed by a period of continuing current flow.

The importance of lightning as an ignition agent for forest fires varies among countries. Lightning strikes account for some 40% of forest fires in British Columbia and 60% of in the western US[454]. However, most lightning strikes only char the tree struck and do not result in a wildland fire. Ignitions in forests usually involve fine fuels (forest floor duff) or punky (rotted) wood; the latter, of course, also exist on living trees[455]. Healthy trees may be damaged by strikes, but are only occasionally ignited when struck, primarily if they are quite dry. The more common effect on living trees is an explosive shattering which occurs due to moisture being rapidly brought to a boil. In milder cases, only a strip of bark gets peeled off (Color Plate 36); in severe cases, the tree is shattered. Occasionally, even very large trees get ignited and some are able to burn comprehensively, not just thinner material burning off[456]. In rare cases, a lightning strike can ignite a living tree in a smoldering mode, and many months can elapse before the smoldering transitions to flaming. In two known cases, redwood trees were involved in such long-term smoldering[457]. It is suspected that the places on the crown of the tree where the lightning struck contained decayed material that facilitated the smoldering process.

Frydenlund[452] considers that the probability of igniting a house fire from a lightning strike is much higher if the house has plastic plumbing pipes, as opposed to metallic ones. This is because the lightning current may flow to ground through a metallic pipe network, but if electric wiring is the only substantive metallic path, the current is likely to go through electric wiring, where heating will be much greater, due to the smaller area of the conductors.

Stevens has reported a case after lightning struck a house where most of the wiring in the house was devoid of copper, all that was left was floppy plastic insulation[458]. He also reports another case of this phenomenon occurring when power was applied to a shorted wire in a house; in the latter case, breakers were not tripped, despite a 4600 kVA short circuit capacity of the electrical feed.

ST. ELMO'S FIRE

Point discharges occur from nearly any sharp, pointed object that is grounded and protrudes above the earth. It requires an electric field of only about 2 kV m^{-1} for a point discharge to begin. Ions are emitted from the sharp object in a point discharge, but there is no visible luminosity. At ca. 100 kV m^{-1}, corona discharge can occur from sharp points. This is a luminous discharge which is also commonly audible. A prominent form of corona discharge in the open air is called St. Elmo's fire; in meteorological literature, it is also

referred to as a brush discharge or a glow discharge, although in electrostatics brush discharge is not synonymous with corona discharge. This non-violent discharge can occur when a sufficient negative charge builds up in the lower layers of a cloud. The discharge occurs because the pointed object creates a distortion in the electric field, with potential lines being concentrated near its tip. A light can be seen when ions and electrons recombine and emit energy in the visible spectrum.

BALL LIGHTNING

Although a meteorological phenomenon termed ball lightning sometimes occurs during stormy weather, it has also been observed during clear weather and in the interior of buildings and aircraft. It is considered to be the least well understood meteorological phenomenon. Despite countless theories and research (a recent monograph[459] contains more than 2400 bibliographic entries), as of this date it remains an unsolved physics problem. There is no doubt among meteorologists and physicists that the phenomenon is real and countless credible case histories exist. But, surprisingly, while a number of photographs have been published, not a single photograph exists which is considered incontrovertibly genuine—apart from a few hoaxes, most have been challenged as mis-identifications (e.g., weather balloons) or as optical illusions[*]. Since the phenomenon is short-lived and its presence cannot be anticipated, evidently few observers have prepared themselves with cameras.

Ball lightning typically has a diameter of 0.1 – 0.5 m, although sizes from 10 mm up to 1 m or more (in rare circumstances) have been reported[460]. It is a vortex of plasma typically of pale red or orange color, but sometimes white or blue-white. The shape is usually spherical, but may be doughnut- or ovoid-shaped. There may be a corona or sparks or rays seen around it. An event lasts from a few seconds to many minutes, with most reports being in the range of 2 – 60 s. Ball lightning has been reported to decay either silently or explosively. A peculiar slow motion is typically associated with the phenomenon—ball lightning does not 'strike' the way that normal lightning does. In several cases, balls of lightning have wafted through in-flight airliners, gliding at about "walking pace"[461]. The ball itself is sometimes seen to roll, spin or tumble. It almost never reported that the balls rise through the air in a convective fashion, which would be typical of an entity at an elevated temperature. Sometimes there are sounds or a sulfurous smell observed. In one case, a ball came down a chimney, approached a person (who avoided it), went up an old papered-over flue, broke through the paper, and finally burst on reaching the flue top, doing considerable damage there[467].

There are unexplained regional variations in ball lightning. European studies report that 95% of ball lightning occurs in connection with thunderstorms, while statistics collected in Japan indicate nearly 90% of events occurring in cloudy weather, but in the absence of rain or thunder[462].

Switching of electrical equipment drawing very large currents is known to occasionally create fireballs that appear to be similar or identical to ball lightning[463]. Laboratory experiments have been reported which produced ball lightning[464-466], but these have tended to produce smaller and shorter-lived luminous entities than ball lightning observed in the field. In addition, the appearance of these structures were rather different from the spherical objects reported in field sightings. Prof. William Thornton, who was the first to investigate a number of topics in fire science, published probably the earliest research paper in English on ball lightning in 1911[467], although earlier scientists were already pondering the phenomenon even in the 18th century. The first full-length book[468] on the phenomenon appeared in 1923; it was mostly a compilation of reported case histories. Very little progress was subsequently made until 1955, when the topic became of interest to plasma physicists, especially in Russia. One Russian theory[133] holds that ball lightning is a consequence of ordinary lightning and occurs when a flux of positively charged particles hits an object. The speed decelerates and the particles start to form a ring vortex, which becomes ball lightning. The ball is said to consist of positively charged particles inside and negatively charged particles outside, kept apart by centrifugal forces. When the rotation decelerates enough due to friction with air so that centrifugal forces become no longer adequate to keep apart the oppositely-charged particles, a discharge occurs. Another theory holds that ball lightning occurs due to bunching of the electric field when encountering a dielectric inhomogeneity. A focusing effect is created and this leads to a localized discharge of plasma. The plasma itself comprises an inhomogeneity and this further concentrates the electric field lines. This theory in effect considers ball lightning to be a corona discharge in mid-air. Another theory has been proposed by Witalis[469], who considers that a branch of plasma theory called Hall-effect magnetohydrodynamics (HMHD) can explain it. Arnhoff[470] considers that ball lightning can occur when the energy of normal lightning rolls up into a ball; solutions of the Helmholtz equation were shown to exist that correspond to a non-expanding sphere. Stenhoff[459] has summarized and categorized dozens of other theories, none of which could be viewed as definitive.

Fatalities are rarely reported from ball lightning. There are reported incidents, but these are few and of unclear veracity; most have been from the 18th and 19th centuries. The most famous report of a fatality is that of Georg Richmann, a physician who was killed by ball lightning in St. Petersburg in 1753, but it is not clear that the cause of death was not ordinary lightning[459].

[*] However, it must be kept in mind that debunkers do not necessarily have preemptive claim on the truth.

Because of the controversial nature of ball lightning, all reports must be viewed in a questioning manner, nonetheless damages reported from ball lightning include splitting of wood, breaking of glass, shattering of TV sets, and fusing of metallic electrical components. Vegetation, clothing, and curtains have been ignited, but generally the event leads to non-sustained ignition, so that propagating fires do not result. Ball lightning ignited and burned off hair on an airline pilot in flight[456]. There have been reports where a house or a ship was burned down, but these date back to the 19th century[459].

EXPLODING WIRES

Passing a large amount of current through a tiny wire, say around 35 μm diameter, results in a vaporization of the metal and very high temperatures being created. Exploding wires were first used to detonate explosives in 1938, but the phenomenon of exploding wires is very complex and poorly understood. Consequently, a detailed explanation of how initiation of high explosives occurs had also been lacking. The situation is further complicated in that the governing phenomena themselves depend on the magnitude of current density that is passed through the wire. At the typically high current densities that are used, a plasma results, but at more modest densities (10^8 – 10^9 A m^{-2}) the wire shatters and disintegrates in the solid phase[471]. The energy required to heat, melt, and vaporize the wire is normally only a small fraction of the energy that is supplied (usually from a capacitor discharge), thus the bulk of the energy is delivered to the plasma[472].

It is normally considered that exploding wires ignite explosives because of the very rapidly rising current that must be provided from a suitable low-inductance discharge capacitor. The melting temperature of the metal is reached, but for a short period of time its inertia keeps it from flowing out. The molten metal is further raised in temperature until its vaporization point is reached. At that time, current starts to flow in the form of an electric arc through the cloud of the metal vapor, heating and expanding it violently. This expansion manifests itself as a shock wave propagated away from the wire. As the arc is stabilized, its resistance drops and the current flow further increases. Recently, it has been suggested that the electric field surrounding the wire ionizes the surface of a high explosive, and thereby pre-sensitizes it so that a weak shock can then initiate a detonation wave[473]. A number of explosives detonators are built around the use of an exploding bridgewire (the term preferred in the munitions field). Because of the creation of a shock wave, an EBW detonator can ignite explosives which would otherwise not be ignited by the melting of the metal that occurs in an ordinary hot wire igniter, e.g., a blasting cap.

ELECTROMAGNETIC WAVES AND PARTICULATE RADIATION

The main regions of the electromagnetic spectrum are shown in Table 38. For electromagnetic radiation to lead to ignition, not only does energy have to be transmitted, but it must be received. In most cases, the received energy of relevance to ignition problems is directly converted into heat at the target. Targets vary widely in their ability to receive electromagnetic radiation, and the ability invariably depends on the frequency of the radiation. The fraction of incident radiation absorbed by a target is termed the *absorptivity*, and it can vary from 0 to 1. Most gases have small-to-nil absorptivity throughout the spectrum and even those gases that show significant absorption only do so within limited wavelength bands. If a radiant heater ignites a flammable gas mixture, it is because a hot radiating surface was present, not because the gas directly absorbed sufficient radiation. Power-frequency and radio waves are significantly absorbed only in metals. Electromagnetic energy emitted from bodies due to their high temperature falls into the infrared region of the spectrum. Hot bodies emit an insignificant fraction of their radiation at lower-frequency portions of the electromagnetic spectrum. Many solids absorb infrared and visible radiation very well. Apart from radiant heaters, there are many devices which intended to generate electromagnetic radiation; typical examples are radio transmitters, lasers, X-ray machines, and ultrasonic generators. Power generators also create electromagnetic fields, but only a small fraction of the generated power is emitted as radiation, the useful portion being transmitted in wires as electric current to the user. Another class of radiation is particulate radiation. Radiation where small, elementary particles are emitted occurs in cosmic rays, in various laboratory high-energy particle sources, and in nuclear reactions and weapons.

Table 38 Primary regions of the electromagnetic spectrum

Region	Frequency (Hz)	Wavelength (m)
power	50 – 60; 400	7.5×10^5 – 6×10^6
radio	10^3 – 3×10^9	0.1 – 3×10^5
microwave	3×10^9 – 3×10^{12}	10^{-4} – 0.1
infrared	3×10^{12} – 4.3×10^{14}	7×10^{-7} – 10^{-4}
visible	4.310^{14} – 7.5×10^{14}	4×10^{-7} – 7×10^{-7}
X-ray	3×10^{17} – 3×10^{19}	10^{-11} – 10^{-9}
cosmic ray	$>3\times10^{22}$	$< 10^{-14}$

Laser ignition of solid objects has been considered briefly in Chapter 7. Ignition by infrared heating has been considered in Chapters 6 and 7. Light energy as an ignition source is considered in a separate Section below. Here, we will only consider three sources: eddy currents, radio and microwave transmitters, and nuclear weapons. Ignition from radiation by energetic particles would be likely to occur only in highly specialized laboratories.

EDDY CURRENTS

If a metallic object is placed in a strong electromagnetic field, an electric current (eddy current) is induced in the object. This principle is exploited industrially for inductive

heating of metals. If the metal is heated sufficiently, and a combustible substance is next to it, an ignition is possible. Such incidents are rare, partly because large electromagnetic fields tend not to be found except in facilities designed for their use. The electromagnetic field from normal power lines is small, because in the balanced geometry of a power line, the fields from the conductors largely cancel.

While ignitions from inadvertent direct-heating effects are probably rare, it is more likely that eddy currents would lead to arcing which, in turn, can cause an unwanted ignition. This is also rare, but has been documented in connection with explosions of motors on offshore oil drilling platforms[474,475]. During the investigations, it was noted that sparking was actually observed at the joints of the enclosures of other similar motors. Measurements showed that currents in excess of 200 A can be induced by a 2-pole induction motor in a steel motor enclosure as the motor is being started. Sizable currents were documented only in large (over 2000 kW, 3000 HP) motors. The induced voltages are minuscule (1 – 2 V), but, because of the inductive nature of the circuit, testing showed that flammable atmospheres may get ignited.

Dielectric heating is a similar form of heating applicable to insulators. Insulators are not perfect, and the dielectric in a capacitor absorbs a certain amount of energy (dielectric loss). Dielectric heating is used in medical and industrial processes, but likewise appears to have minimal potential for causing ignition. Microwave heating is a related process and discussed below.

RADIO TRANSMITTERS

Ignition in the vicinity of radio transmitters can occur in two ways:

(1) by direct heating of substances from the electromagnetic field (see *Induction heating*, above)
(2) by means of RF (radio frequency) sparks.

To ignite flammable gases by means of RF sparks requires not only a huge electric field but also a flammable gas volume and one that is not be electrically shielded (i.e., within a metal tank). This will normally involve an extraordinarily rare combination of circumstances, and there do not appear to be any verified reports of such explosions. Nonetheless, there has been a great deal of design and regulatory interest in the topic in the UK, which includes an HSE guide[476] and British standards[477,478].

Under normal circumstances, devices intended to collect RF energy are called 'antennas' and are designed according basic electrical principles in order to collect the energy efficiently. But metallic buildings or equipment can serve as adventitious antennas, collecting and possibly delivering RF energy to a locale where a spark discharge might occur within a flammable mixture. Research indicated[479] that vertical structures at ground level do not pose a hazard, since they are effectively RF-coupled to the ground. But loop-type structures, for instance, mobile cranes, are more effective antennas. The frequencies at which there is the greatest danger of collecting unwanted RF energy is considered to be 0.5 to 4.5 MHz[480]. The incendivity of RF sparks is, in general, much less well understood than that of DC sparks. Early laboratory tests showed that in spark discharge circuits where the main impedance was a 50 Ω resistance, RF induced power from a few watts (for frequencies below 1 kHz) to a couple of hundred watts (for frequencies over 100 kHz) was needed to cause ignition of methane/air mixtures. In addition to the RF frequency, the metal forming the discharge electrodes had a very large effect on the power needed. Rusty steel or oxidized aluminum required much less power than clean cadmium electrodes. The effect of raising the circuit impedance was to lower the needed RF power for ignition. Later studies[480] quantified the effect of circuit resistance. For a 1000 Ω resistance, 10 W of transmitter power were needed for ignition of methane in air, 7 W for ethylene, and 3 W for hydrogen. The dependence on the circuit impedance was empirically found to be $P \propto Z^{-0.184}$ where P = transmitter power (W) and Z = circuit impedance (Ω). Similar studies have been performed by Widginton[481] for pulsed microwave transmitters. He found that for ignition of methane/air mixtures to occur, the coupling of unwanted microwave RF into a discharge gap must be sufficient so that around 2.5 mJ energy is discharged in the spark. Knight[482] described de-rating factors to be applied to adventitious antennas when the transmission frequency and the self-resonant frequency are not identical (as they rarely will be).

In terms of minimum induced RF voltage needed for an incendive breakflash discharge, measurements by Rosenfeld et al.[483] on methane/air and ethylene/air atmospheres indicated that 300 V peak-to-peak was needed, provided the source impedance was in range 50 – 3000 Ω (and it was considered unlikely that the impedance of an adventitious antenna system should fail to be within this range). In terms of power capable of being induced in the adventitious circuit, a minimum of 12 W was needed for methane and 9 W for ethylene. The authors did some experiments to show that hydrogen mixtures were more readily ignitable, but were not able to get definitive data. Experiments were then done using 'scrape-flash' electrodes, that is, an arrangement where one electrode was scraped past another, prior to separation occurring. The minimum required voltage fell to 75 V under those conditions, but power required remained unchanged. It was considered that the low work function of the metal oxide aided in the production of electrons, thereby lowering the voltage required. A companion study[484] found that, at the P = 0.1% probability level, 290 V peak-to-peak was necessary for igniting hydrogen/air mixtures, and a corresponding power of 5 W. Somewhat different experimental arrangements were employed by Burstow et al.[485], but with results broadly similar.

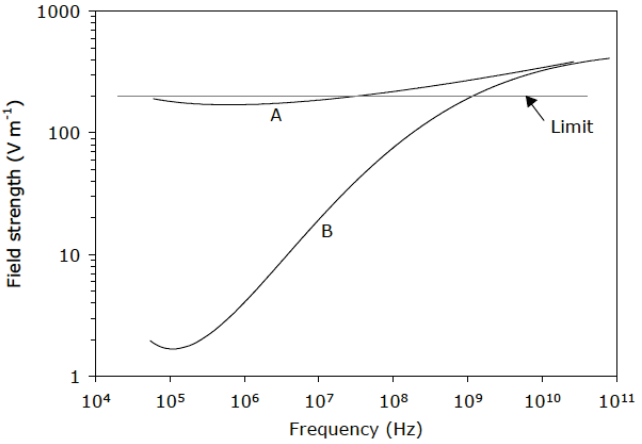

Figure 60 RF transmitter field strength needed for ignition of H_2/air mixtures (**A** antenna of 1 m effective length; **B** longest antenna appropriate to frequency; **Limit** human exposure limit)

Maddocks and Jackson[486] conducted a series of field measurements of voltages induced from transmitters into various antenna-like metal structures. All else being held constant, the induced voltage was found to depend as the square root of the transmitter power. Accompanying the voltage measurements, field measurements were made by connecting up an IEC breakflash apparatus and supplying a hydrogen/air test atmosphere. No ignitions were found for the case of 9 close-by transmitters each putting out 20 kW.

German studies[487] on the same topic concluded that adventitious antennas of about 1 m length would require a field strength of around 200 V m^{-1} to ignite a hydrogen mixture; the 200 V m^{-1} value also happens to be the limit for transmitter field strength that German health regulations consider acceptable for human exposure, so the ignitability potential from short antennas was considered to be inconsequential (Figure 60). A slightly different conclusion was found for extremely long adventitious antennas at low frequencies. The worst-case was found at a frequency around 100 kHz, where a field strength of 2 V m^{-1} would suffice for igniting the most-ignitable concentration of H_2/air.

Burstow et al.[485] also measured the ignition potential in the vicinity of microwave transmitters. The power that can be captured from a given antenna is proportional to the wavelength squared, thus it was found that there was a dominant effect of the frequency of the transmission on the results. In terms of power induced in the adventitious antenna system, very large values were needed for ignition, being 50 – 70 W for hydrogen and 360 W for methane atmospheres.

The ignitions considered above are possible only in the immediate vicinity of a powerful transmitter. Another concern is unwanted RF triggering of blasting circuits. Radio frequency waves can, in principle, spuriously set off an explosion, and this is the reason for signposting against use of transmitters at sites where such work is done. The one extensive study on this subject[488], however, suggests that enormous field strengths would be needed to trigger a blasting cap of reasonable design, e.g., one requiring more than 300 mA to initiate the explosion. In worst-case conditions, 9 V m^{-1} would have been required to reach the 300 mA level. Furthermore, the highest hazard was found to be for frequencies less than 1 MHz, which does not correspond to any legal portable transmission apparatuses usable by civilians. British guidelines (BS 6657[489]) based on this work incorporate a further safety factor of roughly 10×.

Schwab[490] studied gas discharges caused by RF fields and determined that their basic character is essentially identical to DC discharges. Arc discharge, glow discharge, and abnormal glow discharge regimes were found, same as for DC discharges.

The *skin effect* associated with high frequencies confines the flow of current to thin layers at the surface. This has caused some unusual ignitions. A case is reported[410] where a person working on a radio transmitter made contact with an RF-carrying conductor. He felt no sensation until his sock ignited and burned. This was determined to have occurred because a nail through his shoe contacted ground.

It is not difficult to ignite combustible materials inside a microwave oven, but that is a device especially designed to concentrate a large amount of energy within a small space. If a unit produces 700 W and the radiation were uniform across the cross-section, the heat flux would be about 7 kW m^{-2}. If the absorptivity were close to unity, the value would be not much below the minimum heat flux for ignition of some solid combustibles. In addition, hot spots exist and, in those, higher heat fluxes will exist. But the radio frequency used is 2.45 GHz, and most substances are not absorptive at this frequency. The main exceptions are polar molecules (e.g., water) and electrically conductive objects. If metals are introduced into the cavity, an indirect ignition can occur due to high current flow induced in the metallic object and its consequent heating.

Ignition of materials from absorption of microwaves can be treated by theory, since the radiation of electromagnetic energy is described by the well-known Maxwell's equations. The problem of radiation within lossy bodies is far from simple, due to strongly non-linear coupling effects and because the relevant thermal, electrical, and magnetic properties of materials depend on temperature. Many practical substances are non-homogeneous and anisotropic; for those theory can only suggest qualitative outcomes. Microwave heating is used in a number of industrial processes where ignition is possible, but undesired, so a fair amount of effort has gone into trying to understand microwave ignition quantitatively. The studies[491] revealed that hot spots are a phenomenon that is due to the nature of equations themselves, and does not require physical inhomogeneities. Fur-

thermore, the dependence of the material's temperature on applied power commonly takes the form of an S-curve, with a distinct jump. Data properties for a wide range of materials of interest have been compiled by Meredith[492].

NUCLEAR WEAPONS

During the 1950s and '60s, much research was carried on to understand the ignition of combustibles from nuclear weapons. The basic goal was usually to compute the maximum radius of destruction by fire for a given size of weapon. The research studies elucidated the dominant role of atmospheric conditions in the process and even such secondary factors as the reflectivity of nearby large areas. Thus, the results did not lend themselves to being presented as an ignited-radius vs. weapon yield plot, but required numerous other assumptions and calculations. Examples of some of these calculations have been given in a major compendium by Rogers[493].

A nuclear fireball can contain reactions at temperatures of 70,000 K or higher, although an effective radiating temperature of 6500 K is often assumed[497]. About 35 – 45% of the energy is released as thermal radiation, but the fireball thermal radiation characteristics details depend on whether the detonation is at surface level, moderately high, or at a great height. Brode[494] has presented some graphs and calculations for determining fireball radiation. The intensity of radiation varies with time and Thomas et al.[495] found that ignition data can be well correlated by assuming an 'impulse' type of radiation waveform:

$$I(t) = e^2 I_p \left(\frac{t}{t_p} \right)^2 e^{-2t/t_p}$$

where I_p = peak value (same units as I), and t_p = time of peak (s).

Field tests (and experience in Japan) indicated that thick materials, such as wood structural members, are generally not ignited directly from nuclear weapons, but thin materials can be. When structures burn down, it is usually due to initial ignition of lightweight materials. For extremely high heat fluxes, the ignition problem becomes secondary, since blast damage tends to flatten the landscape. In addition, the blast wave sometimes extinguishes the fires that were previously ignited by thermal radiation. Because of its high moisture content, it is difficult to ignite living vegetation[496]. This is partly because initial heating produces a steam cloud and the latter acts to some extent as a radiation shield.

In both field and laboratory studies, the ignitability of relatively thin items from nuclear weapons radiation has conventionally been characterized by use of energy fluence, i.e., kJ m^{-2}. In Chapter 7 it was shown that ignition of a thermally-thick solid does not correspond to a constant value of energy fluence; for thermally-thin solids, use of energy fluence as an ignition criterion seems to be more reasonable. In the case of nuclear weapons, not just the energy fluence, but also the duration of the pulse and its wavelength distribution must be considered as factors determining the ignition of materials. Some example values[497] are listed in Table 39 for low-air bursts of three different weapon yields. In view of the environmental/geometric complications mentioned above, these must be understood to be suggestive values only. Additional data for 15 and 32 kiloton weapons were obtained by Bruce[498].

Table 39 Energy fluence needed for ignition from nuclear weapons

Material	Energy fluence for ignition (kJ m^{-2})		
	35 kilotons	1.4 megatons	20 megatons
Bristol board, 340 g m^{-2}	670	840	1700
cotton, dark blue 270 g m^{-2}	590	790	880
cotton, white 270 g m^{-2}	1300	2000	3600
cotton denim, blue 240 g m^{-2}	500	1100	1800
grass, cheat	210	330	420
needles, pine	420	670	880
newspaper, picture area	210	290	500
newspaper, text area	250	330	630
plywood, Douglas fir	380[a]	670[a]	840[a]
rayon, beige 100 g m^{-2}	540	840	1200
rayon, black 100 g m^{-2}	290	710	1000
rubber, black	420	840	1000
tent canvas, olive cotton 400 g m^{-2}	500	750	1200
window shade, green oiled cotton muslin 270 g m^{-2}	290	540	790

[a] – flames only during exposure.

Rough formulas for explosions in air at intermediate heights are[497]:

$$\dot{q}'' = 1.06 \times 10^9 \frac{\tau W^{0.56}}{r^2}$$

$$q'' = 3.33 \times 10^8 \frac{f \tau W}{r^2}$$

where $\dot{q}''$ = incident heat flux (kW m^{-2}), q'' = energy fluence (kJ m^{-2}), f = thermal radiation fraction (0.35 to 0.45), τ = atmospheric transmissivity (--), W = weapon yield (kilotons TNT[*]), and r = distance from explosion to target (m).

Some primary explosives have been studied for sensitivity to initiation from nuclear particles and ionizing radiation. A compilation of laboratory research has been reported[499]. Modest intensity particle beams, X-rays, gamma rays, etc. have not been found to be effective as initiators.

[*] Nuclear weapons yields are expressed as tons (2000 lb) of TNT equivalent. 1 ton = 4.18×10^{12} J.

Light energy, lenses and mirrors

Light from the sun or from other sources can act as an ignition source. The radiant energy available from the sun in a cloudless sky depends on the latitude, time of year, and hour of day. At peak in temperate climates it is on the order of 1 kW m^{-2}, which is insufficient to ignite any normal building materials or furnishings. The heating can be more severe in high-flying aircraft. It is reported that interior temperatures can reach 95ºC in military airplanes[500]. Even this temperature would suffice to ignite only highly sensitive substances.

But it is possible to magnify solar radiation by optical means. It has been known since antiquity that a convex-shaped mirror can be used for this purpose. Already in the 7th century BC, the Romans were using this method of lighting sacred fires[501]. In a more famous episode, in 212 BC, the Greek scientist Archimedes used a mirror to set fire to a Roman ship in battle. Simms[502] reviewed much of the subsequent research on this topic, which continued through the millennia into modern times. Focusing of sunlight to a point may also be done by a concave-shaped converging-focus lens. Moore's 1877 book mentions that accidental ignitions were not uncommon due to this cause, especially in laboratories where glass vessels may serve as the lens[503]. Other incidents occurred in ships where 'bull's eye' glass with a focusing ability used to sometimes be used before fire incidents led to their replacement. In more recent times, accidental fires caused by magnifying glasses[504] and shaving mirrors[505] have been reported. The former case is especially interesting since the investigator was able to duplicate the ignition in reconstruction testing. It is also not beyond the resources of arsonists to exploit this focusing feature, although its drawbacks would be uncertain timing, possible discovery of the device, and no associated accelerant. The Fire Research Station has estimated that 150 to 200 fires occur annually in the UK due to focused sunlight[506]. Some example fires[506] have occurred due to focusing of sunlight by a chrome-plated reflector of an electrical heater (which ignited cardboard in a shop window), a metal bowl in which clothes were placed (which ignited the clothes), and translucent plastic door handle that ignited a bathrobe hanging on the door. In the latter case, testing was done and it was found that paper readily ignited from the door handle's focusing power[507]. Perhaps the most fascinating case is one where the ignition mechanism was water. Investigation revealed that raindrops on a piece of plastic used as a roof acted as a lens and ignited a silkworm hut.

Glass jugs and similar articles have been found at the origin of forest fires, leading to research on ignitability of forest fuels[508]. The results are summarized in Table 40. Multiplication factor denotes the ratio of the heat flux produced with the aid of the focusing power of the substance being tested, versus the heat flux of the unfocused incident radiation. Normally, glass containers have to be filled with a liquid to act as focusing lenses, since actual wall thickness is fairly uniform. Aerosol cans are able to concentrate sunlight when they have hemispherical, reflective bottom surfaces. The results indicate that objects showing multiplication factors down to the 14 – 12 range are able to cause ignitions, while ones with smaller multiplication factors do not.

Table 40 Ignitability of forest fuels from containers concentrating sunlight radiation

Container	Heat flux multiplication factor	Caused ignition in sunlight
glass jug	28	yes
aerosol can, bright	22	yes
" " (another specimen)	20	yes
spherical rose bowl	14	yes
fish bowl	12	not tested
aerosol can, dull	11	no
syrup bottle	7	no
" " (another specimen)	7	not tested
salad dressing bottle	6	not tested

Bull's eye (sometimes termed bullion) and Flemish glass types are occasionally used as decorative window glass in houses (Figure 61), and the Fire Research Station has investigated fires caused by their focusing ability[509]. FRS tested both glass which had been identified as causing a fire, and also additional commercial examples. Heat flux multiplication factors of 10 – 45 were measured, but this varied widely both with the type of glass and with the particular location within the glass. Solar radiation in the UK does not exceed about 0.85 kW m^{-2}, and testing of the glass recovered from the fire showed that it could produce a peak of 34 kW m^{-2}. A special rig was then constructed which simulated solar radiation upon fabrics, including the effect of a motion of 75 – 80 mm h^{-1} of the focused radiation. A fixed exposure time of 10 min was used. At the peak irradiance used of 35 kW m^{-2}, only one out of 6 upholstery fabrics ignited (a cotton-backed PVC imitation leather) and that one only showed flashing ignition. Six carpet samples were tested at 50 kW m^{-2}, but none ignited. The same findings were obtained for six curtain fabrics. Among the curtain samples tested was a fabric similar to the one in the fire being investigated, but that also showed no ignition. Only when the test procedure was modified by preconditioning the samples to 36°C to simulate a hot summer day, and providing a cotton lining, did the curtain involved in the fire ignite during test. But even this ignition was a 'rapidly spreading glowing,' rather than a flaming. A similar glowing ignition was also observed when tests were repeated at 22ºC, but with pleating of the curtain specimen. Because of the marginal ignitability that was found, the conclusion was that, despite concerted efforts to reproduce a realistic solar-ignition environment, some experimental factors still remained biased against ignition. The above non-ignition results should also not be generalized to other forms of radiant heating, since

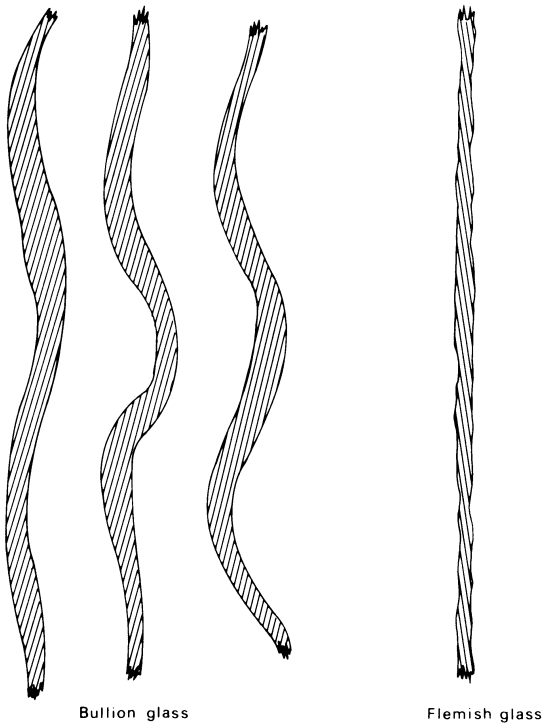

Figure 61 Cross-sections through several types of glass that can intensify radiation
(Copyright BRE Ltd., used by permission)

in the tests here a very small sample area of 30 mm^2 was exposed to radiation. The area selected in the FRS tests was designed to simulate the size of radiation focused from window glass; but as indicated in Chapter 7, materials are substantially more difficult to ignite if very small exposure areas are used.

The above discussion is based on considering light as being converted to thermal energy within the target substance. But there are some highly sensitive explosives which can be initiated by *photochemical excitation*. This occurs if a molecule can absorb a photon of light that has an energy equal to or greater than the energy difference between the ground state and an electronically excited state, the electron can go into the excited state, and this can start a chemical reaction.

It is common for fire investigators who photograph sooty fire scenes to find that the camera flash creates a loud report[510]. This apparently is some form of localized ignition of soot from the light energy, but details have not been studied. No self-sustaining fires from this mechanism have been reported.

Aerodynamic heating

High temperatures can be attained due to supersonic aerodynamic heating. As a potential for ignition, this mode of heating is mainly relevant to aerospace applications, since supersonic movement through air is rare in other circumstances. The stagnation point temperature is given by[511]:

$$T_{stag} = T_o\left[1+\eta_r\left(\frac{\gamma-1}{2}\right)M^2\right]$$

where T_{stag} = stagnation point temperature (K); T_o = ambient temperature (K); η_r = recovery factor (--), often taken as 0.9; γ = ratio of specific heats, $C_p/C_v \approx 1.4$; and M = Mach number (--). Generally, $M \geq 3$ would have to be reached for aerodynamic heating to be of concern.

Further readings

The following recent monographs on electrostatic ignitions cover both principles and practical guidance. The last three also contain copious compilations of case histories; Britton's book, however, offers the most systematic treatment and is the best source of guidance for implementing preventive measures. The topics coverage is sufficiently non-overlapped that the interested reader should refer to all four. All of them assume the reader has at least a moderate familiarity with the principles of electricity.

General precautions

Minimizing the occurrence of ignition is one of the essential aspects of the practice of the fire safety engineering profession. The literature of the field is vast, and it is not appropriate to attempt to summarize it here. Thus, in this Chapter we will only (1) cite some salient reference works on the topic; and (2) discuss in some detail a few selected hardware-based ignition prevention concepts.

The National Electrical Code[1] (NEC) is perhaps the most notable work in the reference category. It can be viewed as a codification of good practices to guard against electrocution and against electrically caused ignitions. For designing and operating industrial plant where ignitable dusts are generated, a British guide to recommendations exists[2]; it gives some specific precautions and some checklists for surveying the adequacy of an installation. NFPA has published standards, codes, or guides covering a vast array of industries where specialized means for reducing ignition risk are presented.

Measures against static electricity

The first measure against static electricity is proper grounding and bonding. This is almost always necessary, but may not be sufficient. If liquids, powders, fabrics, etc. are handled which are highly insulating, grounding and bonding may not suffice. If flammable atmospheres are present and conductivities of the substances involved cannot be increased, then—in the worst case—inerting with nitrogen or other inert substances may be needed. For the cases where grounding is effective, it may be surprising that a fairly high resistance, generally quoted as 1 megohm (MΩ), suffices. Some standards specify values as low as 10 Ω, but this is not because a value that low is needed to dissipate charge; rather, it is assumed that the grounding system will corrode and progressively fail, and a still-adequate resistance is expected after serious degradation has taken place. Sometimes, just increasing the humidity in the area can reduce static electricity hazards sufficiently.

Another tactic is the use of *electrostatic eliminators*, which are devices that ionize the air, thereby increasing its conductivity and helping to neutralize charges. It can take the form simply of a grounded array of sharp points. A corona discharge forms at the sharp points, creating ions of the opposite polarity to the original charge, thereby serving to neutralize it. The charge can be reduced down to the point where the surfaces are at a potential that is below the threshold voltage for corona discharge to take place. The device can function safely in fuel/air mixtures having a minimum ignition energy greater than about 0.2 mJ, since a corona discharge itself would only be able to ignite mixtures having minimum ignition energies on the order of 0.01 mJ.

A more effective electrostatic eliminator produces ions of both polarities. One way of creating this is with the use of a small radioactive source, typically polonium 210. The alpha particles emitter by the source collide with air molecules and produce a plasma of ionized air. It has the drawback of a short half-life (138 days), requiring continued replacement. Another technique involves subjecting a grid of needle points or wires to an AC source, with a voltage high enough to cause corona discharge. Its main drawbacks are that (a) ozone is produced; and (b) the needle points must be placed within 10 mm of the surface to be neutralized. Additional advice on static eliminators has been published[3].

Anti-static agents are chemicals which typically increase the conductivity of a substance, so charges could leak away more quickly. This can be done by introducing directly a substance which is more highly conductive, e.g., carbon particles. More fascinating is a technique that increases surface adsorption of water at low humidities, that is, a hydrophilic additive. By use of such techniques, conductive *plastics* can be formulated.

In industrial situations which demand it, it is possible to minimize the risk of electrostatic discharge from persons by having operators wear conductive *shoes* and *wrist straps* and providing conductive *floors*. While most materials not specifically designed to be conductive are, in fact, highly insulating, concrete and terrazzo floors have sufficient natural conductivity that static discharges from persons wearing conductive shoes are unlikely. Conductive *gloves* are also available for operations that need them.

Lightning protection

The lightning rod was invented by Benjamin Franklin in 1752. This is a metallic rod which is grounded at one end and raised in the air at the other. When the initial streamers from the cloud start to form, there is not a highly specific place along the ground level where the initial return stroke is preferentially located. By providing a ground-potential conductor in the air, a preference is established, and the lightning current flows down the rod (which must be of adequate dimension in order not to overheat). Franklin recommended that the tip of the rod (*air terminal*, in the jargon of the lightning protection industry) be pointed, because this leads to a point discharge. In earlier times, this point discharge (corona discharge) was considered necessary to 'attract' the lightning stroke. More recently, experiments showed that a smoothly rounded tip is more successful in attracting lightning to itself and avoid strikes to nearby objects[4]. The first comprehensive engineering guide to proper installation of lightning protection systems was published by Anderson[5] in 1879 and, perhaps surprisingly, few of his recommendations have been overturned by more modern research. Müller-Hillebrand[6] reviewed some of the early concepts of lightning protection.

A lightning protection system basically comprises three main components:

- air terminals
- downconductors
- ground terminals.

Franklin recommended that each air terminal provides a downward 'cone of protection,' with the cone's angle from vertical being 58°. The origin of this recommendation is unclear and it was evidently not evolved from experiments. Subsequent experience suggested that this angle is much too large, and during the 19th century the recommendations slowly went downward to about 30°. However, even using a 30° angle of protection, failures were documented[7]. In more recent times, Lee[7] synthesized a design method for protecting buildings, evolved from advanced calculations used by electric utilities for protection of power lines. The method is applicable only to structures of 45 m height or less and is described in the following way: Imagine a rolling sphere of 45 m radius (Figure 1). The sphere starts rolling along the ground from a distance far away from the structure in question, then roll up to and over the structure and its protective air terminal(s). If the sphere only ends up touching the air terminal(s) and the ground and cannot come into contact with the structure to be protected, then air terminals of sufficient height and quantity have been erected, otherwise additional protection is needed. This more realistic protection concept is more liberal than the 30° fixed-angle scheme for low structures and more conservative for high structures. The 45 m dimension is used because it corresponds to the typical length of the stepped leader, which is about 50 m.

In view of the enormous currents of around 20,000 A that are involved in a lightning strike (see Chapter 11), it is perhaps surprising that gigantic-size downconductors are not required to safely conduct the electricity. The minimum size of conductor does not need to be huge since the flow of current is so brief—much less than 1 s—and heating is proportional to the time of current flow. The simplest model that can predict this is the adiabatic lumped-capacitance model:

$$W = I^2 Rt = \rho CV(T_f - T_o)$$

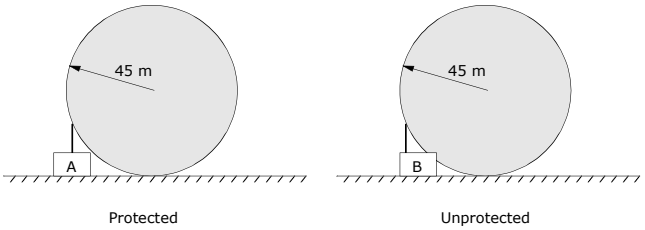

Figure 1 Sphere of protection from an air terminal: structure A is protected, structure B is not

where W = energy (J) flowing into a piece of metal, I = current (A), R = resistance (Ω), t = time (s), ρ = density (kg m^{-3}), C = heat capacity (J kg^{-1} K^{-1}), V = volume (m^3), T_f = final temperature (ºC), and T_o = initial temperature (ºC). This assumes that the current flow is constant over the time t; if the current flow is varying, then the expression becomes:

$$W = R\int I^2\, dt = \rho CV(T_f - T_o)$$

where R is assumed to be time-invariant and has been taken outside the integral. Applying the above relation to copper wire, ρ = 8890 kg m^{-3}, C = 385 J kg^{-1} K^{-1}, $V = A{\cdot}L$, where A = cross-sectional area (mm) and L = length (m). The resistance of a copper wire can be expressed as:

$$R = \rho_e \frac{L}{A}$$

where ρ_e = electrical resistivity of copper = 1.7241×10^{-8} Ω·m. The initial temperature T_o can be taken as 20ºC, while the final (allowable) temperature T_f must be set to some reasonable value below the melting point. Since the downconductor may come into contact with combustibles such as dry leaves, it seems appropriate to limit T_f to 200ºC. Based on studies of lightning discharges, $\int I^2\, dt = 5\times10^6$ $A^2{\cdot}s$ is commonly used. The equation can then be evaluated as:

$$1.7241\times10^{-8}\left(\frac{L}{A}\right)\cdot 5\times10^6 = 8890\times385\,(A\cdot L)180$$

and it can be noted that the actual length of the wire sensibly cancels out of the equation. This gives $A^2 = 1.4\times10^{-10}$ m^4, or $A = 1.18\times10^{-5}$ m^2 = 11.8 mm^2. If the temperature criterion were the melting point of copper (1083ºC), then A = 4.9 mm^2, using the same 'action integral' of 5×10^6 $A^2{\cdot}s$. The lumped-capacitance model is highly simplified since it ignores the variation of resistivity with temperature and ignores reactance in the circuit. Nonetheless, a simple model appears adequate and it formed the effective basis for sizing conductors in Poland; installations sized in this manner were found to be 95% effective[6].

In the US, however, a more conservative approach is taken, with conductor areas being greater than 11.8 mm^2, in order to allow for mechanical damage, some unusually potent lightning strikes, etc. The most commonly followed guidance is that published by NFPA[8]. NFPA 780 divides structures into two Classes, Class I being those up to 75 ft (22.9 m), with Class II being those higher. For Class I structures, the required downconductor area is 29 mm^2 for copper and 50 mm^2 for aluminum. The cross-sectional area required for copper conductors in Class II service is 2× that for Class I. Generally, stranded or braided conductors are used, to minimize loss of current-carrying capacity due to skin effect (this electromagnetic effect pertains to transient current flows and leads to current flowing disproportionately near the surface). A lead coating is often used to minimize loss of metal due to corrosion from flue gases. Properly-installed and maintained lightning protection systems are highly effective, with one report[9] quoting old US studies giving 99.3 and 99.9% effectiveness values.

For configuration of the air terminal, modern studies by Moore et al.[10] concluded that the optimum tip-height to tip-radius ratio is about 680. Thus, a rod erected at 10 m height ought to have a tip of 14.7 mm radius.

For protection of electric installations or electronic equipment, additional protection is often appropriate to provide in the form of *lightning arresters*. These provide a bypass path for current to ground so that it would flow in a path that does not lead to destruction or ignition. A variety of devices are available for this purpose, the most common ones being:

- spark gaps
- gas discharge tubes
- varistors.

High voltage transmission lines are so arranged that a ground conductor is at the topmost position; this plays a similar role to the lightning rod on a building. But a lightning strike can induce excessive current surges in power lines, even if the actual strike current goes into the ground conductor. Thus additional surge protection is usually installed, which often takes the form a spark gap. This is merely a fixed gap between a grounded conductor and one at an elevated voltage. The gap size is chosen so that the air will not break down under normal voltage conditions, but will break down under a lightning-caused surge. The bulk of the current then flows to ground instead of propagating along the network. For low-power equipment, the most common lightning arresters are metal-oxide varistors (see Chapter 14). Telephone companies traditionally used carbon block protectors, which, similar to a varistor, function as a voltage-dependent resistance. Gas discharge tubes, which are basically spark gaps in an enclosed, controlled atmosphere, are used in medium voltage applications where a permanent device is needed (varistors are sacrificial).

Another form of lightning protection is the *Faraday cage*—a cavity within a grounded metallic enclosure. Electric fields may exist outside the cavity, but the cavity remains field-free. The Faraday cage principle is serendipitously

exploited in the motor vehicle, where the occupants inside can expect to be safe from lightning.

Worldwide, the IEC standards[11,12,13] on lightning protection are the most widely followed. The IEC scheme is more calculationally oriented than the primarily-empirical NFPA standard. A good summary guide for the designer on the use of the IEC standards has been published by Wiesinger and Zischank[14]. Other guides to lightning protection include IEEE Std. 142[15], IEEE Std. 1100[16], UL 96A[17], and a variety of military and NASA standards.

Arresters—flame and spark

FLAME ARRESTERS

Flame arresters (sometimes called "flame traps") are devices that typically make use of the quenching distance principle. As was presented in Chapter 4, a flame cannot propagate through a small enough tube or cavity. This principle was recognized in 1815 by Sir Humphry Davy[18] who designed the first practical miner's safety lamp; a comprehensive review of the history of miner's safety lamps has been published[19]. The simplest flame arrester would be just a metal tube with a diameter less than d_T. But unless only a tiny flow is needed, a tube of diameter ca. 1 mm would not be practical. One solution is to make a sufficiently large bundle of tubes. Practical devices using this method have been made, as have ones where the cluster of tubes is replaced by a honeycomb structure. Other configurations include: crimped metal ribbons, sintered metal, metal foam, etc. A crimped metal arrester consists of layers of crimped metal, separated by layers of flat metal. This arrangement creates a series of cells, roughly triangular in shape.

Surprisingly, flame arresters that are effective for certain applications can be made from combustible materials. The US Air Force uses polyurethane foam as a bulk filling material for aircraft fuel tanks, to resist explosions caused by incendiary bullets fired into the tank[20]. The material was found to be about as functional as crimped or honeycomb aluminum arresters, but carrying a smaller weight penalty. The drawbacks are that, when a fuel/air aerosol passes through the foam, electrostatic charging can occur[21] and this has led to some accidents[22]. Thus, in certain applications, metallic flame arresters are required due to electrostatic aspects.

If a bundle of tubes is a viable flame arrester, can it be made short? A very short bundle of tubes or honeycomb, of course, becomes just a perforated metal sheet. Wire gauze is functionally nearly identical. There is disagreement about the efficacy of wire gauze and perforated metal flame arresters. Palmer[23] considers them suitable only for undemanding applications, and not viable elsewhere. The Health and Safety Executive[24] considers that a single-layer gauze arrester is viable if the maximum flame approach speed does not exceed 10 m s^{-1}; higher speeds can be tolerated by multilayer arrangements, but advice is not given. However, an extensive US Coast Guard testing program[25] concluded that wire mesh flame arresters are effective in a rather demanding application of 152 mm pipelines. In their test program, they found satisfactory performance with acetaldehyde, butane, diethyl ether, gasoline, methanol, propane, and toluene; only for ethylene were failures encountered. An arrester can also be made by passing the gas stream through a body of water or other liquid, since flame will not propagate through the bubbles[26,27]; these find use in specialized applications (Figure 2). For gases not compatible with water, fluids such as ethylene glycol or mineral oil are used. An incident is reported where hydraulic flame arresters successfully stopped the propagation of a detonation in a large acetylene pipeline[28].

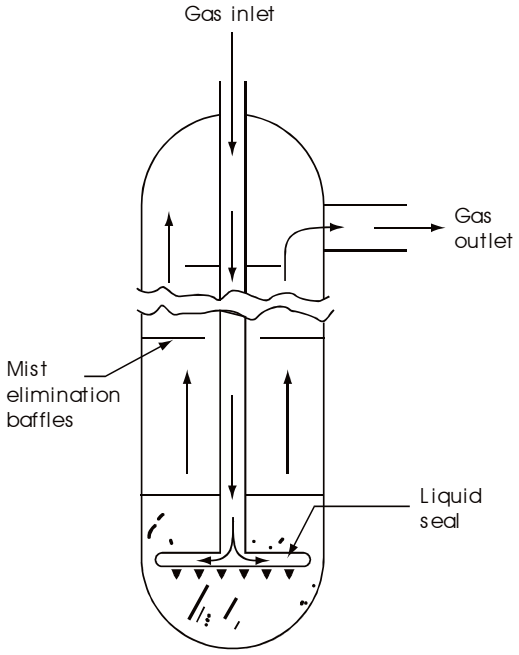

Figure 2 A hydraulic flame arrester
(Copyright © 1975 AIChE)

Certain types of flame arresters use neither quenching distance nor a liquid seal. Instead, they are based on the inability of a flame to propagate backwards into a mixture when the flow velocity through the orifices exceeds the velocity at which flame could propagate backwards[29]. Before this principle is adopted, it is prudent to consider whether there are operating conditions (e.g., startup or shutdown) when unexpected low velocities may occur, yet a flashback hazard still exists. The stoppage of pipeline deflagrations or detonations can also be accomplished by active systems, i.e., a quick-acting gate valve activated by a suitable pressure sensor[28].

The substances with the smallest quenching distances are carbon disulfide, acetylene, and hydrogen. Because acetylene is used in industry more widely than carbon disulfide, performance testing of flame arresters is often focused on

acetylene or acetylene mixtures with air or oxygen. In addition, the AIT of acetylene (ca. 300ºC), is lower than average for industrial gases, although in this respect acetylene is outranked by a number of other gases.

The design or testing of a flame arrester starts with the knowledge of the flame speed of the mixture. The actual flame speed, however, is not a handbook value but depends on turbulence. If long pipe lengths, obstructions, etc., cause a transition from deflagration to detonation to occur, the flame speeds become exceedingly large. This does not preclude design of flame arresters to cope with detonations, but the flame arrester must be robust enough, both mechanically and thermally, to survive an explosion. In some cases, mixtures can be expected to possibly detonate. When flame arresters are designed for such applications, mechanical strength becomes a top issue, since the pressures to be resisted for a detonation may be around 50 atmospheres, contrasted with 8 atm for deflagrations. Metal foam arresters have been shown to be able to resist acetylene detonations, if certain design guidelines are followed[30]. Sintered metal flame arresters have also been studied in connection with detonations of various gases[31].

Based on simple heat loss considerations, Palmer et al.[32] proposed that, provided each hole is smaller than the d_T for the fuel in question, a heat balance for the holes can be developed as follows. The Nusselt number is assumed to be a constant = 2.4. Then, the heat transferred convectively per unit wall area of tube is $2.4\bullet(T_f\text{-}T_w)/d$, where d = diameter of opening. The heat transferred per unit face area of the arrester is then $\dot{q}'' = \frac{2.4\lambda(T_f - T_w)}{d}\cdot\left(\frac{\pi y}{d}\right)\cdot\left(\frac{4F_a}{\pi}\right)$, where y = depth of each opening and F_a = fraction of face area occupied by openings (--). The flame front has a thickness x and travels past the arrester at a velocity v. Then the time that the arrester is exposed to flame heating is x/v. The heat that can be removed from the flame per unit face area of the arrester then is:

$$q'' = \frac{9.6\lambda(T_f - T_w)yF_a}{d^2}\frac{x}{v}$$

Now, if it is assumed that quenching occurs when q''' heat is removed per flame volume, then the maximum flame speed for which a perforated metal, gauze, or crimped metal flame arrester can be successfully used is:

$$v \le \frac{9.6\,\lambda\left(T_f - T_w\right)}{q'''}\frac{yF_a}{d^2}$$

where v = flame speed relative to arrester (m s^{-1}); λ = conductivity of flames (W m^{-1} K^{-1}); T_f = mean temperature of flame gases (K); T_w = temperature of flame arrester (K); and q''' = heat removal for quenching (J m^{-3}). For most hydrocarbons[33], at stoichiometric conditions the group of variables $\frac{\lambda(T_f - T_w)}{q''}$ is approximately 1.34×10^{-3} m^2 s^{-1}. This gives:

$$v \le 0.013\frac{yF_a}{d^2}$$

The relative velocity of flame is given by:

$v = S + |u|$ for flame propagation in the direction of gas flow

$v = S - |u|$ for flame propagation opposing the direction of gas flow

where S = laminar (or turbulent, as appropriate) flame speed (m s^{-1}), and u = bulk flow velocity of gas in pipe or vessel (m s^{-1}). Two cases arise (Figure 3) because the flame propagation may need to be stopped either in the direction of the gas supply or in the direction of products venting. Palmer showed reasonable agreement with experiment, but it must be remembered that theoretical computations can only be viewed as an aid in design of flame arresters, not as a proof of their performance—actual performance can only be evaluated by test.

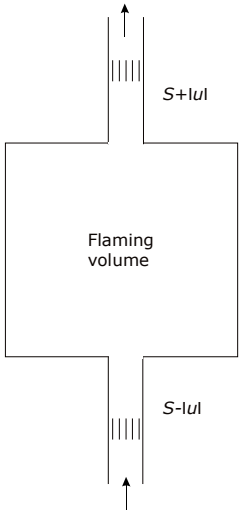

Figure 3 Two cases of flame velocity versus flow velocity

It is essential to appreciate the role of T_w in Palmer's equation. If T_w rises, then the velocity that the arrester is effective against will drop. Thus, if a flame is allowed to play upon an arrester for some time, it will likely break through.

While F_a may, in principle, vary from 0 to 1, in practical devices the range of variations will not be large. Thus, Wilson and Atallah[34] suggested that a useful correlation can be had without including that factor:

$$v \le \frac{0.005y}{d^2}$$

In all of the above equations, if the apertures are not circular, then the diameter should be replaced by the hydraulic diameter $d_H = 4A/P$, where A = area (m) and P = perimeter (m).

Unless the system can tolerate a large pressure drop, it is necessary that the flame arrester be fitted into a pipe section which is of much larger diameter than the normal pipe diameter. Cubbage[35] offers guidance on this point; commonly a diameter 3.5× the pipe diameter is suitable.

The development above assumed that there is negligible pressure rise for the flame. In systems where a substantial explosion pressure may be developed[24], the permissible velocity must be reduced by the ratio P_o/P, where P_o = atmospheric pressure (absolute), and P = explosion pressure (absolute). The performance of many flame arresters is very sensitive to pressure and an unanticipated overpressure can readily cause failure[36]. The condition of flame arresters must be carefully monitored if satisfactory performance is expected. Some large explosions have been attributed to damaged flame arresters, where a previous flame challenge had created void spaces[36].

The Bureau of Mines[37] developed a series of heat transfer models for predicting flame arrester performance; all of these, however, require use of computer programs and do not lead to closed-form equations or graphs.

Some practical advice on selecting flame arresters is given in a UK Guide[38] and by others[24,39]. The testing of flame arresters in the US is according to UL 525[40]. The standard is highly prescriptive and can be viewed as a specification, accompanied by a laboratory testing component. The UL 525 standard has a Continuous Flame test, which is used to examine the flashback potential from the flaming region into the premixed, unignited gas supply. There is also a non-preheated test that devices must pass and an optional test where the flame arrester is subjected to a series of explosions (deflagrations) and has to perform its function under those conditions. Separate test procedures govern devices intended to withstand pipeline detonations. IMO has a standard which governs the testing of flame arresters in tanker vessels[41]. Some practical experience with this test method has been reported by Dyer et al.[42]. In 2002 AIChE published a book[43] dealing with applications for and installation of flame arresters, including detonation arresters. A British method for testing flame arresters has also been published[44]. Howard offers a brief, but instructive guide from the US industry viewpoint[29]. Case histories of failures and design guidance is given by Lapp[45]. Babkin[46] has summarized recent Russian research on flame arresters.

SPARK ARRESTERS

Combustion engines can emit carbonaceous particles in the exhaust stream which may set vegetation and other combustibles on fire. For this reason tractors, locomotives, and other engines are often fitted with spark arresters. Spark arresters fall into two broad categories: screens and cyclones, although designs exist which combine both features. Screens are normally usable only if very few particles are being produced, since they could readily clog otherwise. Cyclones function by creating a swirl flow and using centrifugal force to deposit particles out of the gas flow stream and into a receptacle. Automotive mufflers do not function as effective spark arresters[47], fortunately there are not normally many sparks produced by gasoline-powered automobile engines.

The US Forest Service maintains a facility for testing spark arresters. Detailed descriptions of devices that pass the test are published in separate books for locomotive and general-purpose arresters[48] and for multi-position small engine arresters[49] used on chain saws and hand-held, gasoline-powered gardening equipment. The hazard is considered to be largely due to particles over 0.6 mm diameter, thus, the standards used for testing, SAE J335 and J350, are designed to trap or pulverize particles that are larger than 0.58 mm.

Pellet stoves often produce large quantities of burning particles, yet their exhaust systems rarely contain spark arrester devices. By contrast, fireplaces are often equipped with screens (sometimes called 'spark guards' or 'fire guards'). As discussed in Chapter 11, low density materials can be readily ignited by very small particles, and particle mass must be lower than about 30 mg before the ignition probability drops below 10%. For coal particles, 30 mg corresponds to a diameter of about 3.4 mm. Consequently, commercial screens having a grid size on the order of 12 mm would be of minimal effectiveness. The density of other fuels likely to be used in a fireplace is lower, but the theory discussed in Chapter 9 indicates that particle diameter is of greater importance than the mass in determining the smoldering ignition of a fuel bed, thus brands from other fuels may not require a much greater diameter to achieve ignition.

Design of electrical equipment for flammable atmospheres

In manufacturing, extraction, and related industries, there can be locations where atmospheres may contain flammable amounts of gas or dusts. If electrical equipment needs to be used in such a location, means have to be taken to ensure that the electrical equipment does not cause an explosion. The technology for achieving this has been in existence for a long time, starting in Germany with the massive studies of Beyling[50] in 1906. In the US, the primary guidance on the subject comes from the NEC. In most other countries, the requirements of the International Electrotechnical Commission (IEC) are used. In EU, the regional standards body CENELEC is further interspersed between international and national standards. A number of the concepts used by IEC have recently been introduced into the NEC and are here discussed under NEC Art. 505.

NEC REQUIREMENTS

The Code views that protection measures need to take the following into account:

- the likelihood of the atmosphere being flammable

- the ease of ignition of the atmosphere from an explosion occurring within a nearly-closed apparatus
- the ease of ignition from high temperatures.

To address these concerns, different provisions are made. The likelihood of the atmosphere being flammable is treated by the Classification of locations. The ease of ignition from internal explosions is dealt with by placing fuels into Groups. The ease of ignition from high temperatures is treated by use of 'T ratings.' The NEC then makes provisions for safe installation practices within the various locations. The actual details of design for electrical equipment intended to be suitable for hazardous locations (e.g., intrinsically safe or explosionproof) are left to UL standards to regulate. There is a large number of those, with the primary ones being UL 913[51], UL 1604[52], and UL 2279[53].

Originally, there was only one way according to which Classes, Groups and T-ratings were established. Starting with the 1996 edition, however, there are two parallel schemes—the traditional North American scheme (Art. 500), and the IEC scheme (Art. 505). Since most of the world followed the standards of IEC, it was considered helpful to multinational companies to permit, as an option, the international scheme.

ARTICLE 500 (TRADITIONAL CLASSIFICATION)

According to the traditional scheme, areas in which electrical equipment might need protective features against explosion hazards are divided in the following way:

- Class I, Division 1: flammable gas mixtures exist under normal operating conditions.
- Class I, Division 2: flammable gas mixtures exist only in closed containers or closed systems.
- Class II, Division 1: flammable dust mixtures exist under normal operating conditions; or presence of conductive dusts in hazardous quantities.
- Class II, Division 2: flammable dust mixtures may exist in case of equipment malfunction.
- Class III, Division 1: easily ignitable fibers exist under normal operating conditions.
- Class III, Division 2: easily ignitable fibers are stored or handled.

The Code is deliberately vague in its definitions of the Divisions to allow needed flexibility. Some experts consider[54] that if an explosive concentration is present > 100 h per year, the location should be Division 1, if between 10 and 100 h per year, Division 2, and if < 10 h per year, not Classified. A guide[55] has been developed in the UK which attempts to quantify the classifications by use of hazardous-substance release calculations and risk assessment, but it is not clear that real advantages accrue over 'intuitive' classification.

The actual atmospheres themselves differ in their hazards and their protection requirements. Thus, atmospheres are divided into Groups:

- Group A: acetylene. No other substances are placed into this Group.
- Group B: hydrogen. Also, butadiene, ethylene oxide, propylene oxide, acrolein.
- Group C: diethyl ether. Also, ethylene, cyclopropane, etc.
- Group D: gasoline. Also, numerous other gases and vapors.
- Group E: combustible metal dusts; other dusts having a resistivity less than 1.0 Ω·m.
- Group F: carbon black, charcoal, coal and coke dusts. Resistivity between 1.0 and 10^6 Ω·m.
- Group G: combustible dusts with a resistivity of 10^6 Ω·m or greater.

The Groups for gases/vapors were set out in terms of a 'reference material,' rather than by chemical properties. This establishment of the Groups was a committee action, not derived from a scientific study of the problem, although accompanied by *post hoc* testing at UL. The primary criterion for placing a substance into one of the Groups was the MESG value, as determined from UL's Westerberg apparatus. Only a small number of substances were actually tested and, for most, values were simply derived on the basis of committee opinion. Woinsky[56] attempted to deduce formulas that could assign substances into the NEC Groups, but this was not a fully successful venture, since the Groups were not evolved on the basis of quantitative computations.

In the original testing*, acetylene and hydrogen showed identical MESG values, but were placed in different groups, since acetylene is an unstable substance, while hydrogen is stable. Carbon disulfide was considered to be too hazardous to be included in any Group, even Group A. Unfortunately, the MESG is not the only criterion that has been used in the traditional classification of Groups for NEC. The Committee also factored in the maximum explosion pressure observed during test in the Westerberg apparatus. This is the reason for the dual classification of some substances. If the conduits connected to the electrical equipment placed in the hazardous location are sealed according to certain prescriptions, then the pressure-rise restrictions are considered not to apply, and the milder Grouping is used. For example, ethylene oxide is in Group B, but if the conduits are sealed it becomes Group C. The Groups for various gases and vapors are shown in Chapter 15.

Magison[54] has written at length about the problematic logic of the pressure-rise based Group treatment. There are basically two problems: (1) tests are done in the Westerberg apparatus under conditions that are dissimilar—and much harsher—than would be any explosion propagation that might reasonably be expected to occur in an electrical conduit installed in accordance with NEC provisions; and (2)

* UL later corrected the value for hydrogen, and it rose three-fold; see the discussion of MESG in Chapter 4.

when two rating factors are conflated to produce a single Group, the Group ratings can no longer be used for correlation to any physicochemical variables.

For the classifications of dusts, the NEC does not make this clear, but the National Academy of Sciences (NAS) study (see below) points out that not all combustible dusts fall within the NEC groups. Dusts of low ignition sensitivity and low explosion severity are not classified into the Groups needing special measures. The NAS study also recommended that Group F be abolished and that a breakpoint of 10^3 Ω·m be used to divide Groups E and G. Consequently, in the 1984 edition of the NEC, Group F was abolished. Group F was reinstated in the 1987 edition, because explosionproof motors intended to operate in metal-dust atmospheres need very close tolerances, and those are not required for conductive carbonaceous dusts. The classification of dusts continued to be contentious and substantive changes have been made in this section with nearly every new edition. In general, it has been observed[54] that there is no relation between the conductivity of a dust cloud and either its ignitability or the severity of a consequent explosion. Thus, any classification based on conductivity and, specifically, providing more stringent treatment for conductive dusts does not have a sound basis. The origin of the provision was the perception that conductive dusts might lead electrical parts to short out, and that this creates greater risk than non-conductive dusts. However, the whole purpose of dust-tight, pressurized, intrinsically-safe, etc., apparatus design is to arrange matters so that this does not happen; Magison[54] discusses in some detail the improbability of accidents occurring in the fashion envisioned by this provision.

The classification of gases, vapors, and dusts into the seven Groups has had a complicated history. Expert panels of the National Academy of Sciences were formed on behalf of the US Coast Guard and the Occupational Safety and Health Administration (OSHA). The panels had overlapping membership, but were not identical. Both panels were chaired by Homer Carhart, long-time head of fire research at the Naval Research Laboratory. The work for the Coast Guard resulted in a series of reports[57-61] during 1970 – 1976. These addressed only the classification of gases and vapors. The work on behalf of OSHA spanned 1979 – 1982 and comprised the NMAB 353 series of reports. Reports NMAB 353-1[62] and NMAB 353-5[63] classified gases and vapors, continuing the earlier Coast Guard work. Reports NMAB 353-2[64] and NMAB 353-3[65] were interim studies on the classification of dusts; these were superceded by NMAB 353-4[66]. The summary report was NMAB 353-6[67].

For dusts, arbitrary indices have been developed to determine whether a dust needs to be included in one of the Groups or not. Ignition sensitivity is defined as:

$$\text{Ignition sensitivity} = \frac{T_c \times E \times C}{(T_c \times E \times C)_{\text{Pittsburgh coal}}}$$

where T_c = dust cloud ignition temperature (ºC), as determined in the Godbert-Greenwald furnace; E = MIE of dust (J), as determined in the Hartmann apparatus; and C = minimum explosible concentration (g m^{-3}). The reference values for Pittsburgh coal are: T_c = 610ºC, E = 0.06 J, C = 55 g m^{-3}. Explosion severity is defined as:

$$\text{Explosion severity} = \frac{P \times \frac{dP}{dt}}{\left(P \times \frac{dP}{dt}\right)_{\text{Pittsburgh coal}}}$$

where P = maximum explosion pressure (atm), and dP/dt = maximum rate of pressure rise (atm s^{-1}), with both values being determined in the closed steel Hartmann apparatus. The reference values for Pittsburgh coal are: P = 5.56 atm, dP/dt = 156 atm s^{-1}. The criteria are that if Ignition sensitivity ¤ 0.2, or if Explosion severity ¤ 0.5, then the dust is included in one of the NEC Groups, otherwise it is not.

The actual classifications to be used in connection with NEC requirements are not published within the NEC itself but, rather, are given in NFPA 497[68] for gases and in NFPA 499[69] for dusts. In general, a user would only need to perform tests and use the above criteria if a substance is encountered that is considered to potentially be one that falls into one of the Groups. A number of special hazards, e.g., pyrophoric materials, are not placed under the general Class/Division/Group scheme, but require specific protection measures. In addition, a large number of NFPA standards deal with protection methods for specific industries or installations.

In order to avoid ignitions from hot surfaces, equipment for use in hazardous locations is to be marked with a temperature rating (T-rating). The equipment can then only be used in locations where the AIT of the gas or the layer ignition temperature of the dust is greater than the marked rating. For simplicity (although it hardly seems simpler), the ratings are not actual temperatures, but codes denoting temperature ranges, the code always beginning with the prefix 'T.' For example, T2B denotes a maximum temperature of 260ºC. The user must then find the AIT for the desired gas in NFPA 497 (or NFPA 325[70]) or the layer ignition for the dust in NFPA 499. As discussed in Chapter 4, the use of the AIT as a limit value for hot-surface ignitions is a very conservative approach, since the hot-surface ignition temperature will normally be hundreds of degrees Celsius higher than the AIT.

In the 1997 edition of NFPA 497 and the 1999 edition of NEC, the 'expert judgment' scheme for placing substances into various Groups was fundamentally reoriented and an IEC-based scheme adopted, as shown in Table 2. Curiously, this was not accompanied by a reclassification of actual substances, which remained listed in the groups as previously established.

Table 1 Revised criteria for Article 500 (traditional) classification 'Division system' of gases and vapors

Group	MESG (mm)	MIC ratio (--)
A	Acetylene only	
B	≤ 0.45	≤ 0.40
C	0.45 to 0.75	0.40 to 0.80
D	> 0.75	> 0.80

ARTICLE 505 (IEC CLASSIFICATION)

In this scheme, as originally developed in IEC 60079-10[71] and in use throughout most of the world, the classified areas are termed Zones:

- Zone 0: ignitable concentrations are present continuously, or for long periods of time
- Zone 1: ignitable concentrations are present in normal plant operation
- Zone 2: ignitable concentrations are present only in case of equipment failure.

Roughly, Zone 0 and Zone 1 correspond to Division 1, Zone 2 to Division 2. Within IEC, the classification into zones also extends to dusts, and is done according to IEC 61241-3[72]:

- Zone 20: hazardous atmosphere with regards to dust clouds continuously present
- Zone 21: hazardous atmosphere with regards to dust clouds present in normal operation
- Zone 22: hazardous atmosphere with regards to dust clouds present only for short periods of time

The NEC, however, had not adopted the IEC dust zones as of 2002.

Groups are defined in IEC as an extension of earlier work in the UK by the Safety in Mines Research Establishment:

- Group I: methane only.
- Group IIA: propane, etc.
- Group IIB: ethylene, etc.
- Group IIC: acetylene, carbon disulfide, hydrogen, etc.

Apart from the unique Group I, the others are determined solely by their MESG or MIC data, without need of expert judgment by committee. In the IEC scheme, the MIC (minimum igniting current; see *Ignition from breaking wire or moving contacts* in Chapter 4) is used as a ratio, obtained by dividing the substance's MIC by the MIC of methane. By doing this, it was felt that certain interlaboratory variations would be minimized. The selection rules are shown in Table 2. Note that either MESG or MIC ratio alone is sufficient to classify in most cases, but not all. If the MESG is between 0.5 and 0.55 mm then classification must proceed on the MIC. Conversely, if the MIC ratio is between 0.8 and 0.9, or between 0.45 and 0.5, then classification must be based on the MESG.

As discussed in Chapter 4, the agreement of UL and IEC values for MESG is poor. The reasons for the discordance

Table 2 Criteria for Article 505 (IEC) classification 'Zone system' of gases and vapors

Group	MESG (mm)	MIC ratio (--)
IIC	≤ 0.50	≤ 0.45
IIB	0.50 to 0.90	0.45 to 0.88
IIA	> 0.90	> 0.80

are mostly attributable to design flaws of the UL apparatus[†], thus, there is some expectation that classification will gradually move over to the IEC system. The current edition of NFPA 497 also contains an Appendix suggesting the use of a rule based on Le Chatelier's rule to compute MESG values for gas mixtures. Based on a limited validation, the agreement appears acceptable[73].

The limiting of surface temperatures according to T-ratings is also used in the IEC scheme, however, the groups are fewer in number.

DESIGN OF EQUIPMENT FOR HAZARDOUS LOCATIONS

With low-current electronic and electric equipment, there are two primary ways that they could be the cause of ignition of gases, vapors, or dust clouds: (a) by producing an electric arc; or (b) by becoming so hot that hot-surface ignition occurs. To guard against these eventualities, historically there have been two primary design methodologies: intrinsically safe design, and explosionproof design. For either methodology, one practical tenet is simply to put the minimum necessary electrical equipment into ignitable atmospheres. Thus, it is often possible to only put in simple transducers (thermocouples, float switches, etc.). All of the remaining instrumentation and the control devices (motors, solenoids, etc.) are then ideally located in a non-ignitable atmosphere. In practice, there are instances where such a strategy becomes impossible and, thus, devices such as explosionproof motors can be necessary.

The NEC has traditionally provided for design alternatives as summarized in Table 3. It might be observed that layer ignition temperatures for dusts are hardly similar within each of the NEC dust Groups, thus the logic of across-the-board requirements is unfortunate. With the introduction of Art. 505 in the 1996 edition, the European IEC designs became acceptable, as discussed below.

Letter designations for categories of protection were originally developed in Germany. IEC has taken over the use of these designations and now they are international:

Type 'd' – flameproof. This corresponds to the US terminology 'explosionproof.' Details are given in IEC 60079-1[74].

[†] Some of the problems were corrected when UL redesigned the chamber and provided a corrected (and reasonable) value for hydrogen. No other gases were rerun in the redesigned chamber, however, and there remain flagrant discrepancies (e.g., carbon disulfide, acetylene, pentane) in the official UL data.

Table 3 Summary of design options permitted by the NEC in the traditional scheme

Area	Equipment designs permitted
Class I, Division 1	Explosionproof Pressurized per Division 1 requirements Intrinsically safe *Also*: T-rating for equipment to be ❍ AIT of gas/vapor
Class I, Division 2	Explosionproof (or general-purpose, if only non-incendive or sealed components) Pressurized per Div. 1 or 2 requirements Intrinsically safe *Also*: T-rating for equipment to be ❍ AIT of gas/vapor
Class II, Division 1	Dust-ignition-proof Pressurized Intrinsically safe *Also*: max. temperature according to Group
Class II, Division 2	Dust-tight enclosure General-purpose enclosures permitted in some cases *Also:* surface temperature to be limited to 120ºC
Class III, Division 1	Tight covers, no holes Totally enclosed (in case of rotating machinery) Intrinsically safe
Class III, Division 2	Similar to Division 1

Type 'e' – increased safety. This involves design of equipment so that the probability of failure is made very low. It is described in IEC 60079-7[75].

Type 'i' – intrinsic safety. This is sub-categorized into '*ia*' and '*ib*.' Type '*ib*' is less strenuous than type "ia" and involves only one fault being simulated, instead of two. It is described in IEC 60079-11[76]

Type 'm' – encapsulation. It is described by IEC 60079-18[77]

Type 'n' – this is a catchall category that includes non-sparking apparatus, enclosed-break devices, restricted breathing, and other strategies; formerly called '*s*'. It is described in IEC/TR 60079-15[78]

Type 'o' – oil-immersed. It is described in IEC 60079-6[79].

Type 'p' – pressurization. It is described in IEC/TR 60079-2[80].

Type 'q' – powder filled. It is described in IEC 60079-5[81].

The apparatus itself is marked as "*Ex z*," where z denotes one of the above letters. In addition, the designation *Ex s* is used to denote a mixture of protection methods.

Eckhoff has pointed out that the philosophy of treating, on a more or less similar basis, the possibility of gas and dust explosions inside electrical equipment enclosures is flawed[82]. Enclosures can be easily designed to keep out sufficient dust that an explosible concentration inside cannot build up. Furthermore, it would be extraordinarily unlikely that an internal explosion would then occur at the same time that an explosible concentration continues to exist outside.

EXPLOSIONPROOF EQUIPMENT

Explosion proof equipment typically uses heavy casings to limit energy leakage. Under the explosionproof (also called 'flameproof') philosophy, it is not necessary to limit the generation of arcs or hot spots inside the equipment. Instead, it is presumed that an explosion may occur inside the device, but that the design of the device will prevent it from being communicated to the external atmosphere and causing an explosion in it. Heavy power devices, which could not be engineered to be intrinsically safe, can be qualified as explosionproof. The two main design criteria for explosionproof equipment are:

1. the enclosure must withstand the pressure of an internal explosion
2. all joints of the enclosure must be such that explosion products, as they leave the enclosure, are incapable of igniting gas which may be present in the surrounding atmosphere.

A safety factor is normally applied to the enclosure so that it should withstand 1.5 to 4 times the possible internal explosion pressure. The joints and connections must be tight enough not only to exclude flame from passing through, but also that non-flaming hot gas stream emerging from the enclosure would not be hot enough to ignite the external atmosphere. These requirements mean that physically the device will be enclosed in a heavy casing. In contrast, intrinsically safe devices do not require any special casing.

From an ignitability point of view, the main variable in explosionproof design is the Maximum Experimental Safe Gap (MESG). This is the maximum size opening between two flanges which, for certain specified conditions, will not permit flame propagation from the inside to the outside of the enclosure. There are conflicting constraints on the design process, since smaller gaps lead to higher internal pressures, making it more difficult to design an enclosure that will not shatter during the explosion. For making the experimental determination, IEC has standardized a 20 mL test bomb. Since leakage at flanges in industrial equipment is a common situation that could lead to explosion, the test apparatus creates the gap between two simulated flanges. The test method has already been described in Chapter 4.

For consistency, standard testing and reporting of MESG data on gases and vapors must use a standard flange dimension. The MESG values determined by the IEC or equivalent UK test apparatuses (see Chapter 14) were measured using a 25 mm flange length (length being considered the distance along which escaping gases must travel). The UL

values were obtained with a 19 mm flange. Shorter flange lengths provide less opportunity to cool down the escaping gases, thus effectively requiring smaller gaps in order to avoid flame breakthrough. In actual instruments, flanges greater than 25 mm would be uncommon, but lesser dimensions are common. Magison[54] reviewed literature on the influence of flange length and concluded that each decrease of length by 2× decreases the actual MESG by about 1.3×.

An especially strenuous condition inside explosionproof equipment is a high-power electric arc. Steel enclosures of insufficient strength can be burst, aluminum enclosures burned through by arcing to case, and polymeric enclosures ignited, as shown by a series of German tests[83]. If a high-current arc takes place, it has been shown that transmission of explosion can take place with a flange gap possibly much smaller than the MESG. In one series of tests[83], it was shown that if an arc is so situated that it can directly expel particles through the gap, a gap as small as 0.28 mm may transmit an explosion in methane/air mixtures. But in another study[84] even a 0.2 mm gap transmitted particles that ignited a methane/air mixture. For these incidents, while a flammable mixture explosion inside the case helps to keep the escaping particles hot, it is thought that the phenomenon may also occur without a flammable mixture inside the enclosure at all, merely upon the creation of an energetic arc. The latter would not be likely inside instrument cabinets, but may be very likely within enclosures containing power-switching devices. A practical solution was found to be the introduction of a right-angle bend into the flanges, which effectively decelerates and cools any particles[84]. It was also shown that coal particles exploding inside a case have much too low an energy to cause a particle-ignited explosion outside the case[84].

In some cases, it can take very little leakage to convey a gas to a location where it creates a hazard. Individual wire strands in a stranded-conductor wire have been known to allow a detectable leakage of gas to pass[85].

DUST-IGNITION-PROOF EQUIPMENT

For use in Class II, Division 1 areas, NEC specifies that the design of explosionproof equipment shall be according to UL 1203[86]. The requirements basically involve tight-fitting joints and thick walls. The requirements can be substantially costly, so there is incentive to arrange processes so that areas are in Division 2 rather than Division 1. For Division 2, only normal dust-tightness is required.

INTRINSICALLY SAFE EQUIPMENT

Intrinsically safe equipment is one in which the possible energy/heat sources are such that—under both normal and failure mode operation—an ignition will not occur to an atmosphere where a specific vapor, dust, etc. is present in its most easily ignitable concentration. Such designs normally exhibit the following characteristics:

(1) Very low power consumption.
(2) No electrical components which could store (and later discharge) a significant amount of energy. In practice, this means that values of capacitance and inductance must be kept very low. If higher values are needed, sometimes it is possible to arrange diode shunts which do not interfere with normal function, but which limit the amount of energy that could be made available in case of fault.
(3) Protection circuits to limit the current that can flow into the device. Zener diodes placed across power supplies are a common way of meeting this requirement.

Devices with minimal capability of storing or generating energy can automatically qualify as intrinsically safe equipment. A device which cannot generate or store more than 1.2 V, 0.1 A, 20 mJ, or 25 mW under normal or failure conditions qualifies without further testing. Such a device is exemplified by a thermocouple, which generally produces less than 0.1 V. The limits are very tough to meet and devices other than transducers will rarely qualify. A device within these limits is sometimes referred to as a *simple apparatus*.

In the English-speaking world, the concept of intrinsic safety was first studied by Wheeler[87] in 1915, although only limited research was done until the 1940s. At that time the Safety in Mines Research Board (now the UK Health and Safety Executive) began concerted research which has been the basis of intrinsic safety designs worldwide, not just in the UK.

In US practice, intrinsically safe systems are designed to be safe against two simultaneous failures of components or wiring. This ensures that the probability of actual system failure is very low. When the application is to areas where the presence of a flammable gas atmosphere is itself a rare event, the consideration of only one component failure should be sufficient. This is the tactic taken by IEC 60079-11[76], which provides for two levels of protection. Type '*ia*' is suitable for Zone 0 and involves simulating two faults; Type '*ib*' is suitable for Zone 1 and involves simulating only one fault. Even the '*ib*' philosophy has been criticized as resulting in a grossly over-conservative equipment design[88] if mechanical failure alone is considered; accidental explosions usually involve human errors and not just equipment failures of approved, intrinsically-safe equipment.

A number of subtle points exist in actual equipment design. For instance, no wire strand should be too *small* in diameter. This is because it takes less current to heat up a thin strand to high temperatures than a thick one. The assumption is made that a wire strand can get detached from the wire of which it is part, short out against some other component, then proceed to heat up.

Non-incendive equipment is a less robust category of intrinsically safe equipment, with less stringent requirements. In the NEC, it is permitted in Division 2 areas where there is only a low probability of flammable gas mixture presence. Within Europe, the various forms of protection encompassed within IEC 60079-15[78] are effectively non-incendive designs.

Test methods: UL 913 and IEC 60079-11

The UL 913 standard[89] is primarily a prescriptive document on how intrinsically safe equipment must be designed. Additional parts of the document comprise an extensive series of instructions on how multiple faults are to be created in the test equipment, and a demonstration that must be made that the faults do not lead to potential ignition conditions. Apart from physical testing, the primary test which is called out in UL 913 is the break-flash apparatus developed at the Physikalische-Technische Bundesanstalt (PTB) in Germany and adopted in IEC 60079-11[76]. The apparatus consists of an explosion-proof chamber which is charged with a particular flammable gas mixture pertinent to the certification sought. Components in the equipment under test are identified where a spark discharge might occur under some failure condition. In place of that component, the electrodes of the break-flash apparatus are substituted and electrical conditions imposed which represent a circuit fault condition which it is desired to simulate. The history leading to adoption by the IEC of the PTB apparatus, in preference to devices developed in several other countries, has been reviewed by Bossert[90].

The electrode arrangement consists of two counter-rotating discs. One disc is a metal contact plate, while the other disc holds out 4 tungsten wires. The contact plate has two grooves and the tungsten wires rotating past alternatingly make and break contact. To pass, 400 revolutions without ignition are required for DC circuits and 1000 revolutions for AC circuits. The test apparatus can only be inserted into a low-current device[91], since the 0.2 mm diameter tungsten electrodes are not capable of carrying currents over 3 A.

A break-flash arrangement is used, since at the low voltages present in most intrinsically safe equipment, contact separation is the main means by which an incendive spark might be produced. In the break-flash test, the conditions needed to cause ignition are conventionally described in terms of a current for a given circuit inductance; calculation in terms of actual energy is not undertaken. A cadmium plate is used because it results in the lowest ignition currents being recorded. The test has been criticized[92] for this reason, since cadmium would not reasonably be specified in intrinsically safe equipment (although cadmium is commonly used in general-purpose electrical equipment and a possibility can may exist that cadmium-containing devices might be improperly introduced during repairs or maintenance). A BM study[93] indicated that brass and lead are the next most sensitive materials, with steel being the least sensitive. A UK study showed that the MIC reported in the IEC/PTB apparatus is directly proportional to the minimum arc voltage for the particular metal used for making the disc (see Chapter 11), and cadmium shows one of the lowest values. The sensitivity results are roughly proportional to the boiling point of the metal, cadmium being the lowest boiling point metal used in the testing. As a consequence, UL 913 permits the substitution of a brass plate, if cadmium, zinc, or magnesium are not used in the circuit. It is not clear why the characteristics of the wire electrode do not need come into the relation, especially since tungsten has one of the highest values for minimum arc voltage and for boiling point. Even without the use of a cadmium plate, the UL 913 standard represents an extraordinarily conservative strategy. While, by itself, this cannot be a criticism, the fact that neither a risk analysis nor a cost-benefit analysis ever appear to have been undertaken as tools for identifying desirable safety factors can be viewed as a limitation.

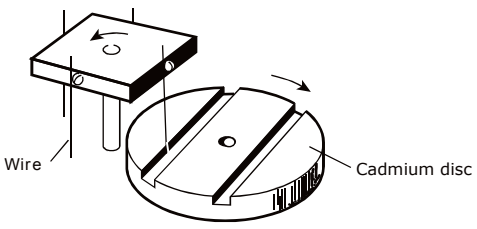

Figure 4 Detail of the counter-rotating mechanism in the IEC/PTB break-flash apparatus

A detailed explanation of the arc behavior in the IEC/PTB apparatus has been provided by Zborovszky[94]. The stochastic nature of ignition in the test apparatus has been studied by Cawley[95], who demonstrated that the probability of ignition has a power-law dependence on the circuit current, $P \propto I^n$. Over the experimental range of $10^{-6} < P < 10^{-3}$, he suggested $n \approx 10$ but Thomas[96] recommends $n \approx 16$. Zborovszky provided experimental details indicating that the large amount of statistical variability is due to the fact that only rare discharges are of a long enough duration (> 1 ms) so that a significant amount of power can get transferred into the arc; for unexplained reasons, in other trials arcing terminates quickly and ignition cannot then take place. Zborovszky[97] criticized the use of tungsten (rather than copper) wire in the IEC/PTB apparatus, since it creates an unrealistic worst-case scenario.

Test methods: HSE high-current apparatus

The IEC/PTB is not designed to cope with conditions that represent battery-operated apparatuses, i.e., a low-voltage, high-current, limited-duration (under short-circuit conditions) power supply. Consequently, HSE recently developed an apparatus for this purpose[98]. The apparatus is called STA, spark test apparatus, and basically involves a further development of the IEC/PTB apparatus to address the needs of the new test conditions.

Test methods: SMRE tests

The Safety in Mines Research Establishment in England conducted extensive research on intrinsically safe equipment for coal mines and developed two test apparatuses: (1) Break-flash Apparatus No.3; and (b) the Intermittent Break-flash Apparatus. The Break-flash No.3 apparatus[99] (Figure 5) simulates a fast snapping break of a wire. The physical device resembles an automotive distributor and provides a current break every 2 s. In a typical circuit, the slow cycling will provide for a potentially incendive spark only at the 'make' position of the contacts. The test method is intended to be used to simulate high-inductance circuits. The Intermittent Break-flash Apparatus simulates a failure where individual strands of wire may brush against another contacting surface in a random manner. This device cycles rapidly and provides a spark at both the 'make' and 'break' positions in most circuits. The test voltage is 24 V, because this corresponds to a voltage commonly found in coal mine equipment. The test method is intended to be used to simulate low-inductance circuits (typ. 1 mH). The history of these test equipment has been reviewed by Haig et al.[100] Thomas has reviewed some more rarely used equipment[101]. It is considered that the SMRE break-flash apparatus No. 3 is not as sensitive as the IEC/PTB apparatus, that is, the values of MIC reported from it are higher than those from the IEC apparatus[54]. The SMRE tests are now only of historical interest.

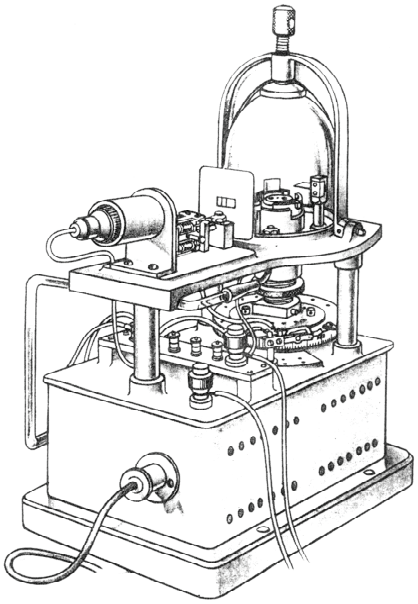

Figure 5 The SMRE Break-flash No. 3 apparatus (the contacts can be seen inside the bell jar)

INCREASED SAFETY PROTECTION

This is an old German protection system which has become part of the IEC system as Type 'e' protection, and in English is known by the very vague '*increased safety*' name. Its application is mainly to devices that use or produce significant amounts of power, e.g., motors, generators, transformers, and power distribution equipment, rather than to instruments and control systems. Conceptually, the scheme is similar, but less robust than intrinsic safety, Type 'i' protection. Consequently, unlike intrinsic safety, which can be used in all Zones, Type 'e' protection can be used in all Zones except Zone 0. Rules for constructing Type 'e' equipment are given in IEC 60079-7[75]. In the US, this document has been the basis of ISA S12.16[102], but usage of this means of protection in North America has been limited.

PRESSURIZED ENCLOSURES

In some cases, it is possible to avoid the cost and complexity of intrinsically safe or explosionproof equipment by providing a clean source of purging air for electrical equipment. These are termed pressurized enclosures (or *purged enclosures*) and design details are specified in NFPA 496[103]. Additional guidance is given in ISA RP12.4[104]. The international equivalent is IEC 60079-2[80]. For Group A or Group B gases, the MESG values are so small that it can be difficult to build large explosionproof equipment to the needed tolerances. Consequently, the pressurized option can allow a more economical design.

SEALED, ENCAPSULATED, OIL-IMMERSED, AND POWDER-FILLED DEVICES

Safety of electrical equipment can be ensured by surrounding the electrical parts with a medium through which flame will not propagate. This is more commonly done for small parts than for entire instruments, and is more common in Europe than in North America. In the case of sealed (sometimes called *hermetic sealed*) equipment, a gas-tight physical barrier creates the separation. The nomenclature implies that no gas can pass the barrier, but this, of course, is not true, since even good seals can be slowly permeated by gas. Thus, in principle, such a scheme should not be used in locations where the external gas concentration is always above the LFL, since eventually a flammable concentration could build up inside the encapsulated equipment. Within the US, ISA S12.12[105] describes testing and qualification of sealed equipment; internationally, IEC 60079-15[78] governs sealed equipment.

Encapsulation is very similar to sealing, but denotes that the device is completely potted in compound of very low gas permeability. Internationally, IEC 60079-18[77] governs encapsulated equipment; no comparable standard exists in the US.

Immersing the contacts in oil can also separate an arc from a flammable atmosphere, but this is not true for all oil-filled equipment, some of which are not intended for use in hazardous atmospheres. In the US, UL 698[106] prescribes requirements for oil-immersed equipment. Internationally, IEC 60079-6[79] governs.

Powder-filling with sand, for example, effectively acts as a flame arrester. Internationally, IEC 60079-5[81] governs; its use in the US is not common.

MISCELLANEOUS PROTECTION STRATEGIES

Several additional design strategies are used in Europe and are outlined in IEC 60079-15[78] but are not common in North America. *Enclosed-break* protection is similar to explosionproof design, but with less stringent requirements. *Restricted breathing* protection is of Swiss origin[107] and involves design of equipment to be used in locations where only temporary excursions above the LFL will occur. The principle ensures that gas concentration within the equipment will stay below the LFL during these events.

DESIGN OF EQUIPMENT FOR MINING

Because of historical reasons, most countries have had (and continue to have) different requirements for explosion safety in mining applications than in manufacturing industries. The requirements in the US for 'permissible electrical equipment' are set out by the Mining Safety and Health Administration (MSHA) under Title 30 of the Code of Federal Regulations (CFR). MSHA carries on the system of approving equipment that was previously administered by the Bureau of Mines.

Arc fault and cord fault interrupters

As discussed in Chapter 14, in branch circuit wiring the current flow through an arc fault is unlikely to trip a circuit breaker. Thus, the patent literature contains a wide variety of devices invented to react to an arc fault. By definition, these devices analyze and act upon a signature of the arcing condition that is not simply an over-current. A survey conducted as part of a 1995 UL study[108] identified that at least 16 US patents had been issued for arc fault protection devices up to that time. According to the National Electrical Code, certain circuits will have to be protected by AFCI (arc fault circuit interrupter) devices starting in 2002[109].

Based on the 1995 study, and a 1996 study[110] which examined various non-sinusoidal waveforms associated with normal-use equipment (e.g., welders, motors, lamp dimmers, etc.), UL issued standard UL 1699 on arc fault interrupters in 1999.

The two best-known solutions to the AFCI problem are those by Blades and by Engel. The Blades invention[111] consists of monitoring for radio-frequency noise induced by arcs. A microprocessor-based signal radio-frequency monitoring device receives signals in the range of 1 – 10 MHz. The signal caused by arcing is unique in that it drops to zero 120 times per second, i.e., at every zero crossing of current. The circuit then identifies an arc as present if (a) a strong enough RF signal is present on the power line; and (b) the signal goes to zero 120 times a second. It was found that it is possible to distinguish the arcing signal from solid-state control devices that might also introduce RF into the lines since the latter introduce spikes of much shorter duration than does arcing. The detector can be incorporated into a conventional circuit breaker. But it is also possible to construct a stand-alone, plug-in detector which sounds an alarm upon decoding the arc fault signal.

The Engel et al. invention[112,113], commercialized by Cutler-Hammer/Eaton Corp., was designed to avoid the cost of a microprocessor. It creates a signal which is proportional to a step-increase in current. An analog integrator is used to cumulate this signal so that either one very large step-increase or a rapid succession of smaller ones suffice to trigger the interrupter. The time constants of a circuit of this kind have to be such as not to lead to nuisance tripping when sizable loads go on-line, nor when dimmers or other devices that create abrupt steps in current go into service. Physically, the device is incorporated into a regular molded-case circuit breaker.

In selecting an arcing signature to detect, an arc fault interrupter must avoid false shutdown due to normal-use devices that exhibit unusual voltage or current waveforms. Such devices include switching-mode power supplies and light dimmers[114]. There will be an arc when some devices are turned on or off and a viable AFCI must not be triggered by such benign arcing[115].

An interesting ignition-preventing concept for electric cords has recently been described[116]. In this cord, termed CFCI—Cord Fault Circuit Interrupter—each conductor is separately shielded with a braid over the individual wire insulation. In normal operation, the braid does not carry any current. Current which does start flowing in the braid indicates a fault has developed and an integrated current-sensing device is triggered which interrupts current to the primary conductors. This scheme is similar to the ground fault circuit interrupter which measures the current flowing in the circuit (hot and neutral) and opens the protection device in the event of an imbalance.

Further readings

NFPA publishes a huge variety of Standards, Guides, and Codes offering guidance on preventive measures. AIChE and its subsidiary, Center for Chemical Process Safety, publish a wide variety of material on preventive topics in connection with the design of chemical manufacturing plants.

Wolfgang Bartknecht, **Explosions: Course, Prevention, Protection**, Springer-Verlag, Berlin (1981). Contains a good, wide-ranging presentation of flame arresters.

Ernest C. Magison, **Electrical Instruments in Hazardous Locations**, 4th ed., ISA, Research Triangle Park NC (1998). This is the most comprehensive US monograph on the topic; it is not an introductory tutorial and presumes that the reader is already familiar with most of the concepts.

Peter E. Schram and Mark W. Earley, **Electrical Installations in Hazardous Locations**, 2nd ed., NFPA, Quincy MA (1997). This book is focused primarily on detailed interpretations of NEC requirements for chemical plant engineers.

Alan McMillan, **Electrical Installations in Hazardous Areas**, Butterworth-Heinemann, Oxford, UK (1998). This is similar to Schram's book, but written for the designer needing to understand how to comply with European CEN requirements for hazardous areas.

Wiring Practices for Hazardous (Classified) Locations Instrumentation. Part I: Intrinsic Safety (ANSI/ISA PR12.6), ISA, Research Triangle Park NC (1995).

Explosions in buildings

Building explosions generally occur because an enclosed space was accidentally filled with natural gas (which is primarily methane), LP gas (largely propane), gasoline vapors, or some other flammable gas or vapor. Apart from failures of gas piping (Figure 1) and equipment inside buildings, another way that gas enters buildings is through basements or crawl spaces. It is not even necessary that gas piping be provided into a building for entrance of gas to take place. A number of incidents have been recorded where a gas main in the street develops a leak (due to corrosion, shrinkage during cold weather, construction activities, etc.), it finds its way into buildings then through drainage pipes, cracks in walls, and other existing flow paths[1]. The installation practice whereby the gas supply pipe entered a basement underground was a common source for gas inflow, since an annular void is often present around pipes due to settlement. Thus, once an external leak occurred, a preferred path into the building existed. For this reason, the current practice in the US for gas utility companies is not to pipe directly into buildings underground, but rather to bring out the pipe aboveground and make an aboveground entry into buildings. In climates subject to freezing, gas mains should be laid below the frost line[1].

In order to determine the potential for explosion, the question of whether a flammable gas that has entered a building will form a certain layer, or whether it will be mixed relatively uniformly into the existing atmosphere is of utmost importance. It is an intuitive expectation that if a space is unventilated, has minimal thermal gradients, and a light gas is slowly introduced at the top, it will stay as a layer at the top. Similarly, if a heavy gas is introduced at the bottom, layering might also be expected. Since the molar mass of air is 28.96, methane (W = 16) is lighter than air and propane (W = 44) is heavier. Gasoline has a wide variety of constituents, but a value of W ≈ 100 to 105 is normally taken, thus its vapors are much heavier than air. Unfortunately, things quickly become non-simple (and possibly unintuitive) since it takes very little—under some circumstances—

Figure 1 Effects of a massive explosion in a New York high-rise building due to a break in a gas pipe which filled elevator shafts with natural gas[4]
(Photo: NTSB)

to stir and mix the volume. If the fuel gas is introduced with a finite flow velocity, this velocity alone may act to stir the volume of the space. The stirring may be mechanical, for instance, with an HVAC system. Persons walking around also stir air mechanically. But stirring can be done by thermal means, too. Heaters of all sorts will create a rising gas plume above it. The plume entrains air and thereby creates a convective current helping to stir up the environment. Even a very small object such as a gas pilot light will create a plume above and stir the air. The sun shining through a window will create large temperature differences as can cold walls or infiltration from wind blowing on the structure. The heat of a body and breathing can be adequate to mix a small volume, such as within a camper vehicle. Also, buoyancy can be created by density differences alone, temperature gradients are not necessarily required. Releasing a lighter-than-air gas at some non-zero height below the top of the room, or a heavier-than-air gas at some non-zero height above the floor intrinsically sets up convective flows within the room, which help to mix the space[2]. A very important rule is that: *Once mixed, gases do not separate out, even if they are of widely different densities*[3].

A number of experimental studies exist on the topic, but they may not necessarily cover the circumstances of interest to the user. The experimental studies can be grouped into ones using carefully constructed test enclosures that were maintained at uniform temperature, versus real-house experiments. In experiments of the former type, when a lighter-than-air gas is released with negligible velocity at ceiling level, it is normally found experimentally to stay in a layer predominantly at the ceiling level. Conversely, a heavier-than-air gas, if released at floor level, will stay predominantly at floor level. In one study[5], gases were introduced into a 5 × 5 × 6 m high room at very low velocities. For methane introduced at ceiling level at a rate of 0.5 m^3 h^{-1}, even 1.5 h later there was negligible concentration at 1 m below the ceiling. A rather similar result was found for propane introduced slowly at floor level.

Harris[3] conducted experiments where natural gas was introduced into a room which was sealed except for a tiny pressure-relief opening. Figure 2 shows typical results for a leak near the ceiling, which suggest that the concentrations are grouped into 3 zones: Above the position of the leak, there is a zone of nearly-uniform concentration, but below the leak there are two zones: a transition zone and a near-ambient-concentration zone. Harris also showed that better mixing and a deeper ceiling layer occur if the leak's velocity is directed downwards, rather than horizontally or upwards.

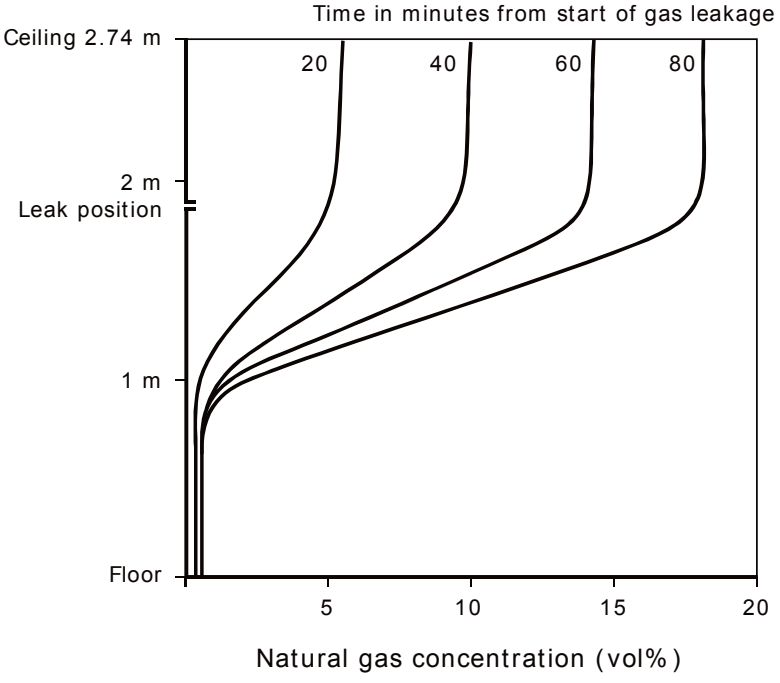

Figure 2 Layering of natural gas in a room with no ventilation (leak near ceiling)

Ventilation, if present, will change the layering of gases. In further tests, Harris explored various ventilation patterns and found that, for natural gas leaks, conditions where air inflow was at the bottom and outflow at the top led to thinnest ceiling layers and the lowest gas concentrations therein. The converse (in at the top, out at the bottom) led to the worst conditions, while various other patterns (e.g., in one side, out the other) led to intermediate results. In practice, of course, unless powerful ventilating systems exist, flows will be created by an interplay between leakage areas and temperatures.

Clodic[6] created leaks of propane and isobutane in a 16 m^3 room and found generally the inverse of the natural-gas results. Leaks created near floor level led to strong concentrations of gas near floor level, while leaks higher in the room resulted in much less steep concentration gradients. Fletcher and Johnson[2] released CO_2 gas into a 3.45 × 3.56 × 2.95 m high unventilated enclosure. This gas is heavier than air and will behave similarly, at least in a qualitative sense, as a release of propane. Figure 3 shows that a two-zone representation is approximately correct—most of the CO_2 remains below the point of discharge and is relatively uniformly mixed in that zone. Above the point of discharge there is only a small concentration found. The authors also conducted several experiments with mechanical ventilation present in the enclosure, but it is harder to capture general trends from these experiments.

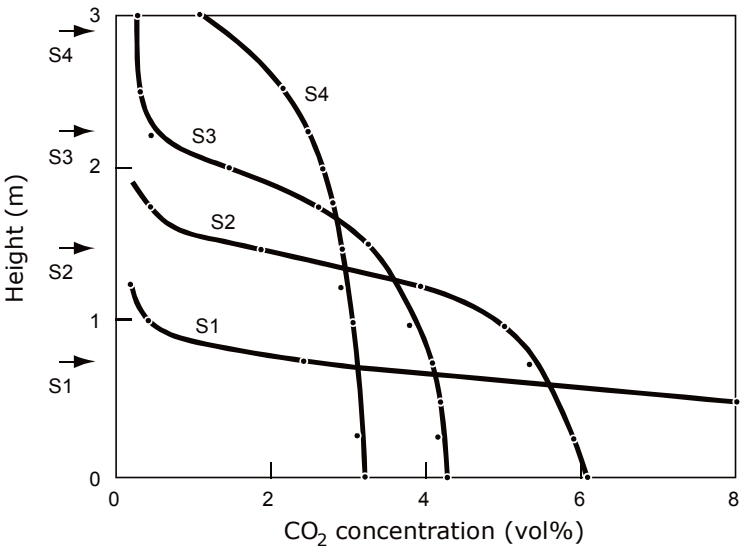

Figure 3 Room concentrations found 1 h after start of CO_2 release at a rate of 15 L min^{-1}. Four different source locations, marked as S1 – S4, were used.
(Copyright Elsevier Science, used by permission)

Very different results from the preceding have been obtained by researchers conducting *whole-house tests*. Weckman[7] created several basement leak scenarios and measured methane concentrations throughout the house. Mixing was nearly complete and only very modest evidence of layering was found, with concentrations at basement floor level being just slightly lower than at ceiling height. Experiments of using natural window ventilation to clear the gas were also performed. The results varied according to wind conditions, but it was found to be quite difficult to clear dead spaces and volumes near ceiling level. Weckman's results, even though limited, are of significant importance, since they point out that houses are generally leaky and are unlikely to be environments of uniform temperature. Essentially the same results were obtained by UL[8] who released propane into a small, unventilated building and found that uniform mixing rather than layering occurred. Existing temperature gradients were apparently sufficient to result in thorough mixing of the volume.

The only type of gas-filling problem that can readily be solved in closed form is one where the volume is assumed to be perfectly stirred and the ventilation (air flow rate), if any, is known. This problem is the standard 'single-compartment model,' as it is known in toxicology. If F_g = inflow rate of fuel gas (m^3 s^{-1}), F_a = ventilation rate (m^3 s^{-1}), V = volume of space (m^3), and t = time (s), then the concentration of fuel gas C (vol%) at any time t after filling has started is:

$$C(t) = \frac{F_g}{F_a + F_g}\left[1 - e^{-\left(F_a+F_g\right)t/V}\right] \times 100$$

Since laboratory experiments described above show a 2- or 3-zone behavior, with significant concentrations present only below the point of discharge for propane (and above the point of discharge for methane), Lapina and Sokalski[9] suggested that the filling with propane be modeled by perfect mixing, but only in the partial volume from the height of the floor up to the leak (or up to the ignition source, if the latter is higher). This is a reasonable strategy for representing the laboratory experiments, however, the few available whole-house experiments suggest that such layering will not happen. Instead, the whole space may have to be treated as a single mixed zone. Cleaver et al.[10] described a more sophisticated 3-zone model, however, no closed-form solutions were provided.

In some cases, a *pocket* of flammable fuel/air mixture may be formed within a larger space. This could be in the early stages of a leak or even much later, if a semi-enclosed volume exists where ventilation by diffusion and convection is poor. Bodurtha[11] suggests that these cases be treated conservatively by assuming that the flammable gas is in a pocket which is uniformly at its stoichiometric fuel/air ratio. Upon ignition, pressure in the pocket will rise to 7 – 8 atm*, and this will then be equilibrated with the rest of the volume. The Bodurtha concept can be visualized as the

* Although if there are numerous partial separations and encumbrances in the volume, *pressure piling* may greatly raise the actual pressures, and the possibility of this must be considered.

explosion of a balloon filled with the specified uniform mixture. But in any actual release of flammable gas, a fraction of gas will be unable to participate in the initial explosion, since not only will it not be at the stoichiometric concentration, but it will be at a location where the concentration is well outside the flammability limits. Thus, the scheme is quite conservative. Nonetheless, a more-conservative-yet scheme was put forth by Ogle[12], but experimental data are lacking that might validate any of these schemes.

Apart from real-house tests and tests within highly-controlled room enclosures, the cylinder geometry has been studied. Valentine and Moore[13] conducted a theoretical study, augmented by experiments where propane was admitted at the bottom of a 2.5 m high cylinder. In one experiment, where they discharged propane at a rate of 0.135 g s^{-1} m^{-2}, at the end of two hours the concentration at floor level was 92%, at 1 m height it was 10%, and at 1.3 m it was at approximately the LFL of 2.2%. Beyond 1.3 m, there was zero detectable concentration of propane. For a smaller filling rate of 0.02 g s^{-1} m^{-2} and a longer filling time of 4 hours, the concentration was 35% at the floor, 2.4% at 1 m, 2.2% at 1.1 m, and zero concentration above 1.3 m. Apart from providing computed and experimental results, the authors did not offer a general prediction scheme.

Diffusion of flammable vapors from spills

The evaporation of liquid fuel spills is a question of great practical importance, both in arson investigations and for certain accidental fires. Under quiescent conditions, with no convective currents, the diffusion of liquid-fuel vapors through air is extremely slow. Liebman et al.[14] demonstrated this in a 200 mm diameter open-top beaker holding gasoline—it took 25 min for the LFL to be reached at 130 mm above the liquid surface. Perhaps surprisingly, they also found that if large petroleum tanks are loaded slowly, then the height of the flammable region does not rise rapidly above the surface of the liquid; this appears to be in contrast to experiments in small tanks, where the contents get stirred relatively quickly. Similarly, Steen[15] reports that, in the absence of wind, butane and propane spills lead to laminar spreading velocities of less than 0.1 m s^{-1}. Another illustration of the extremely slow pace of processes governed by diffusion, without air movement induced by wind or convection, comes from Médard[16] who reports an incident where a hydrogen cylinder was emptied (down to 1 atm), the valve was unscrewed, and the tank left standing, with the top open, for one week. Since hydrogen is some 14 times lighter than air, the expectation was that all of the gas would diffuse out. At the end of that time period, a worker lowered a miniature light bulb into the tank for inspection. The light bulb broke while swinging against the metal and a small explosion ensued, indicating that the tank was not free of hydrogen. Had there been another opening in the bottom, so that a convective through-flow were possible, the hydrogen would undoubtedly not have remained.

When wind, convective currents, movement of persons, or other factors exist that can stir the air space, mixing may be pronounced and vapors may travel large distances. A strikingly long travel distance of gasoline vapors has been reported[17] when a woman cooking at her stove suddenly became enveloped in flames. It turns out that an individual was washing gasoline cans some 90 m away, and sufficient vapors were able to drift to the location where they could be ignited from the flames on the stove. Cooper[18] reports an incident where "Methylated-spirit vapour from a vessel of moderate capacity is believed to have been ignited at a cottage fireplace several hundred yards away." The pilot lights on water heaters sometimes ignite vapors when gasoline has been spilled in the vicinity. This topic is discussed in Chapter 14 under *Water heaters*. Experience indicates that raising the height of this potential ignition source is a useful, but not foolproof, safety strategy. Vigorous stirring can produce a flammable concentration with certain spills even if the water heater has been raised the recommended distance (0.457 m) off the floor.

Because of the complexity of the problem, modeling cannot yet provide practical guidance, even though several models have been presented. The British Government[19] proposed a simple method whereby the liquid vaporizes at a finite rate, but the entire volume is assumed to be fully-mixed. It is assumed that a fraction n of the floor area is covered by the spilled liquid and that the liquid evaporates at a rate $\dot{m}''$ (g m^{-2} s^{-1}). If the LFL of the liquid, expressed on a mass basis, is c (g m^{-3}), then the time for the room volume to reach the LFL is:

$$t = \frac{Vc}{\dot{m}''nA}$$

where V = volume (m^3) and A = area (m^2). But the latter two variables can be eliminated and replaced by the room height h (m):

$$t = \frac{hc}{\dot{m}''n}$$

The evaporation rate, in turn, depends on the local wind speed and on the turbulence; in addition, the evaporation rate is not independent of the spill area but, rather, decreases somewhat for larger areas. The authors suggested that c = 47 g m^{-3} be used as the LFL for gasoline and that very limited, unpublished data for evaporation of gasoline show $\dot{m}''$ = 0.14 to 0.25 g m^{-2} s^{-1}. Unfortunately, the fully-mixed assumption is unconservative, unless the ignition source is located at the ceiling. A flammable region will form at the lower portion of the room much earlier than the average concentration of a full-stirred volume would reach the LFL. The authors also proposed another simple, fully-mixed model for a room that has forced ventilation. In that case, the LFL will never be reached if at least the following ventilation rate is provided:

$$\dot{V} = \frac{\dot{m}''}{c}$$

where $\dot{V}$ = ventilation rate (m^3 air, per second, per m^2 of spill area).

The next more complex treatment considers that the problem resembles that of an open-top beaker which contains an amount of liquid on the bottom. The beaker sits in an environment where the atmosphere to which the top is open is continuously swept away, so the concentration of the liquid's vapor at the top of the beaker is always forced to be zero. This is sometimes known as the Stefan problem and Munoz-Candelario and Alvares[20] applied it to the case of the liquid spill. By simplification of the basic diffusion equation, they evolved the expression:

$$\left(\frac{1-X_A}{1-X_{A0}}\right) = \left(\frac{1}{1-X_{A0}}\right)^{z/h}$$

where X_{A0} = mole concentration of vapors at the surface of the pool, X_A = mole concentration of vapors at height z, and h = height of room (m). Commonly, the question to be answered is whether the vapors have or have not attained the LFL at a certain height where an ignition source is present. Thus, the value of X_A which is of main interest is the value that corresponds to the LFL; to obtain X_A (mole fraction) from a published value of LFL (vol%), simply divide by 100. Despite the fact that a simple solution can be obtained, it is not evident that conditions in real rooms will resemble the assumptions that are needed to be made to produce a tractable solution. In addition, the necessary input data may not be readily obtainable. For a pure substance, e.g., acetone, the value of X_{A0} can easily be obtained from the Clapeyron equation for vapor pressure, as discussed in Chapter 6. Gasoline, kerosene, and other substances which are mixtures, however, do not have a time-independent vapor-pressure/temperature relation, since lighter fractions evaporate first. This means that the flammable region from a spill of these liquids first expands, then contracts, as the lighter fractions are lost. An equation of the kind used by Munoz-Candelario could still be applied if experimental data for the initial (non-aged) vapor pressure of the fuel were available, but this may require special testing. Same as with the British model, no experimental evaporation data for real rooms were offered by the authors to validate their model. Tamanini[21,22] provided a model of greater complexity, where evaporation from a spill in a room under still-air conditions was computed. Despite drastic simplifications, the model is complicated to use and its validity has been examined only to a very limited extent.

Real spills will typically present an intractable problem, since they are unlikely to be symmetric, be exposed to a constant wind speed, be located in a room of a simple, symmetrical geometry, etc. Thus, it must be concluded that at the present time there do not exist methods which allow a reliable estimation to be made of the fuel vapor concentration that develops above a spill. In addition, all models such as discussed above need data (or a sub-model) to quantify the liquid's evaporation rate. Numerous theories[23-28] for this have been proposed, but none have been adequately validated against data of practical interest, e.g., gasoline spills of a practical sizes. Even if a validated theory were available, application would not be easy, due to reasons such as effects of substrate and lack of detailed knowledge of wind velocities. Neither can needed evaporation data be expected to be available from empirical studies, because the latter have been extremely limited for substances of practical concern. Apart from the British study mentioned above, more recently DeHaan[29] studied the gasoline evaporation rate for a single 0.15 m diameter pool and found an initial rate of 2.4 g m^{-2} s^{-1}, decreasing to half that value in about 6 minutes. His finding does not necessarily conflict with the British results, since the per-unit-area evaporation rate decreases with increasing pool diameter and the British results were evidently for much large spills, although the diameter was not specified. In addition, heat losses to a concrete floor would be greater than to DeHaan's insulated glass dish. For camping fuel tested under the same conditions, DeHaan found a rate of about 0.5 g m^{-2} s^{-1}. DeHaan also studied pure pentane pools and found a large decrease in evaporation rate with increasing diameter, but not enough data points were available to justify a quantitative fit. Mackay and Matsugu[30] reported some limited data on evaporation of gasoline from a deep, square pool of 1.22 m dimension. Over the first 10 minutes, evaporation rate was about 3.7 g m^{-2} s^{-1} under unspecified wind conditions. Some indirect conclusions may also be drawn from test data[31] on square, insulated pools of 1.22 m dimension where butane was evaporated. For nearly-still conditions, a rate of 2.0 g m^{-2} s^{-1} was found; this increased to 7 – 8 g m^{-2} s^{-1} in a wind of 5.5 m s^{-1}. Under nearly-still conditions, Lennert[32] found an evaporation rate of 0.4 g m^{-2} s^{-1} from an 0.2 m diameter pool of methyl ethyl ketone. The vapor pressures at 20ºC of these pure liquids are: butane 207 kPa, pentane 59 kPa, MEK 9.7 kPa. As discussed in Chapter 14, the vapor pressure of gasoline is in the range 62 – 108 kPa.

Wren and Martin[33] used a complex calculational model to predict gasoline evaporation rates (but not the concentration of vapors above the pool) for pools for several sizes. For a circular pool of 2 m diameter, they predicted an evaporation rate of 7 g m^{-2} s^{-1}, while for pools of 40 – 80 m diameter, a rate of 9 g m^{-2} s^{-1} was predicted. But since this effort was not accompanied by large-scale validation experiments with gasoline pools, reliance cannot be placed on such computational results.

The above studies show values for the evaporation rate of gasoline that span a range of more than 60 : 1. Some of the differences (e.g., due to pool size or wind conditions) are clearly due to physical environment differences, but nonetheless it must be concluded that credible guidance is currently unavailable. In turn, if the basic evaporation rate is

unknown, then calculational schemes for obtaining vapor concentrations cannot be successful.

Ignition of gas jets from broken pipes

If a pipe carrying a fuel gas at a reasonably high pressure suffers a break, a high velocity jet will be discharged into the atmosphere. Near the mouth, the fuel concentration will be nearly 100% while far downstream it will reach negligible values. In between lies a flammable region. Smith et al.[34] studied the ignitable regions for jets of several fuel gases discharged vertically up into the atmosphere. They concluded that, at the jet centerline, the probability of ignition falls to zero at the height where the mean concentration has fallen to about ½ of the LFL. Ignitions of a free jet are not necessarily sustained, in that the flame may extinguish by blowing off. The height beyond which a flame will blow off was found to correspond to the height of the LFL.

Damages and ignitions from gas explosions

It has sometimes been hypothesized that lighter-than-air gases, layering near the ceiling, will cause more damage at ceiling height and that, similarly, heavier-than-air gases will cause more damage at floor level. In a series of large-scale tests, DeHaan et al.[35] demonstrated that this is not true. The pressures were nearly equal throughout the compartment and greater structural damage would occur in places where the construction was weaker, not in places where the fuel gas was originally localized. Color Plate 38 illustrates this phenomenon from another experimental program on this topic that was conducted in Canada.

When a gas explosion occurs, it is usually accompanied by a fireball. Whether the event leads to a sustained fire depends on the nature of the combustibles present. Because high temperatures occur only briefly during a gas explosion, direct ignition of thermally thick materials is not to be expected. But ignition of lightweight 'kindling,' such as lint, clothing, hair and paper is possible. Ignition of heavy materials and structural components can then occur if there is a chain of kindling fuels (Color Plate 37).

The problem was studied in small-scale by Hagimoto et al.[36], who used a cubical chamber of 0.3 × 0.3 × 0.3 m size. In the first series of experiments, they closed the top and bottom of the chamber with brass plates, but the remaining four sides comprised a thin film held on with grease. Test specimens were sited parallel to the floor and ceiling and at various distances away from the metal surface of the chamber. The following specimens were used: polyethylene film (10 mm × 50 mm × 20 μm); paper (10 mm × 50 mm × 90 μm); cotton fabric (10 mm × 50 mm); and PVC insulation from an electric 'zip cord' (50 mm long). Ignition was with a 1 J spark at the center of the chamber. Table 1 shows the results. They indicate that it is easier to ignite specimens from explosions of mixtures that are near-limit, rather than close to stoichiometric. This is not surprising, in view of slower flame speeds and therefore longer flame contact times. It was also clear that locations near the center of the chamber are more susceptible to ignition than those close to the boundaries, and that it is easier to ignite materials near the ceiling than near the floor.

The authors then did experiments in a similar chamber, but with all 6 sides comprised only of thin film. Tubular rings of paper (130 mm diameter, 10 mm length, 90 and 250 μm thick) placed at the center of the chamber were the ignition targets. In those experiments, it was found that ignition of the paper targets took place at about the time that the flame died out, with shortest ignition times found for mixtures near stoichiometric. For a stoichiometric mixture, flame velocities around 3 m s^{-1} were observed and flame duration

times ca. 0.3 s. Mixtures close to the flammability limits showed velocities ca. 1 m s^{-1} and flame duration times of up to 2.5 s. The thicker paper samples only ignited at gas concentrations near the flammability limits; specimens exposed to near-stoichiometric explosions charred but did not flame.

It is often proposed that an explosion of a fuel-rich mixture is more likely to lead to a serious fire than is a fuel-lean explosion. Hagimoto's data provides only limited support to this notion—the results for PE film do show distinctly more combustion under fuel-rich conditions, but for the other targets it appears that while ignitions are more common in near-limit mixtures, there is not much difference between lean-limit and rich-limit conditions.

A limited amount of data is available from a series of Canadian house explosion tests[37,38]. The experiments showed that the flash fire generates peak heat flux values of up to 230 kW m^{-2}, but in about 2 s the value declines to half that and the fireball is gone in about 6 s (Figure 4). Since the duration is so short and since many locations will receive much less than the maximum flux, it was found experimentally that substantial amounts of fuel can remain unignited. Generally, it was found that only 'spot fires' were present after a test explosion. Upholstered furniture was commonly the item ignited, and this may be due to gas mixtures being trapped within the foam. The organizers concluded, however, that the limited ignitions were not particularly representative of the post-explosion fires that are typically encountered by firefighters.

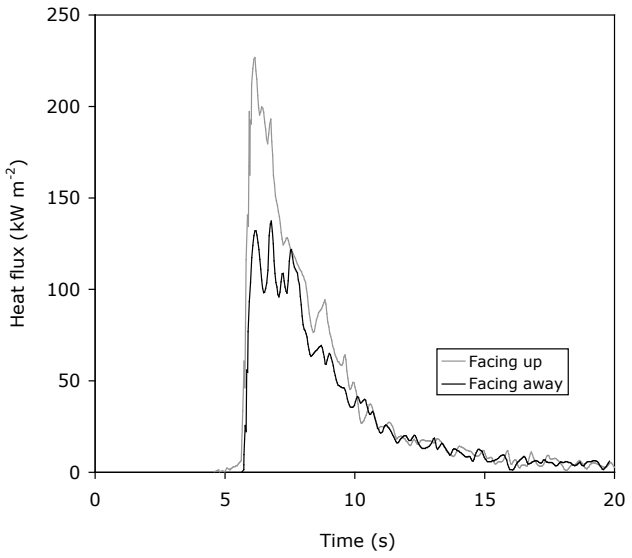

Figure 4 Heat fluxes measured at two sensors in a full-scale experimental natural gas explosion

Ignition in room fires

The question often arises in fire investigations as to what the maximum temperature is that can be expected in room fires. The temperature of a post-flashover room fire is over 600ºC, thus, the ignition temperature of most organic materials will be exceeded in a post-flashover fire. But the question is germane for some hard-to-ignite materials, e.g., metals, which may require a higher temperature for ignition. The adiabatic flame temperature of most common organic materials burning in air is roughly 1900 – 2000ºC. Such high temperatures are approached only in special research burners. In a room fire, much lower temperatures are registered, primarily for three reasons:

(1) The flames are turbulent; consequently the temperature recorded by a thermocouple is an average of reacting flame zones and unreacting 'packets' of air or combustion products.
(2) The combustion is incomplete, with CO, unburned hydrocarbons, and soot being some of the combustion products, not just CO_2 and H_2O; this lowers the temperature.
(3) Radiative losses may be sizable.

Full-scale room fire tests[39] indicate that the peak temperatures in a post-flashover room fire are typically 900 – 1100ºC. Copper electrical wires (T_{mp} 1085ºC) are rarely found bulk-melted (i.e., in areas unassociated with electrical arcing activities) in room fires. It has been reported that some very limited melting of steel (T_{mp} 1350 – 1450ºC) has occasionally been observed in room fires[40], but the caution is also given that reliable determination of whether or not melting or eutectic damage exists needs to be established by metallographic examination with microscopy. Much higher flame temperatures can be attained in the presence of pure oxygen as the oxidizer, or in fires involving exotic fuels (e.g., metals), certain oxidizers, or explosives, although fires with these substances are relatively rare.

The ignition of a second (or subsequent) item from a burning object in a room can occur from direct flame contact or by radiant energy. In the former case, the objects need to be spaced close enough together for such flame contact to occur (maybe < 0.3 m apart). In the latter case, the radiation comes from the flame above the burning object, the hot upper layer in the room, and from the bounding surfaces of the room (ceiling and walls). In hazard analysis calculations, it is most common to only use piloted ignition data, as one cannot be sure that flying brands or other sources of piloting will be absent. For analyzing specific fires which have taken place, judgment should be used as to whether localized sources of ignition could or could not have been present.

For the case of direct flame contact, the ignition time of the second item can be assumed to be the time at which contact occurs. (This assumption is conservative since time is required to pyrolyze fuel and heat the gases produced to their ignition temperature.) For radiant ignition, a simple assumption is that prior to flashover, the radiation from the upper layer and the room surfaces are negligible. Thus, the radiant energy transfer to the surface of the second item all comes from the flame above the first item. Based on this

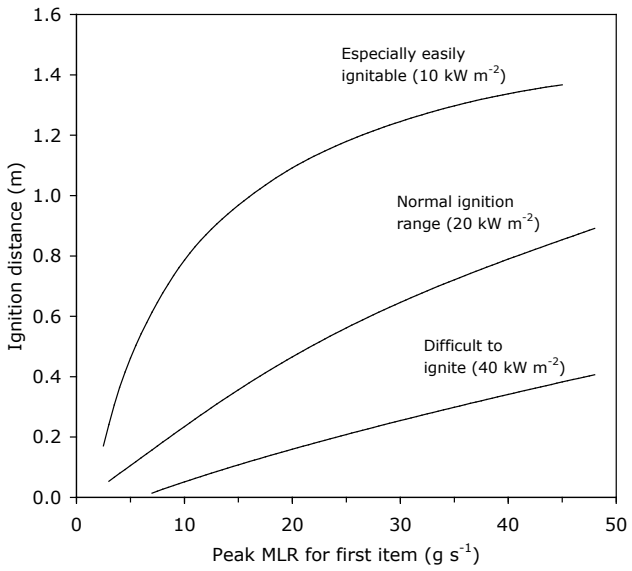

Figure 5 Maximum expected ignition distance for combustibles having various values of minimum flux for ignition, as a function of the mass loss rate of the first burning item

assumption, some years ago Babrauskas[41] developed a procedure for estimating the ignition of the second item. Radiant heat flux values at various distances were obtained as a function of the mass loss rate (MLR) of the first-ignited object. Figure 5 shows results plotted for three values of $\dot{q}''_{\min}$ for the target object (#2 object): 10, 20, and 40 kW m^{-2}. For this purpose, $\dot{q}''_{\min}$ values should be used for a relatively short exposure time, typically 5 minutes or less, since most furniture items do not burn near their peak intensity for longer than that. Curiously, a better fit was found using MLR rather than the HRR of the #1 item; the reason for this is not clear. This estimating procedure is quite conservative, since peak intensity will normally be exhibited only for a short time, and the rest of the time the burning of item #1 will proceed at a slower rate.

A refined strategy is to consider the summation of radiation coming from item #1 and from the room radiation. This is practical to do only in the context of a computer program for computing the time history of a room fire. An example of one way to do the summation has been given by Peacock et al[42]. Once flashover occurs, all remaining combustible items in the room are considered to ignite simultaneously.

UPPER LAYER IGNITION IN ROOM FIRES

In some cases of fire development in rooms, 'flame rollover' is observed. This is a process that can happen (but does not necessarily happen in every fire) if the fuels that burn are located low in the room and their flames are of insufficient height to directly extend to the vicinity of the ceiling. Most fuels in a room fire will burn incompletely, causing a certain amount of heated, unburned, combustible gases to accumulate in a layer below the ceiling. Eventually, the gases in this layer may ignite—this process is termed 'rollover.' If rollover occurs, it is necessarily before flashover, since flashover means not only that the upper layer is ignited and burning, but that it has descended a substantial fraction of the room height below the ceiling. Some room burn tests conducted by DeHaan[43] showed that ignition of the hot gas layer occurred at roughly 500 – 700ºC. Since 600ºC is often taken as the nominal temperature at flashover, it is not surprising that rollover generally preceded flashover by only a brief instant.

Because of the scarcity of controlled experimental studies, details of the rollover process are not well understood. Even the basic question as to whether the process is one of autoignition, or piloted ignition, or either, remains to be answered. Piloted ignition, by the way, might be envisioned as occurring through a flame packet which travels into the upper gas layer. Beyler[44] attempted to quantify the conditions for ignition of the upper gas layer on the assumption that the ignition is piloted. He conducted some small-scale experiments using gaseous and liquid (but not solid) fuels and, based on their results, concluded that Le Chatelier's Rule for flammability of mixtures, along with a temperature dependence of the LFL, as expressed by the Burgess-Wheeler law were sufficient to characterize the ignitability. The actual combustible gas concentrations would rarely be known in practice. What may be possible to compute is the equivalence ratio φ pertinent to the lower-layer burning. If φ is high enough and the upper-layer temperature is also high enough, then ignition may occur. His relation for the minimum value of $\varphi_{\min}$ at which ignition can occur is:

$$\varphi_{\min} = \frac{K}{K - \frac{1}{r} - 1}$$

where

$$K = \frac{2800}{(T_L - T)}$$

r = stoichiometric air/fuel mass ratio (--) for the lower-layer combustion, T_L = adiabatic flame temperature at the LFL (ºC), and T = actual temperature of the upper gas layer (ºC). For this purpose, Beyler suggests using T_L = 1427ºC. Also, usually $r >> 1$, so its contribution may then be ignored in the expression for $\varphi_{\min}$.

Sherman[45] attempted to construct a mathematical model for rollover by incorporating Beyler's results into a two-zone room fire model. A two-zone model, by definition, assumes that the temperature of the hot gases in the upper layer is identical throughout and that there are no variations in concentration of anything. Based on experimental observations of the process in actual rooms[43], it does not appear that uniformity of the upper layer is a good assumption. The effect is rapid, transient, and non-equilibrated; most commonly it appears in the form of an expanding fireball. Thus, while the rollover process should certainly be amenable to mathematical modeling, a more sophisticated model will be

needed if experimentally-observed phenomena are to be reproduced.

Backdrafts and smoke explosions

NFPA 921[46] defines backdraft as "An explosion occurring from the sudden introduction of air into a confined space containing oxygen-deficient superheated products of incomplete combustion." According to NFPA 921, the term 'smoke explosion' is synonymous to 'backdraft,' however, some authors[47] recognize it as a more general term. One way that a smoke explosion can occur is if a smoldering fire releases significant amounts of unburned pyrolysates, which accumulate in the upper portions of the room, but cannot burn there due to low temperatures and an absence of overt ignition source. If the gas layer is within the flammability limits and it descends low enough to encounter a local ignition source, an explosion may result. The term 'gas explosion' is normally reserved for situations where the combustible gas involved is not the unburned pyrolysate of an ongoing combustion. Furthermore, while NFPA 921 limits the backdraft definition to explosions, sudden-combustion events which do not produce a loud report can occur with products of incomplete combustion. The latter have not been studied extensively, however simple room geometries leading to explosive backdrafts have been studied experimentally in some detail[48,49]. Croft[47] has reviewed case histories of backdrafts and smoke explosions; Dunn[50] discusses several cases from a firefighter's viewpoint. Weng and Fan[51] proposed a theoretical model for backdrafts, but have not attempted to validate it with experimental data.

Experimentally, it is very easy to create a backdraft[52,53] by constructing a well-insulated compartment where sizable surfaces of cellulosic materials are burned. There is a door opening, but once the compartment has gotten quite hot, the door is shut. The oxygen level drops and combustion largely ceases, although active pyrolysis (and generation of unburned flammable vapors) continues due to the high temperatures. The door is then quickly opened and a short while later an explosion is heard and a fireball is seen rolling out. Once the door is opened, mixing occurs due to the 'gravity current' which develops as a consequence of the difference in density between the heated gases and the cold incoming air. No ignition source is normally necessary, since it is common for the hot gas layer to be above the AIT of the pyrolysis gases. Backdrafts are facilitated if a combustible ceiling is present, since uncombusted fuel can more readily be accumulated at ceiling level in such cases; saunas are particularly susceptible to this[54]. Color Plate 42 illustrates the fireball from a backdraft created in large-scale experimental studies.

When a backdraft does occur, part of the danger is because there is a substantial delay (typically about 15 s) between opening the door and the time when an explosion propels a large fireball out the opening. This can create a false sense of security to individuals approaching the doorway. It appears that the main variable governing whether or not a backdraft will occur under the conditions described is a presence of a specific amount of fuel vapors in the room. In small-scale tests with methane, Fleischmann et al.[48] experimentally determined that a minimum of 0.10 mass fraction (20 vol%), unburned methane needed to be present in a compartment for backdraft to occur. In a larger-scale follow-on study, Bolliger[55] determined that a mass fraction of methane over 0.15 was needed for a backdraft to be possible. Methane has a combustion chemistry dissimilar to other gases, however, so these results would not necessarily apply to pyrolysis gases of solid or liquid fuels, which rarely contain a significant methane component. Thus, possibly more direct guidance can be taken from the work of Gottuk et al.[49], who determined that for diesel fuel, a mass fraction of 0.16 or more was needed for a backdraft to occur.

While most backdrafts involve a fire where the ventilation conditions were changed at a certain time, studies indicate that opening or closing of doors is *not* necessary, but that simply burning under very poor ventilation conditions can suffice. Sutherland[56] studied smoke explosions in a model scale room where wood cribs were burned under very highly vitiated conditions but the room ventilation was not changed during test. Smoke explosions occurred unpredictably 0, 1, or 2 times during a room fire. By making gas chromatographic measurements of gas samples, Sutherland concluded that the primary fuel for the smoke explosions was unburned hydrocarbons and not CO. He also observed that the process was a direct consequence of *puffing combustion*. Puffing combustion describes burning which periodically oscillates between active combustion inside the room and rapid, vigorous ejection of flames or combustion products; it is a symptom of highly oxygen-starved conditions. Fires exhibiting reasonably steady burning did not involve smoke explosions. The puffing was understood to first extinguish local flaming, leaving a hot fuel surface, and then to bring in fresh oxygen into the volume. A peak pressure of 2.5 kPa occurred in his experiments; this is large compared to pressures in normal fires (around 10 Pa), but much smaller than pressures associated with gas explosions (around 1 MPa). Rather similar experiments were made by Hayasaka et al.[57] They used wood cribs and a wood wall in a model-scale room having a small ventilation opening of 0.20 × 0.24 m at the center of a 0.82 × 0.85 m wall. In a typical experiment, the fire burned in a flaming manner for about 10 min until oxygen concentration near the ceiling (Figure 6) dropped to a very low value. At that point, the fire became a *ghosting* fire for a short while. A ghosting fire is a thin fire of low luminosity that wanders around the room and is not anchored to the fuel bed. At 13 min, the ghosting fire extinguished and the wood only smoldered. Oxygen levels somewhat recovered during this phase. At somewhat over 23 min, the first backdraft occurred, followed by a second and a third. During a backdraft, the fireball originated near the ceiling (Color Plate

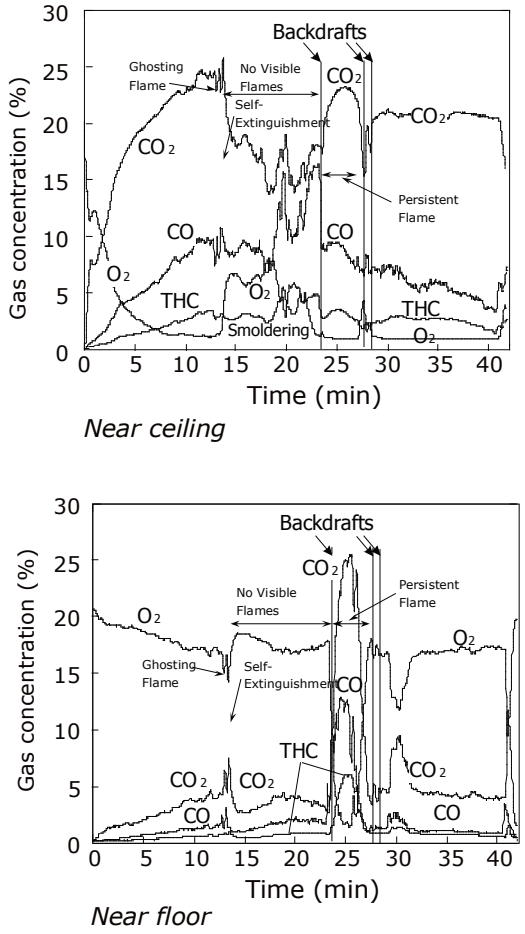

Figure 6 Gas concentrations in the backdraft experiment of Hayasaka et al.

39) and roughly at the center of the compartment, rapidly spreading to the floor and to the ventilation opening.

Chitty[58] studied numerous backdraft incidents and concluded that the following are warning signs of backdraft:

- a fire in a compartment having few openings
- pulsating smoke from openings
- blue flame in the hot gas layer
- roaring or whistling noises
- sudden reversal of smoke flow
- oily deposits on windows (although this is quite common in fires in general).

Backdrafts can occur due to improper firefighting operations. These include use positive-pressure ventilation under inappropriate circumstances[59] and improper roof ventilation. If holes are cut in a roof to ventilate a fire taking place underneath the roof, with sloped roofs care should be taken to cut the openings at the top of the roof. In one case, two backdrafts occurred when the ventilation opening was improperly cut on a lower part of the roof[60].

Color Plate 40 shows a smoke explosion that occurred in a pellet stove. The explosion blew out the glass front which was propelled over 10 m. through a house, and a portion of it penetrated the victim's stomach. The stove was a sealed-combustion system, which employed an air-intake tube that was routed up through the chimney and terminated in open air at the chimney-top level. This is design feature which allows for a counterflow heat-exchanger action between the combustion products and the incoming air. It also creates a system which does not have a pressure differential with regards to atmospheric conditions. The explosion occurred because the air intake tube within the chimney broke and separated, leading to recirculation of combustion products back into the stove.

A smoke explosion that took place in a fireplace is shown in Color Plate 41. It was caused by improperly installing a wood stove by venting it into a large, blocked-off fireplace rather than directly into the chimney.

Rekindle ignitions

A rekindle occurs when a fire has been suppressed to the point of no visible flames, yet later re-erupts in flaming. Why do rekindles occur? To investigate this, it is important to understand what happens when water is applied to a fire. Water may be applied in two ways: (1) as a solid stream, hitting a burning surface, cooling it, and possibly leaving a film of water on it; or (2) as a fog stream, introducing small droplets into the air, which then evaporate and consequently extract heat from the hot gases. Flaming stops when the gas temperature drops below the minimum at which combustion can be sustained. If only the gas-phase cooling were done, then flaming would likely re-erupt very quickly upon stopping the fog stream. This will occur if the burning material is still above its fire point. If the water-vapor laden gases serving as a heat sink are convected out faster than the surface can cool below the fire point, re-ignition will take place. Liquid pools, because of their high thermal inertia, do not cool quickly, thus they may often re-erupt if extinguished only in the gas phase (in practice, restricting oxygen availability to the pool through use of long-lasting foam is a more effective tactic than attempting to cool down the bulk of the liquid).

But if the burning object was extinguished by literally dousing its surface in water, and assuming the fire point is above 100ºC, how can it rekindle? There are several mechanisms. If the mass and heat capacity of an inert object are high, and the surface is abruptly cooled off, the interior portions do not drop in temperature to nearly that level. Thus, once the agent cooling the surface is gone, heat moves back from the center to the periphery, and the surface temperature starts to climb. If the object (as it perforce must be) is not inert, then a self-heating mechanism may need to also be considered. In addition to the heat retained in the central portions, heat is being generated, and that generation can be rapid if the center is sufficiently hot. Finally, the presence of porosity promotes both smoldering and self-heating. If the fire largely involved wood materials, the members were probably originally thick and well-separated from the neighbors. Af-

ter sufficient combustion has taken place, the remainder may now form a heap where each fragment is close to, but not flush against its neighbor. The pieces have gotten smaller and thus there may now be a porous, self-heating body to consider.

Practical aspects of firefighting operations necessary to minimize the possibility of rekindles have been discussed by Dunn[61]. A thorough 'overhaul' procedure is necessary to avoid rekindles. It often requires considerable skill to overhaul sufficiently, yet to leave as much of the scene as possible to fire investigators. The use of a thermal imaging camera can be helpful, since it can pinpoint hot spots that would otherwise not be detected visually. Gustin has suggested that the two most common features associated with rekindles are cellulose insulation and low-density fiberboard[62]; not surprisingly, these are the two most common construction materials that can easily be made to smolder. Rekindles are also common with upholstered furniture, especially those containing latex foam or cotton. Some types of polyurethane foam smolder under certain circumstances and thus can also lead to rekindles. A detailed story on the repeated extinguishments and rekindles of a haystack that had ignited due to self-heating has been published[63]. The use of a surfactant in the overhaul process can help reduce the incidence of rekindles by allowing the water to penetrate the cracks and fibers associated with above mentioned materials.

Unconfined vapor cloud explosions (UVCEs)

An unconfined vapor cloud explosion (UVCE) is an explosion of a flammable gas cloud which is in the open air and not enclosed in a vessel or a room. The explosion must generate a significant overpressure for the term UVCE to be applied; otherwise the event is a *flash fire*. UVCEs are among the most deadly of industrial accidents. Catastrophic events occurred in England at the Flixborough plant of Nypro (UK) Ltd. on 1 June 1974 where a leak of cyclohexane in a nylon-producing plant killed 28 persons[64]. More recently, a UCVE at a Texas plant of Phillips Petroleum Co. on 23 October 1989 killed 24 persons. A UVCE occurs when an ignitable gas or vapor is released into the atmosphere and the cloud subsequently ignites. This type of explosion is 'inefficient,' since much of the fuel is not well enough mixed in order to participate in the combustion. Thus, a maximum yield of only 10% of the theoretical heat of combustion has been reported to be found for UVCEs[65]. A UVCE would not exist at all, of course, if there did not occur a region in which the fuel concentration is within the flammable limits. A UVCE produces a fireball and various blast effects, but these do not include the kind of pulverization which can be seen with high explosives. The definition of UVCE requires that ignition occur subsequent to atmospheric dispersion; explosions where the ignition is concomitant with the release are not classed as UVCEs.

A UVCE can be either a deflagration or a detonation. Only a minority of UVCEs are detonations, but these can show overpressures in excess of 15 atm[66]. One propane cloud detonation incident has been investigated in detail by the Bureau of Mines[67]. If a detonation occurs, it can be the result of either a detonating initiator (e.g., TNT) or by a deflagration-to-detonation transition. The former would be uncommon in peacetime, but the latter can very easily occur. The propensity for deflagration-to-detonation transition can be explained on the basis of the obstacle-laden immediate environment that can be common in a chemical plant near the source of the leak. A release away from any structures would avoid the turbulence creation which leads to flame acceleration and transition to detonation. However, chemical plants are normally laden with assorted piping, stacks, support structures, etc., all of which can serve to promote flame acceleration.

Of all the common gases, acetylene, ethylene oxide, and hydrogen are the easiest to detonate in a UVCE and methane the most resistant. It requires about 1000 times the initiator energy to detonate methane, in comparison to acetylene[65]. Other common gases, such as propane or butane, require 50 – 80 times the energy as for acetylene. When a UVCE does occur, greater damage is also expected with acetylene, due to its greater potential for flame acceleration and higher flame speeds that can be expected. A model has been published for allowing rough damageability estimates to be made[68].

An extensive database of some 165 UVCE incidents has been published[69], primarily covering the period 1945-1977. An important finding is that in 60% of the cases the ignition source (e.g., refinery flare) pre-existed and the explosion occurred when the cloud reached the ignition source. Design guidance for situations involving potential UVCEs is given by the Dutch government[70] and AIChE[71]. The US military has developed weapons which generate a UVCE by releasing and vaporizing a liquid fuel into the air; in their terminology such purposive UVCEs are called *fuel-air explosives* (FAE).

Flash fires have been studied only to a limited extent. AIChE summarized most of the scant data available[71]. Peak heat fluxes in the vicinity of 180 kW m^{-2} are associated with large spills. The effect of size is probably small, since heat fluxes of almost identical magnitude have been measured in much smaller scale house explosions, as shown earlier in this Chapter 13.

BLEVEs (boiling liquid, expanding vapor explosions)

A BLEVE occurs when a tank holding a compressed (pressure-liquefied) gas—commonly propane—undergoes rapid venting. The venting is often caused by overheating, followed by failure of the tank, but this is not a necessary sequence of events. In one case, a BLEVE with a 100 m fire-

ball was produced when pressure was inappropriately released in an industrial autoclave reactor[72]. The majority of cases, however, involve overheating. The overheating can occur due to various sources. It can simply be due to an ongoing fire engulfing a tank. In other cases, overfilling or another cause of overpressure will produce a discharge of the gas through a pressure-relief valve (PRV). If this discharging gas ignites, then an external source of heating exists close to the tank. Further discharge will result in continued flames, which, if impinging on the tank, will progressively raise its temperature and weaken steel that is present above the liquid line. The process leads to runaway, since normally a PRV cannot be practically provided which will keep up with the increasing pressures and flows[*]. The tank then ruptures, resulting in a massive fireball (Color Plate 43) and flying metallic fragments.

While most BLEVE incidents have involved flammable gases, it is not necessary that the gas be flammable for a BLEVE to occur. A BLEVE is basically a physical explosion, and heating from the combustion of the substance itself is only one of the ways that excessive over-pressure can occur. Prugh examined case histories for major BLEVE accidents during the period 1926 – 1986 and identified that, apart from propane/butane/LPG, accidents have volved[73,85]:

acrolein	ethylene oxide
ammonia	gasoline
butadiene	hydrogen
carbon dioxide	methyl bromide
chlorine	phosgene
2-chloro-1,3-butadiene	propylene
diethyl ether	vinyl chloride
ethylene	water

A number of the older accidents happened because of absence of proper valves and safety precautions against overfilling. Shown in Color Plate 44 are views of the fireball from the BLEVE that took place on 21 June 1970 in Crescent City, Illinois upon derailment of a train hauling propane tank cars. After the 1970s, this source of accidents in the US significantly decreased due to tighter regulations and greater safety awareness. But the most disastrous BLEVE took place in relatively recent times—1984—in Mexico[74], killing approximately 500 persons and injuring another 7000. 'Tub rockets' were propelled as far as 1.2 km in the incident, which entailed nine separate explosions, some of which were severe enough to register seismically. BLEVE fireballs from this disaster are shown in Color Plates 45 and 46, while the aftermath is illustrated in Color Plate 47.

[*] This is true for the case of normal *vapor*-discharge PRVs. It would appear to be readily possible to equip many types of tanks with a secondary, *liquid*-discharge PRV. Since the mass of material which can be discharged from a given opening is vastly greater for liquids than for vapors, anti-BLEVE safety could be provided. The secondary PRV would be set to discharge at some suitably higher pressure than the primary PRV.

A BLEVE is defined as an explosive release of expanding vapor and boiling liquid when a container holding a pressure-liquefied gas fails catastrophically[75]. But a failure of a tank holding a pressure-liquefied gas does not necessarily lead to a BLEVE. In general, if, for whatever reason, a fissure arises in a vessel holding a pressure-liquefied gas, there are three outcomes[76]:

(1) The fissure stops growing; there is no BLEVE, only a partial failure with jet release.
(2) Rocketing (partial failure with a liquid and vapor jet propelling the fragments).
(3) Total loss of containment and boiling liquid, expanding vapor explosion (BLEVE). This can occur either all at once or in two stages, as explained below.

For a BLEVE, as opposed to the other two failure modes, to occur, the liquid fill must be *below* a certain level. This is because a minimum energy must be available in the vapor volume to cause the crack in the metal to fully propagate[77]. This finding, of course, should not be taken to imply that tanks should be overfilled. Propane tanks are normally filled to 80% capacity. If a tank is overfilled, when it is subjected to heating (by a rise in ambient temperature, for example) the pressure inside the tank may rise sufficiently to cause discharge from the PRV. Many accidents have been reported where a discharge of this kind ignited, then caused flames to be applied to the tank, heating it further. This chain of events has ended in a BLEVE in many such incidents. Additional studies of non-BLEVE tank failures have been published[78].

Research by Birk and colleagues[76] at Queen's University in Canada and by Venart[79] at the University of New Brunswick identified the following sequence of steps as being characteristic of a BLEVE caused by flame impingement, and these are considered in some detail below.

- When flames impinge upon a tank, the liquid-filled portion stays cool due to heat-sink effects, but the steel around the vapor space rapidly heats up. Stresses increase, while strength has decreased due to the elevated temperature.
- Stresses in the tank wall are especially concentrated at the liquid/vapor interface.
- A crack develops in the tank wall, commonly located in the vapor-space portion, but near the liquid/vapor interface.
- Venting of the vapor results in a pressure drop within the tank and the liquid contents become superheated.
- The superheated liquid flashes, rapidly converting a sizable fraction of the liquid into vapor.
- If the vessel is fairly full, then vapor bubbles in the liquid cause the liquid volume to swell, resulting in a choked, two-phase liquid/vapor flow through the wall break. But if the vessel's fill level is low at the time of the BLEVE, then the two-phase outflow will comprise a mist/vapor discharge, rather than a highly turbulent liquid/vapor discharge.

- The pressure in the tank may drop, rise, or stay steady, depending on a complex interplay of a number of factors. Re-pressurization is discussed further below.
- At some point in the process, the fissure grows along the length of the tank and the tank catastrophically unzips with nearly instantaneous release of its contents. The crack propagation can be as slow as 1 m s^{-1} or as fast as 200 m s^{-1}.

Within this general BLEVE sequence, Birk[80] identifies two sub-categories of BLEVEs:

(1) A very rapid event transpiring once the original hole is formed, with the vessel opening up in 0.1 s or less. The energy in the vapor phase is the driving force in this type of BLEVE, since release of energy by flashing liquid would be too slow to contribute significantly. Vessels of low wall strength typically show this type of BLEVE.

(2) A slower event requiring 1 – 3 s for completion. In this type, crack growth slows down sufficiently after initial formation to let the liquid respond to the pressure drop created by venting. The boiling of the liquid then re-pressurizes the vessel and re-energizes the crack propagation process. This type of BLEVE is typical for vessels of higher wall strength.

Fire impingement upon the portion of the tank comprising the vapor space is much more dangerous than impingement to the liquid portion. When heating is applied to the vapor space, it is not necessary for the liquid phase to sustain an appreciable temperature rise before tank rupture occurs. Birk[81] has documented BLEVEs where the liquid temperature was close to 20ºC. Birk et al. also provided an argument (and limited data) to suggest that, in some cases, a partially-engulfed tank is more likely to BLEVE than a fully-engulfed one. This is related to stratification in the liquid and time required to de-stratify upon initial operation of the PRV.

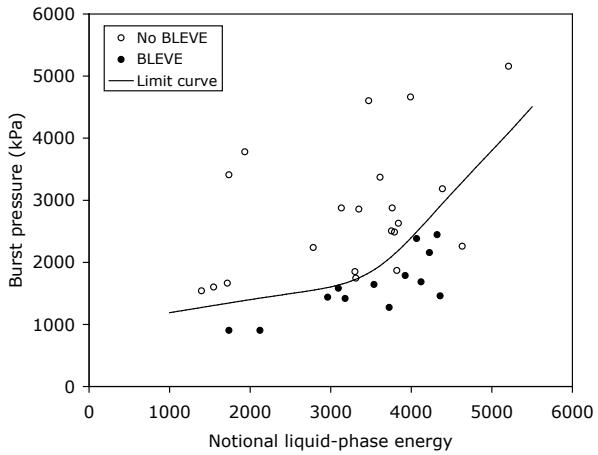

Figure 7 'BLEVE map' proposed by Birk et al. for estimating the likelihood of a tank to undergo a BLEVE

On the basis of a series of medium-scale experimental tests, Birk evolved a 'BLEVE map' (Figure 7) which is intended as a simple estimating tool to characterize the potential for a BLEVE. The x-axis is a simplified representation of the liquid-phase energy, defined as the average liquid-phase temperature (ºC) × fill percentage (%). The y-axis is a measure of the tank's strength, expressed as the burst pressure (kPa):

$$P_{burst} = \frac{2\sigma t_w}{D}$$

where σ = ultimate strength of wall material, taken at the average temperature of the wall surrounding the vapor-phase contents (kPa), t_w = wall thickness (m), and D = tank diameter (m). At failure, for steel tanks the average wall temperatures were measured to range from 580 to 780ºC. A peak value of ca. 800ºC is found; when steel reaches this temperature, very little strength remains (ca. 12%). A suitable expression for the ultimate strength of the grade of steel commonly used to make propane tanks gives:

$$\sigma = 2.85\times10^5 - 1.75\times10^5 \arctan\left(\frac{T-530}{75}\right)$$

where T = temperature (ºC). NFPA's tests[88] showed that, at failure, the wall stresses were 140 to 180% of the *room-temperature* yield stress.

The explosion usually involves a shock wave and must be attributed to more than just fracture of metal. It is found that a pressure *rise* can occur due to rapid depressurization of a tank which is otherwise at a stable pressure and temperature condition. Details of the repressurization process have been studied in small scale by Barbone et al.[82]. They found in their experiments repressurization levels up to 90% of the original pressure drop, but many tests showed a much smaller repressurization. McDevitt et al. conducted tests on small tanks holding R22, a non-flammable refrigerant gas[83]. The tank was heated to 65ºC, then an armor-piercing bullet was fired to open the tank. Pressure measurements showed drop from 2.7 MPa to 2.3 MPa after the bullet was fired in, then rising to 3.4 MPa, before ultimately dropping. Thus, the highest pressure was recorded *after* the hole was made, and the rise occurred due to initiation of boiling of a superheated fluid. The events were rapid, with the ultimate pressure drop only about 1 ms after bullet entry. These results, however, may be influenced by unique aspects of the bullet-firing scenario, i.e., the cavitation that is formed in the liquid behind the bullet, leading to a shock wave formation upon collapse of the bubble.

Reid[72] considers that the explanation involves the boiling process of liquids. Just before tank wall failure, the liquid/vapor system is saturated, that is, there is equilibrium of the vapor with the liquid. After the wall fails, pressure drops rapidly and the liquid should boil and drop its temperature to the value that it would have at 1 atm. But boiling does not start quickly, since initially there are no nucleating sites. Thus, for a while the liquid stays at a temperature above the equilibrium temperature. The explosion

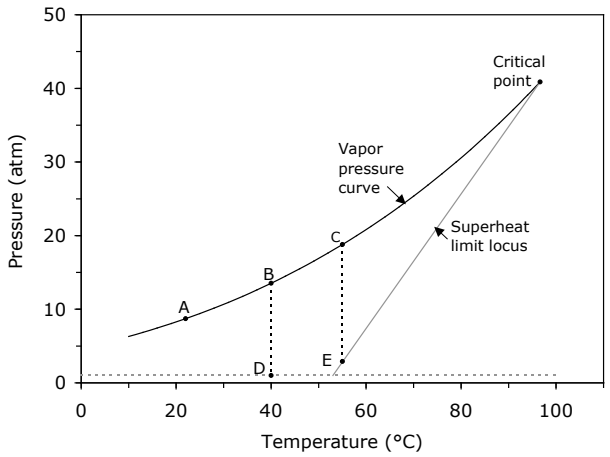

Figure 8 Propane tank depressurization, with and without superheated liquid-vapor explosion

which then occurs follows the theory of superheated liquid/vapor explosions. The conditions for propane are illustrated in Figure 8. In normal storage (point A), propane at room temperature is at a pressure of 8 – 9 atm. If a tank is heated up to point B and rapidly depressurized (to point D), the depressurization will not involve a superheated liquid-vapor explosion. But if the tank is heated up to point C (any temperature above ca. 53ºC) and then depressurized, point E intersects the superheat limit locus, thus the depressurization will generate a superheated liquid-vapor explosion. The temperature at point C is called the *superheat limit temperature* (SLT) and represents the maximum temperature to which a liquid can be superheated without cavitation (boiling).

The pressure in the vessel is the pressure of saturated vapor in equilibrium with the liquid at the vapor/liquid interface. This makes numerical treatment complex, since when heated, the liquid stratifies and the temperature at the vapor/liquid interface becomes higher than the average temperature of the liquid. After the PRV opens, however, the internal boiling tends to mix the liquid and reduce stratification. The flow through the PRV will generally be liquid with bubbles mixed in, as illustrated in the experiments of Sumathipala et al.[84] Data from Birk's tests[76] are shown in Figure 9. They indicate that the *average* liquid temperature is invariably lower than the saturation curve (BLEVE points are all to the left of the curve). If interface temperature and average temperature were identical, then the points would lie along the curve. It is also clear that all points are to the left of the superheat limit line. It is sometimes erroneously thought that BLEVEs can only occur if the average liquid temperature reaches the superheat limit temperature. The results indicate that BLEVEs occur substantially before this limit is reached, as also noted by Prugh[85]. Birk considers that appreciable superheat is uncommon in propane tanks, since nucleation sites are generally abundant[72].

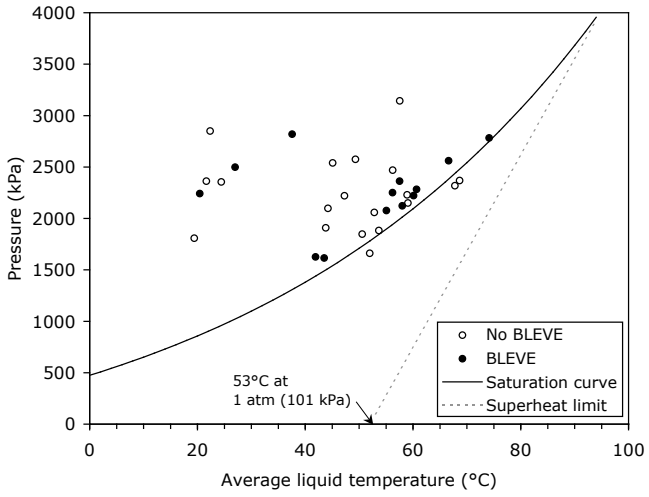

Figure 9 Average liquid temperature and pressure in 400 L propane tanks as a determinant of BLEVE potential

In the US, propane tanks are commonly equipped with a PRV set at 1800 kPa (for small tanks) or 2600 kPa (for large tanks). These correspond to propane saturation temperatures of 52ºC and 70ºC, respectively. Lower pressure settings lessen the likelihood of a BLEVE; to have a reasonable chance of being effective against a BLEVE scenario, Birk et al. urge that the setting be below 1700 kPa, which corresponds to a saturation temperature of 50ºC. It must be kept in mind, however, that PRVs are not designed nor intended to actually prevent BLEVEs, but rather to cope with milder incidents. Birk et al. also found that tank wall thickness has a much greater effect on failure than does the PRV setting, although it must be noted that the tanks in the Mexico City disaster had very thick walls.

Despite the ferocity of the fireball and possible shrapnel, the blast (overpressure) wave in air is moderate, at least as compared to high explosives. In one series of tests on BLEVEs from 400 L propane tanks, peak overpressures of only about 8 kPa (0.08 atm) were measured. The low overpressures are due to the low explosion energy of propane. Birk et al. point out that the explosion energy of TNT is 4680 kJ kg^{-1}, while the explosion energy of propane, evaluated as the isentropic expansion of liquid propane to atmospheric-pressure vapor is only 63 kJ kg^{-1}, or 1.3% of TNT. This figure does not include the energy released due to combustion, but experiments indicate that a BLEVE blast is produced by vapor expansion and not by the subsequent fireball combustion. The character of the blast is different from that of high explosives, since the blast is preferentially concentrated along the cylinder axis, rather than being axisymmetric.

Tank fragments can be propelled to fairly large distances. In one case, metallic fragments from the tank were recovered 229 m away[86]. In another case[87], a rail car fragment weighing more than 18,000 kg was propelled 366 m. In Birk's

tests on 400 L propane cylinders, shrapnel was propelled up to 200 m from the tank (Figure 10). In NFPA's tests on 1893 L propane cylinders[88], shrapnel was propelled also up to about 200 m. Larger distances are possible if the tank becomes propelled as a rocket. This form of propulsion is rare, but in the Mexico City disaster[74], 36 m^3 LPG tanks rocketed up to 1100 m, while projectiles from larger tanks only reached much shorter distances. This accident was extreme and it is rare for projectiles to be propelled farther than about 500 m.

The combustion of flammable material released in a BLEVE can have the character of a jet, a fireball, or a combination of the two. In some cases, a portion of the material remains as a pool, and this can burn as a pool fire on the ground. The effects of a fireball can be estimated with the equations given in Chapter 11 if the mass released is known. The mass that is flash-vaporized corresponds to the heat available to cool the liquid down to its boiling point[25]. While the specific heat and the latent heat are both temperature-dependent, an approximation can be made that they are constants, in which case a heat balance on the vaporization process gives:

$$\Delta h_v \, dm = C \, m \, dT$$

where Δh_v = latent heat of vaporization, m = liquid mass, C = liquid heat capacity, and T = temperature. By integration, the fractional amount of liquid remaining is:

$$\frac{m}{m_o} = \exp\left(-\frac{C}{\Delta h_v}\left(T_o - T_b\right)\right)$$

where m_o = initial mass, T_o is the initial temperature, and T_b the boiling point. The flash-vaporized fraction is then = $(1 - m/m_o)$. But the error from assuming constant Δh_v and C values becomes large unless the critical temperature, T_c, is much higher than the temperatures of interest. This, unfortunately, is not necessarily the case, and Prugh[85] computed more accurate values for the flash-vaporization fraction of a number of liquids (Table 2). Experimentally, it is found for propane that a BLEVE flash-vaporizes 40 – 50% of the contents, with the remainder being either large droplets or left as a liquid pool[77]. Thus, it should be reasonable to estimate fireball effects from LPG BLEVEs by assuming that 50% of the initial mass goes into the fireball. The fireball from a BLEVE can be somewhat different than one from a gas release, since bubbles rapidly develop in the superheated liquid and break, with the expelled fuel being partly an aerosol, not just a vapor. This has not been studied in detail.

Table 2 Flash-vaporization fractions computed from theory by Prugh

Substance	Temperature (°C)			Flash-fraction at SLT (%)
	T_b	SLT at 1 atm	T_c	
ammonia	-33	83	132	40
butadiene	-4	104	152	54
butane	-1	105	152	58
carbon dioxide	-79	-6	31	34
chlorine	-35	93	144	45
cyclohexane	81	220	280	61
ethylene	-104	-24	10	51
hydrogen chloride	-85	11	51	41
octane	126	240	296	67
phosgene	8	126	182	81
propane	-42	53	97	52
propylene	-48	52	92	51
sulfur dioxide	-10	50	158	21
water	100	280	374	36

Estimating the jet fire effects can be done if the mass release rate of the BLEVE is known. This requires modeling the development of the fissure in the tank and is not readily estimated by simple means, although Birk et al. reported

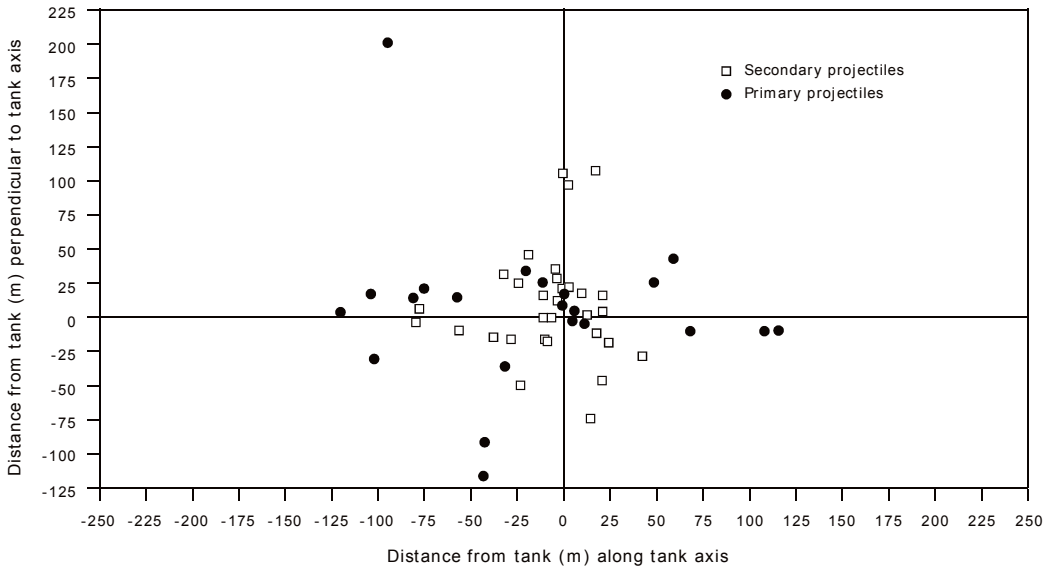

Figure 10 Distances to which shrapnel was propelled in BLEVE tests on 400 L tanks conducted by Birk et al.

reasonable success using a computational model.

According to Leiber[89], some BLEVEs of rail cars do not have external explanation, i.e., they are apparently 'spontaneous.' He studied a series of accidents and concluded that the mechanism is the same phenomenon as Venart's BLCBE: a resonance instability in the liquid, induced by a sudden, coherent collapse of bubbles within it. It is not clear, however, that a 'spontaneous' initiation is possible, i.e., one not precipitated by a mechanical failure causing an initial depressurization.

Some residential (home heating type) propane storage tanks were found to have a design defect that has led to BLEVE incidents[90]. These accidents took place due to corrosion of the tank causing the tank wall to lose sufficient thickness so that it could no longer withstand the pressure. It was found that (a) corrosion preferentially occurs at the tank weld rather than at bulk material; and (b) it is facilitated by accumulation of debris adjacent to it. The design defect consists in locating the weld along the bottom of the tank, where debris is likely to accumulate, rather than at the side, where it would not.

There are some LPG tanks that are made of *aluminum*, not steel. Birk and VanderSteen[91] conducted fire tests to determine the relative performance of small (36 L) LPG tanks of both materials. The test fire exposures were designed to be moderate, rather than severe, and comprised heating the test unit with one, two, or three torch flames, using low-velocity diffusion flames. Of three aluminum tanks tested, all ruptured, with one exhibiting a BLEVE; by contrast, of three steel tanks tested, none failed. These results are not surprising, given the fact that the temperature at which ultimate strength drops to 50% is about 600ºC for steel, but only 260ºC for aluminum. The authors noted that both types of cylinders, steel and aluminum, are claimed to conform to the industry standard, CGA C-14[92], which requires that either a bonfire or a chimney test be passed. The published description of these tests represents them as severe tests and the authors expressed concern that apparently the test methods are either mis-designed or mis-applied, since their own much less intense tests produced gross failures of the aluminum cylinders. Not surprisingly, the authors concluded that "The use of aluminum cylinders for LPG in all applications should be reviewed, along with the appropriate standards that apply to them."

For fire-caused BLEVEs, there are generally three preventive strategies[93]:
(1) prevent the initial fire
(2) prevent the fire from heating and, especially, weakening the tank
(3) prevent the buildup of pressure in the tank.

One of the main preventive measures against BLEVEs is tank insulation. After a slew of LPG rail ranker disasters in the 1970s[87,94-96], the rail industry retrofitted its flammable gas tank cars with external thermal insulation[*]. The thermal insulation serves to break the feedback loop by reducing or eliminating the warming up of the tank when external flames impinge upon it. More recently, thermal insulation jackets have been developed and tested[97] for small (7 to 47 kg) propane tanks. While it will not be typically applicable to tanks except on-site at a chemical plant, an interesting protection strategy is to ensure that a tank is always full, since steel will not be readily weakened if a liquid is available at the back face of the shell to act as a heat sink[93]. An industrial tactic using this approach is to have an auto-fill arrangement that adds water to a tank as the consumable liquid is withdrawn; the liquid, of course, must be compatible with water. Another way to use water in protecting fixed-installation tanks is to install a deluge water spray system. It is generally considered that a safety valve alone cannot be expected to protect against BLEVEs caused by exposure to a fire[93], however Moodie et al.[98] reported on a series of tests where a 5-T uninsulated road tanker was tested. The tanker was filled with LPG from 22 to 75% capacity in a series of 5 tests and subjected to external heating from a kerosene fire producing heat fluxes up to 100 kW m^{-2}. Despite heating for 10 – 30 minutes, no BLEVEs occurred. In each test, however, the PRV valves (two were fitted) operated and resulted in a tall flare burning. Thus, while the possibility of a BLEVE must be seriously considered when uninsulated tanks are engulfed, it is not a foregone conclusion that one will take place. Sometimes pressure regulators and fittings are made of a low-melting-point metal, e.g., a zinc alloy. The melting of this type of component is judged to have contributed to the severity of at least on BLEVE accident[99].

With propane tanks, a BLEVE will generally involve a fire. But there are exceptions. Color Plate 48 shows a tank which was overfilled and on which the PRV was defective and unable to operate. The ambient temperature rise from the time the tank was filled to the warm part of the day suffice to BLEVE the tank, but did not cause a fire.

Many jurisdictions permit 1000 gallon (3785 L) propane tanks to be located within 3 m of buildings. Birk[100] conducted a worst-case theoretical analysis of a tank placed near a re-entrant corner of a combustible building, so that it is 3 m from either of the two walls. The calculations indicated that a BLEVE is highly likely if the tank gets exposed to a fire occurs which involves burning of both walls in the corner, but it must be noted that only the worst-case scenario was treated, and that no validation data were available.

A major Canadian research project[75,81,101] has provided engineering guidelines on calculating the effects of BLEVEs and on appropriate response tactics. Experience has indicated that applying a water stream onto a tank engulfed in flames can itself trigger a catastrophic failure[99]. The TNO

[*] The industry prefers the term *thermal protection*, which includes alternative measures, such as intumescent coatings.

Yellow Book[70] and the AIChE manual[71] contain much useful design guidance for minimizing BLEVE potential at chemical plant installations. A collection of simple design formulas has been compiled by Prugh[73].

Oxygen-enriched atmospheres

In many of the preceding Chapters, oxygen concentration was considered as a variable which can encompass values both higher and lower than 20.95%. Because there are important safety issues associated with elevated-oxygen systems, in this Section we consider these issues specifically. Many metals are relatively safe in atmospheres at normal pressure and oxygen concentration, but turn out to be ignition-prone under elevated oxygen and pressure conditions. Many elevated-oxygen systems and processes are also ones that operate at high pressures, thus the role of high pressure must commonly also be taken into account. Ignitions in high-pressure oxygen systems can be difficult to eliminate since if the materials are functionally usable (e.g., strong enough, not too brittle) then they are also likely to be ignitable—the designer's role then being restricted to choosing less-ignition-prone ones rather than unignitable ones. Apart from industrial and NASA systems, enriched oxygen atmospheres are also common in hospitals; de Richemond and Bruley[102] reviewed a number of case histories. The entire available history of reported accidents within enriched-oxygen or hyperbaric chambers was reviewed by Sheffield and Desautels[103], who provided details on 39 accidents from 1923 through 1996 entailing 82 fatalities. The ignition sources identified by the authors are given in Table 3. In recent decades, most of the accidents have tended to be in countries which do not have strict regulations for enriched-oxygen activities. In pure-O_2 hyperbaric chambers, the consequences of fire are severe—the authors note that "No one has survived such a fire."

Table 3 Ignition sources leading to fires/explosions in enriched-oxygen or hyperbaric chambers

Ignition source	Number of accidents
electric spark/arc	15
electrostatic	8
hand warmer	4
smoking	4
external source	2
child's toy	2
welding	2
unknown	2

Basic guidance is available in a series of ASTM Guides[104-106] which provide useful procedures for identifying and mitigating hazards that might exist in oxygen-enriched environments. NFPA 53[107] provides additional guidance on ignition potential in oxygen atmospheres. The NASA standard on oxygen systems, NSS 1740[109], is comprehensive and offers excellent, practical advice which is useful in all oxygen-enriched applications, not just those of NASA; it has formed the basis of ASTM's newly-issued Manual 36[108]. These guides and standards all stress selecting materials that are more ignition resistant and less flammable as well as the importance of identifying and eliminating ignition sources. In oxygen service, autoignitions are considered rare, compared to situations where a localized form of igniting energy is present. Ignition due to adiabatic compression, however, can occur, and this is one form of non-localized energy that has sometimes been problematic in oxygen systems. Oil contamination can also lead to ignition without a localized source of energy present.

In oxygen-enriched systems, ignition mechanisms have to be considered which may be rare otherwise. NASA[109] considers the following to be important:

- Particle impact. The impact in an oxygen-enriched atmosphere of a small particle upon a surface may cause the mechanical strain energy to be converted to heat and to ignite the particle itself, and to then ignite the impacted surface.
- Mechanical impact. An example is a solenoid-actuated valve striking the valve seat. Aluminum, titanium, lead, and tin alloys are susceptible to this mechanism, but iron, nickel, copper, and cobalt alloys are not.
- Adiabatic compression. High-pressure oxygen released into a dead-end tube can ignite most polymers, although extra high pressures can also ignite metals. Pneumatic impact is considered to be the most common cause of ignition of polymers in oxygen systems. Slow-opening valves are often mandatory in oxygen systems.
- Promoted ignition. Ignition of contaminants, e.g., oils, can ignite adjacent components.
- Galling and friction. Heat from rubbing parts together, especially with the removal of protective oxide film is involved.
- Resonance. Acoustic oscillations in cavities can be sufficient for ignition. This was demonstrated at least for 400-series stainless steels.
- Electric arcing. Even corona discharges (which lack sufficient energy to ignite flammable atmospheres under normal conditions) may be incendive in high-pressure, enriched-oxygen systems since MIE values are much lower under those conditions.
- Flow friction. The interaction of leaking oxygen with a polymer seal or seat has been thought to cause ignition. This has been observe to occur in systems where a pressure differential greater than 6.8 MPa exists across the seal. The specific heat generating mechanism is not understood, but several such ignitions have been observed.
- Metal fracture.

A basic recommendation[106] on suitability of metals for high-oxygen atmospheres is:

Most suitable: Ag, Au, Cu, Ni, Pd, Pt

Least suitable: Ca, Be, Hf, Mg, Ti, Zr

The most-suitable metals are usually characterized by having low heats of formation, while the least-suitable ones have high heats of formation. Alkali metals do not follow this relation, but all of those are wholly unsuitable for oxygen service. Nickel-copper alloys (Monel) are the most ignition- and burn-resistant alloys for use in oxygen systems, followed by copper-based alloys. Nickel-iron alloys (Inconel) are also commonly suitable for use in oxygen systems. Stainless steels are less desirable than nickel-copper alloys because of their poor thermal conductivity, which makes them more reactive in oxygen service[110]. Aluminum alloys, iron alloys (apart from stainless steels), titanium, and magnesium are all readily ignitable in oxygen systems and should be avoided[109]. If these alloys are used, great care must be taken to ensure that the ignition mechanisms are identified and minimized or controlled. In 1997, a large air separation unit exploded in Malaysia, and the cause was determined to be ignition of aluminum used as vaporizer fins in a cryogenic distillation column through which LOX was circulated[111].

It is not necessary that a metal be finely divided for it to ignite and burn, if it is exposed to oxygen-enriched, high-pressure atmospheres. For example, a 6 mm layer of molten stainless steel can ignite and fully burn up if exposed to an atmosphere having over 3.7 atm of O_2 partial pressure[112]. The ignition temperatures of metals in oxygen atmospheres generally decrease with pressure, as shown in Figure 11[110,113], and this effect alone can explain a number of accidents. The results shown in Figure 11 must be viewed as only general guidance—actual ignition temperatures depend a lot on the details of the experiment. For example,

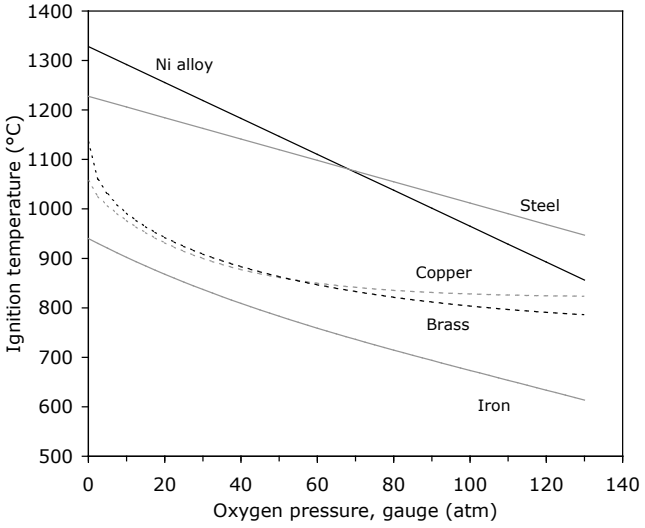

Figure 11 Effect of pressure on ignition temperatures of several solid metals in pure oxygen atmospheres

Bates et al.[114] found ignition temperatures of only 350ºC for ductile iron and for type 304 stainless steel at 50 atm. In addition, it appears that some metals show a reverse trend; data for zinc indicate that ignition temperature rises as the pressure is increased[115].

Enriched-oxygen accidents are mostly confined to industrial and manufacturing uses, however some consumer accidents also occur. Yallop[17] reports that cases have occurred where individuals mistakenly used an oxygen bottle to fill a vehicle tire. The compression was sufficient to ignite lubricants in the tire, with the resultant combustion bursting the tire and causing injury.

Frictional ignitions of metals in high pressure (6.9 MPa) gaseous oxygen environments were studied by Benz and Stoltzfus[116]. They constructed an apparatus where two identical metals were rubbed one against each other at high speeds. The results are given in Table 4. The sensitivities found vary by about 3 orders of magnitude. To be a correct expression of power delivered from frictional heating, the results should also be multiplied by the friction coefficient. Since this was not done in their experiments, the results should only be viewed as relative; in addition, the authors demonstrated that changing various test conditions will also affect the values obtained. The authors measured the bulk temperatures at ignition for a few metals and found that the values were, in certain cases, greatly lower than literature values. For aluminum, a value of 375 – 425ºC was found, compared to a literature value of ca. 2000ºC. This is understood to happen because the rubbing process removes the protective oxide film, which otherwise dominates the ignition mechanism of aluminum. A large set of pressure × velocity data has been compiled by Gunaji and Stoltzfus[117].

Table 4 Relative sensitivity of various metals to frictional ignition in high-pressure gaseous oxygen

Metal alloy	**Pressure ⋄ velocity product (MW m^{-2}) needed for ignition**
nickel 200	228 – 238
Inconel 600	199 – 289
Monel 400	142 – 155
Monel K-500	137 – 163
Hastelloy X	93 – 126
brass 360	69 – 117
Invar 36	60 – 94
stainless steel 316	54 – 72
aluminum 6061-T6	6.3
titanium 6A1-4V	0.39

Metallic components of systems that contain hyperbaric oxygen at elevated temperatures may be ignited by *impact of particles* against the metal. A review of the literature on this topic was presented by Benz et al.[118] Systems not intentionally operated at elevated temperatures are not necessari-

ly safe from ignitions of this type. A case incident was reported[119] where an Australian air force airplane was destroyed during the routine servicing of the crew's oxygen-breathing system. It was hypothesized that a thermite reaction involving aluminum and iron was the cause of the heating, with particle impact being the direct mechanism of ignition. The likelihood of ignition from impact of a polymer particle is minimal according to the experimental findings of Dees et al.[120]

Glassman and Law[121] have offered a relatively simple theory to explain the greatly increased hazards for reactivity of metals as the oxygen fraction in the atmosphere approaches 100%. It helps to explain why, for small-diameter, highly-reactive metals, the reaction rate increases drastically and non-linearly as the oxygen concentration approaches 100%. The increase often is sizeable only for oxygen mass fractions > 99%, and consequently the behavior can be governed by the exact amount of gaseous impurities present in the atmosphere. If oxygen concentration is ≈100%, then no limitation of surface reaction can exist due to a diffusional resistance; but if the value drops below 100%, then oxygen concentration can drop at the surface and this causes a reduction in reaction rate.

A very small amount of *contaminants* can suffice to ignite metals which are otherwise suitable for oxygen service. In one study[122], it was found that 1.5 mg of Buna-N rubber sufficed as an ignition source for Inconel 718 alloy. The ignition and explosion hazards associated with oil films in oxygen-handling equipment have been reviewed by Werley[123]. Shelley et al.[124] studied the ignition properties of PTFE tape contaminated with hydrocarbon oil and concluded that ignition properties can be affected, but unreasonably high levels of contaminant were required for this. Barthélémy and Vagnard[125] extracted contaminants (oil and exuded plasticizers) from used PTFE-lined hoses and found AIT values of only 160 – 220ºC using the ASTM G 72 test. They then tested hoses for adiabatic-compression ignition and were able to reproduce failures of the kind associated with actual incidents. But the results were similar, irrespective of whether the hoses were cleaned or not, so they concluded that basic ignition of PTFE is being involved in this type of accident, with little if any contribution from contaminants. Janoff et al.[126] reproduced these findings and concluded that stainless steel, rather than PTFE, hoses should be used in applications where this form of ignition may be a problem. However, Newton et al.[127] tested oxygen regulators with practically-occurring amounts of contaminants and found that the likelihood of an oxygen regulator fire or explosion is significantly increased by the presence of contaminants.

Under medium pressures, nonmetallic substances such as polymers can be ignited simply by impact of a high-pressure gaseous O_2 stream. This phenomenon was of sufficient concern to NASA that it led to the development of the ASTM G 74 test (see below). NASA researchers[128] tried to elucidate the mechanism of ignition and examined the following possible effects:

(1) adiabatic compression of the initial gas volume by the entering air stream (both real-life accidents and the ASTM test fixture involve an arrangement whereby the polymeric specimen is held in a closed test chamber which is rapidly pressurized);
(2) adiabatic compression of gas bubbles within the specimen;
(3) heating of the material by mechanical compression;
(4) interaction of shock waves with the specimen.

A definitive answer could not be reached, but they did rule out #3 since calculations indicated that, within the ASTM G 74 test chamber, a specimen would sustain less than a 100ºC rise from this mechanism. An effort to measure mechanism #1 experimentally was not successful, but a theoretical calculation suggested that, if mixing between the incoming gas and the gas already present within the volume is small, very high temperatures can be attained, more than sufficient for ignition. Hirsch et al.[129] proposed that the mechanism is primarily one of enhanced polymer gasification. At high pressures (e.g., 700 atm), there are essentially no practical materials which are able to resist ignition from the high temperatures which will be created if such pressures are rapidly imposed upon a system[110]. Ignition of metals by *laser* radiation was studied by Bransford[130].

Ikeda[131] measured the AIT for a number of polymers in pure gaseous O_2 at 1 atm; his results are given in Table 5. Hsieh et al.[132] measured the autoignition temperatures for a number of polymers under 100% oxygen, hyperbaric conditions. Their results are shown in Table 6. Certain polymers which have superior ignition properties at ambient oxygen conditions may not be acceptable in oxygen systems; silicone rubbers are an example[109]. Addition of glass-reinforcing material to polymers may similarly cause an unexpected worsening of ignition performance.

Table 5 Autoignition temperatures for polymers tested in 100% oxygen at a pressure of 1 atm.

Polymer	AIT (ºC)
Buna-N	489
Kalrez	429
Kel F-81, unplasticized	384
Neoprene	306-317
polyethylene	226

Tefzel	243
Viton A	268-322

Same as with fuel gases, oxygen may linger for surprising lengths of time in spaces supposedly opened up to the atmosphere. An accident is reported where elevated oxygen concentrations remained in an oxygen tanker that had been emptied of its contents and its manhole and all other openings left open for three weeks[16]. Testing of the oxygen level in one part of the tanker did not reveal an elevated concentration in another portion.

Radiation from oxygen-enriched fires is greater than from fires in 21% oxygen atmospheres. In an oxygen atmosphere, flame temperatures can be higher by 1000 K or more than they would be in air. This has strong implications for the ignition of *targets*, since radiant heat flux depends on temperature to the 4th power.

A related hazard of oxygen-enriched atmospheres is that some combustibles which, when ignited in normal air, do not show sustained combustion, may burn well in an oxygen atmosphere.

TEST METHODS

ASTM G 72 AUTOIGNITION TEST

A special test method has been developed for the autoignition of liquids or solids in hyperbaric 100% oxygen atmospheres. The test[133] is normally run at a pressure of 10.3 MPa and can be used for determining autoignition temperatures in the range of 60 – 425ºC. A stainless steel bomb of 0.11 L is surrounded by a heating jacket. A 200 mg sample is placed in a glass sampleholder, which is placed into a glass test tube, and the latter is put into the stainless steel bomb. After being filled with oxygen, the bomb is then heated at a rate of 5ºC per minute. Ignition is recorded as a rapid temperature rise of over 20ºC.

ASTM G 124 PILOTED IGNITION TEST FOR METALS

In this method[134], a stainless steel test chamber is used wherein a cylindrical shaped specimen, 3.2 mm diameter and 150 mm long, is placed. The bottom of the specimen is coated with magnesium or aluminum to act as combustion promoter and is ignited with a Nichrome or Pyrofuze (aluminum/palladium) igniter wire. The test chamber is filled with oxygen to the desired pressure and the igniter wire is powered. If sustained burning of the sample does not occur, a higher pressure is investigated. The basic reported result is the minimum oxygen pressure at which sustained burning occurs. The results are meaningful only in the context of the environment of the test apparatus.

ASTM G 74 GAS STREAM IMPACT TEST

In aerospace, chemical manufacturing, and other applications, situations exist where metals or other solids may be ignited by the high-velocity impact of pure oxygen or other oxidizer streams. ASTM G 74[135] subjects a 1.52 mm thick test specimen at room temperature to an oxidizing gas stream impacting at 69 MPa. Five cycles are performed and ignition or non-ignition is reported. Werley[136] has analyzed some of the test's features. Hirsch et al.[129] demonstrated that there is a strong correlation between the results of this test and the material's AIT, provided the test is run in a way as to determine a quantitative value for the impact reactivity level, not just a go/no-go result. For AIT values in the range 170 – 450ºC, the relation is:

$$I_{50} = 0.423\,T_{ig} - 0.192$$

where I_{50} = impact reactivity level (MPa), calculated at the 50% probability, and T_{ig} = AIT (ºC), as determined in the ASTM G 72 test.

ASTM D 2512 AND ASTM G 86 MECHANICAL IMPACT TESTS

The ASTM D 2512 method[137] is an impact tester developed by the Army Ballistic Missile Agency. Liquids or solids are tested. Liquids are poured as a 1.27 mm layer in a 16.7 mm diameter sample cup. Solids are prepared as a disk of 17.5 mm diameter and 1.52 mm thickness, although other thicknesses may be used. The test cavity is pressured with gase-

ous oxygen, or liquid oxygen may be poured into the test assembly when testing for LOX service. A mechanical drop hammer is released to provide the impact to the specimen. NASA and other agencies have collected extensive data with this test method. ASTM G 86[138] uses the same test apparatus as ASTM D 2512, but adapted for testing at elevated pressures of up to 68.9 MPa.

ASTM G 125 OXYGEN-INDEX TEST FOR OXYGEN-ENRICHED ATMOSPHERES

The ASTM G 125 test[139] is a slight variant of the standard ASTM D 2863 oxygen index test for use by individuals interested in evaluating materials for elevated oxygen service. The same principle of examining the candle-like burning of materials in atmospheres of various oxygen contents is used. Same as with the ASTM D 2863 test, a strong caution must be applied that there is little generality in the results thus obtained.

Wildland-urban interface

A cluster of ignition-related problems tend to occur at the wildland-urban interface, that is, in locations where houses abut wildlands, which can be forests or grasslands. Losses of houses due to ignition from wildland fires has been a serious problem in Australia, California and elsewhere. Ignition of houses from wildland fires involves one or more of these mechanisms:

- radiation
- direct flame contact
- firebrands (embers).

Thus, over the years a number of studies have been conducted to elucidate both the relative contribution of various construction features towards the vulnerability of houses, and to evolve recommendations for improved construction practices.

An early Australian study in 1945 identified the pivotal role of flying brands[140]. The study concluded that:

- the materials of the external walls were of minor importance
- the preponderance of the highly destructive fires started *inside* the house, most commonly due to ingress of flying brands.

Consequently, the recommendations were:

(1) to provide mesh on all openings into attics and subfloor spaces. Eaves should preferably be covered by a board along the bottom and not by mesh.
(2) concerning clay roof tile, to use only types that do not have opening allowing ingress of brands.
(3) both clay-tile and corrugated-iron roofs should use a fascia board which closes off openings at the edge of the roof.

The study also documented brick-veneer houses where window glass sagged, but wood window frames did not ignite. Current Australian recommendations[141] are that, in general, firebrands should be expected to be severe for houses located up to ½ km away from the perimeter of a forest.

In later decades, statistics were collected in Australia about certain characteristics of houses that lead to their ignition and destruction, or not, when confronted with a wildland fire. After a series of 1994 fires, a statistical study[142] focused on the effect of cladding material (Table 7). Clearly, the ignitability of the material plays a strong role, but the authors pointed out that there are intervening 'style' variables. For instance, more wood-clad houses had unenclosed subfloor spaces, which served to promote destruction of houses. Thus, these findings do not necessarily contradict the earlier ones.

Table 7 Effect of exterior cladding materials on house survival

Cladding material	Percent		
	Not ignited	Damaged	Destroyed
masonry	68	15	17
cement boards	48	13	39
wood	33	7	59

In that study, statistics obtained on houses where firebrands were either the sole ignition mechanism, or where ignition was due to a combination of firebrands and heat radiation are shown in Table 8.

Table 8 Materials first ignited by firebrands in Sydney, Australia houses surveyed after the January 1994 wildland fires

Material first ignited	Houses ignited	
	By brands	By brands and radiation
fascia board	9	6
wood deck	13	–
wood window frame	6	6
wood door frame	4	2
wood cladding	5	–
interior contents via broken window	–	4
exposed wood structural member	4	–
wood shingles	2	–
wood stairs	2	–
door mat	2	–
plastic roof panel	2	–
asphalt roofing	1	–
canvas awning	1	–
other	1	–

Another Australian study[143] identified that radiation, by itself, is only rarely the cause of a house to be lost. In a further Australian study[144], it was found that the color of wall cladding did not have a significant effect, but several other factors were quantified with respect to risk of house destruction. Table 9 shows that clay tiles were found the most resistant, presumably due to their low transmission of heat.

It was also found that pitched roofs showed a lower relative risk (0.8, versus 1.0) than flat roofs. A profound difference was found concerning the surrounding vegetation (Table 10); the statistics do not take into account aspects of owner maintenance because evidence was typically destroyed.

Table 9 Effect of roof material on risk of house destruction from a wildland fire

Roof material	Relative risk of house destruction
clay tiles	0.6
steel deck	1.0
corrugated iron	1.4
asbestos-cement	1.5

Table 10 Effect of vegetation type on risk of house destruction from a wildland fire

Vegetation type	Relative risk of house destruction
grass	1.0
shrubs	3.5
trees	8.6

In 1984 Wilson presented a calculational scheme for predicting the probability of house survival in a bushfire[145], based on the study of 450 houses affected by the 1983 Mt. Macedon fire. Six different factors are to be evaluated, as shown in Table 11. If the score is 6.3, then there is a 50% probability of survival; for a score of 4.0 the probability is 90%, while for 8.5 it drops to 10%. Fire intensity is to be estimated on the basis of fuel load (Table 12); a correction factor is applied to the fuel load if the ground slope is not zero. Wilson's scheme indicates that if the fire intensity is very high, the probability of house survival is low, irrespective of how it is constructed or protected. But for lower fire intensities prudent construction practices will affect the outcome, of which the most important is roof material. Nearly as important is the presence of a responsible adult, who may be able to extinguish embers, etc.

Table 11 Factors in the Wilson scheme for estimating the probability of house survival in bushfires

Factor	Points
Fire intensity (kW m^{-1})	
> 10,000	5.2
1,500 – 10,000	3.6
500 – 1,500	2.3
< 500	0.0
Attendance by residents	
unattended	2.2
attended	0.0
Roof	
wood shingles	2.4
metal, fiber, or slate, w. pitch > 10°	1.4
tiled, incl. steel pressed tiles	0.0
any material w. pitch < 10°	0.0
Wall material	
combustible	1.1
non-combustible	0.0
Presence of flammable objects	
present	0.8
absent	0.0
Presence of plants > 5 m high and within 40 m of house	
present	0.6
absent	0.0

Table 12 Fuel loads corresponding to various fire intensities in the Wilson scheme

Fire intensity (kW m^{-1})	Fuel load (tonnes/hectare)	
	Grass fuel	Forest fuel
> 10,000	> 1.7	> 14
1,500 – 10,000	0.3 – 1.7	5.3 – 14
500 – 1500	0.1 – 0.3	3 – 5.3
< 500	< 0.1	< 3

Some examples of ignitions from brands are shown in Color Plate 49 through Color Plate 52. The smoldering combustion of a wood fence post ignited during a wildland fire is shown in Color Plate 53.

Other factors were studied in California[146], where prevalent construction types are different. Roof factors (untreated wood shake roofs have been very popular in California) and vegetation clearance factors are given in Table 13 and Table 14. The combined effect is shown in Table 15. There is an overwhelming probability of house destruction in California wildland fires if the roof is flammable and brush clearance is not maintained. No systematic study exists, but experience in southern California also indicates that houses located in *canyon areas* are more vulnerable than ones in flat terrain.

In general, aspects of house construction or maintenance that can minimize the risk of ignitions include:

1. Removing vegetation from close proximity to buildings; replacing vegetation with types considered to be relatively fire resistant.
2. Providing of roofs that are not easily ignitable by fire brands. Testing is done according to ASTM E 108, and acceptable products are classified at least in Class C, although Class B or Class A provide higher protection.
3. Screening of vents in attics and under-eaves with metal screens that can keep out fire brands.
4. Minimizing eaves projections or cantilevers; avoiding construction on stilts. These forms of construction lend themselves to 'trapping fire.' Eaves should be covered on the bottom with non-combustible material.
5. Using double-glazed window, which better resist breakage due to external radiation. A second pane of glass also attenuates further radiation that might ignite curtains prior to glass breakage. Thicker panes of glass or tempered glass can also better resist breakage. In structures where their use will be acceptable, wired

glass or steel shutters over windows should be considered.
6. Non-combustible cladding (e.g., brick) should be considered in vulnerable locations.
7. Roof sprinklers have been found useful in certain instances.
8. Roofs, gutter, and areas around the structure should be kept free of vegetation litter and other combustibles. In many areas, accumulations of vegetative matter in gutters are easily ignitable and can then serve to ignite the eaves, thus, house designs that do not use gutters are safer[147]. Clearing away debris fully, however, may be a hopeless task. In many cases, even if gutters and decks have been cleared of dry leaves a few days before a wildland fire, they will fill again on the morning of the fire[148].

More detailed recommendations on constructing and maintaining homes to minimize the risk of destruction by wildland fire have been published in several guides on the topic. The US Forest Service has developed a guide[149], as have Australian authorities[150]. Documents intended for possible regulatory adoption include NFPA 1144[151] and the ICBO Urban-Wildland Interface Code[152].

Radiant heat ignition or direct flame contact, while not the dominant ignition causes, are more amenable to systematic analysis, thus, a research program has been conducted at the US Forest Service to model the ignition of structures from radiant heat and from direct flame contact. The initial study[153] suggested that a 15 m tall flame would possibly cause an ignition at a distance of 14 m from a normal wood surface if piloted ignition conditions prevailed and the flame front lasted at least 60 s. The study also entailed experiments where wood siding materials were exposed to burner flames of up to 2 m high. Ignition took place in about 1 min from the burner flames, but flaming was not sustained upon removal of the flame source. Smoldering, however, continued and in some cases active flaming could be brought about by wind.

Table 13 Effect of flammability of roofing on house destruction by wildland fire

Roof	Percent of houses destroyed
flammable	81
non-flammable	30

Table 14 Effect of brush clearance on house destruction by wildland fire

Brush clearance of 9.1 m (30 ft)	Percent of houses destroyed
not maintained	62
maintained	22

Table 15 Effect of combined factors on house destruction by wildland fire

Factors	Percent of houses destroyed
roof flammable, brush clearance not maintained	96
roof non-flammable, brush clearance maintained	14

Crown fires in a forest typically show flame heights of twice the canopy height and heat release rates of 35 – 70 MW per meter of flame front[154], but the duration[155] of a crown fire is only about 60 s. A limited amount of full-scale ignitability data have been collected from large-scale experimental forest fires where a wood façade was exposed[155]. These indicated that scorching, but not sustained ignition occurred from a flame front 10 m away (Color Plate 54). When actual flame contact was made with the wall, however, ignition occurred.

Determining ignition properties in fire investigations

In general, any fire properties can be determined in one of two ways: (1) by looking up values in a handbook, or (2) by conducting tests. The investigator may have identified that a "standard" material or product was involved, one which shows up in handbook tabulations. Thus, there is a temptation to simply analyze the fire by assuming the flash point temperature, minimum flux for ignition, etc., on the basis of handbook data. However, if there is any remaining material to be tested it is generally wiser to actually test the material. For some fire properties, tests can be very expensive, thus they are commissioned only as a last resort. Ignition tests, however, are invariably modestly-priced. One major benefit of having tests conducted on the exemplar substance is that impure or contaminated substances are identified. The tank *may* have held kerosene, but the kerosene was contaminated with gasoline and had a much lower flash point. The flash point test will establish this, and it is simpler to run and less costly than a comprehensive chemical analysis of the specimen, for instance, using GC-MS. However, a flash point test requires a substantial amount of specimen, compared to quantities of less-than-one-drop needed for a GC/MS analysis; thus, specimen availability may be a determining factor.

Introduction

In this Chapter, detailed information is presented for a variety of substances which are of special interest in regards to their ignition characteristics. Also collected in the same alphabetic arrangement is information on some ignition sources which have been studied in detail. The meaning of various physicochemical constants cited is explained in the pertinent theory chapters, for example, to understand the meaning of E and P, the reader should refer to Chapter 9.

Accelerants in incendiary fires

The breakdown of types of ignitable liquids found by a large commercial testing laboratory[1] during a 5-year period is shown in Table 1. Some older data[2] from a State laboratory are given in Table 2.

Acetylene and related compounds

Acetylene, C_2H_2, is highly combustible, subject to exothermic decomposition, and has a particularly wide flammable range. Much of its special nature is due to the presence of the triple bond (C≡C). Most of the use of acetylene is in gas form, or in its storage form as dissolved in acetone. The rarely-used liquid acetylene has been subjected to various explosion tests and performs roughly similarly to picric acid, a sensitive explosive[26]. Solid acetylene, which has essentially no commercial uses, is fairly insensitive. Additional information on handling liquid or solid acetylene is given by Urben[3]. The standard reported LFL for acetylene is 2.5%, but its UFL can be 100% if it decomposes and is around 80% for normal oxidation. Tested in a 5 L volume, an LFL value of 2.2% was found[26]. The AIT, measured in small vessels or in 12.5 mm tubes[4], is 290 – 300ºC and is surprisingly independent of concentration, over the range of 20 – 80%. For concentrations below 20% or above 80%, the AIT rises to higher values in the 400 – 600ºC range. The AIT is the same regardless of whether the atmosphere is air or pure O_2. The AIT shows a moderate decrease for moderately elevated pressures, but relations have not been reported at higher pressures[9]. For spark ignition, the 0.02 mJ energy required[5] (at the optimal fuel concentration of 9%) is about a factor of ten lower than for most other common hydrocarbons. MIE values in the decomposition regime[9] (fuel concentrations greater than about 80%) are very large, ca. 250 J. At elevated pressures, MIE $\propto P^{-n}$, where n = 2 to 3. The quenching distance in air is 0.65 mm. In oxygen, an accurate value has not been determined, but it has been estimated as about 1/6 that in air[9]. To detonate[6], not just ignite, acetylene/air mixtures at ambient pressure requires, in the worst case, a spark energy of 3.7 mJ; this corresponds to a mixture of 40% acetylene/60% oxygen. The needed detonation energy is very sensitive to pressure, but the effect has only been studied for sub-atmospheric pressures. For pure acetylene (without air or oxygen), explosive decomposition is expected at 800ºC at 1 atm and at 540ºC at 2 atm pressure (absolute), the latter being the highest pressure at which pure acetylene is normally handled[7].

Acetylene is an unstable molecule which can undergo several exothermic reactions—polymerization, 'condensation' reactions, and decomposition. Benzene is the most common polymerization product, but an extensive list of other products has been found when acetylene spontaneously regroups into larger molecules[8]. If the resulting product is not composed of identical repeating units, then the reaction is known as condensation instead of polymerization. The activation energy for some condensation reactions is close to zero, indicating they will not need much heating in order to occur. Heterogeneous condensation reactions also occur—many metals act as catalysts upon which condensation reactions can occur. Surface condensations on finely divided platinum, iron, nickel or cobalt occur at room temperature and incandescent temperatures are found. Rapid heterogeneous reactions on many other surfaces can occur at elevated temperatures.

Table 1 Results of analysis of fire debris samples for accelerants at a large commercial forensic testing laboratory during 1997 – 2001

Ignitable liquid found	Percent

turpentine	5.1
paint thinner	4.9
cigarette lighter fluid	1.9
charcoal lighter	1.5
alcohol	1.3
other	5.5

The decomposition of acetylene occurs as:

$$C_2H_2 \rightarrow 2C + H_2$$

the reaction being exothermic, with a very high heat of reaction of 226.7 kJ mol^{-1}. Decomposition does not occur at room temperature without an ignition mechanism, but if an external energy input is provided, explosive decomposition of pure acetylene (i.e., with no oxygen in the system) can occur at ambient temperature (25ºC) under certain conditions. Apart from flames, the ignition mechanism can com-

prise an electrostatic spark, a hot body, or compression heating due to shock. The probability of any particular energy source sufficing to cause a decomposition explosion increases with increasing pressure of the acetylene[16]. Research into the combustion chemistry of acetylene through 1969 has been reviewed by Williams and Smith[9].

Typical safety recommendation is that end users of acetylene should not use gaseous acetylene at pressures over 2 atm (absolute) or 1 atm (gage). This is probably justified by generally good experience when abiding by this recommendation, but research[10] has indicated that it is possible to explode acetylene in small vessels at pressures as low as 1.4 atm (absolute). The vessels in question were 200 mm by 270 mm and 51 mm by 305 mm. The explosion hazard is related to the size of the pipe or vessel, and Zabetakis[4] has reviewed the literature on decomposition explosions of acetylene in pipelines. His summary (Figure 1) indicates that under initial conditions of atmospheric pressure (1 atm abs), deflagration can occur for tube diameters greater than ca. 130 mm. But with increased pressures, even very small tube sizes can sustain an explosion. Detonation at atmospheric pressure has not been observed, but will generally (in the linear portion of the curves) require a diameter about 2× of what is the minimum for deflagration. While these conclusions of Zabetakis are the best available, nonetheless the experimental data on this must be considered scanty. The data of Nelson[11], not specifically included in Zabetakis' analysis, suggest that beyond about 100 mm diameter, the deflagration limit also reaches a plateau and that further increases in pipe size do not lead to lower minimum pressures required for explosion. In some cases, deflagration flames propagating in pipes can turn into detonations if the pipe is long enough. The length required for this to occur is usually from a few to many meters, but decreases for smaller diameters and for higher initial gas pressures[12]. Thus, a small pipe diameter is helpful towards avoiding an explosion, but is a drawback towards avoiding a transition to detonation if an explosion does occur. The compression heating of a Bourdon gage tube due to rapid opening of a cylinder valve has been evaluated and found not to be sufficient to cause compression ignition[8].

Similar guidance is not available at elevated temperatures. Clearly experimental details (sizes, wall materials, exact pressure used) do make some difference since the data spread is so large, but a systematic accounting for these effects is not available.

The decomposition-explosion of pure acetylene using a heated platinum wire as the ignition source was studied by Detz[13]. He found that the wire temperature needed to be raised to quite high temperatures, as indicated in Figure 2.

The temperature required for acetylene to undergo explosive decomposition can be highly influenced by contaminants. Miller and Penny[14] report that, under certain experimental conditions, a small amount of powdered substances such as rust or pipe scale lowered the temperature from 450ºC to 280–300ºC. The explosive decomposition of acetylene can be readily initiated when copper acetylide is present. This substance, itself highly susceptible to explosive decomposition, can serve as initiator for acetylene explosion. A film of copper acetylide can be formed on the inside of copper tubes exposed to acetylene. Such copper acetylide films, however, are much less prone to spontaneous decomposition than copper acetylide produced by wet-chemistry reactions. But wet-chemistry reactions do happen. In gen-

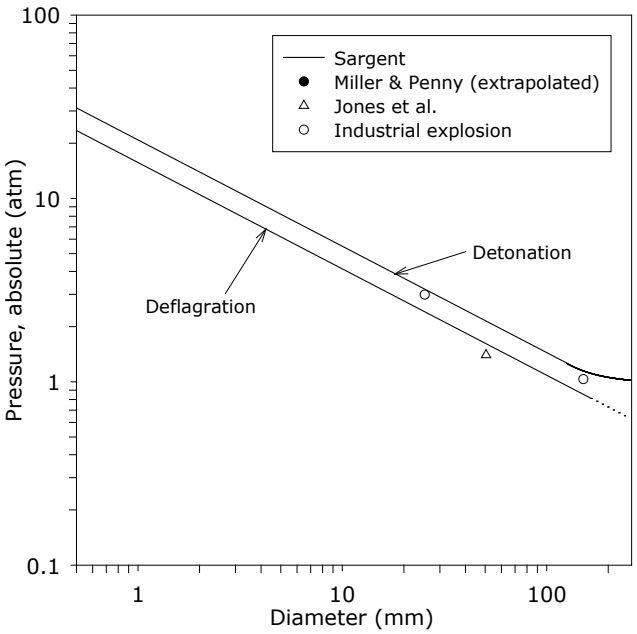

Figure 1 The explosive decomposition limits for acetylene at 25ºC[4]

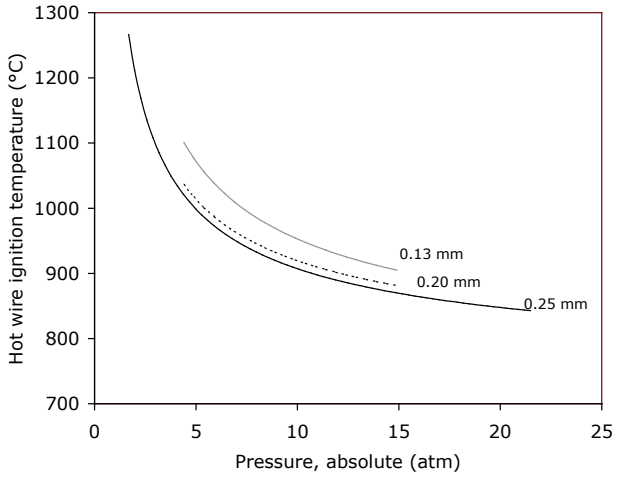

Figure 2 Hot wire temperature needed for decompositional ignition of pure acetylene

eral, the problems found with brass materials are fewer and brass is considered relatively safe[8]. But a series of explosions originating in brass valves of cylinders being filled at a manufacturing plant identified a way that copper acetylide explosions occur[16]. Calcium chloride solution was improperly used for leak testing and this etched some of the brass surface by removing the zinc component and leaving a highly porous, reactive copper surface. The remaining, undried solution reacted with acetylene to form copper acetylide which subsequently detonated. Unfortunately, despite the easy explosibility of copper acetylide under the worst circumstances[15], there does not appear to be any literature quantitatively defining the limits of explosion for copper materials used in conveying acetylene of reasonable purity. Thus, precautions against use of copper fittings are perforce of a vague nature.

It has been found in operating acetylene plants that the most common reason for ignitions is when foreign matter gets on to a valve seat and then gets crushed in operating the valve[16]. Despite this operating experience, the event is difficult to reproduce in laboratory. Miller and Penny[14] conducted numerous laboratory tests under a pressure of 20 atm, but could not produce a single explosion. Their study involved 10,000 tests with a clean valve, 10,000 tests with a valve gritted up with rust and concrete dust, and 10,000 tests where the valve seat was contaminated with a mixture of charcoal and copper acetylide. A standard safety recommendation to minimize the chances of rust or scale sloughing off and getting into valves is to coat the insides of pipes lightly with oil[16]. It has also been found that oil inside valves helps to stop propagation of detonations; the phenomenon is not fully understood, but it is felt to relate to the heat of vaporization needed to gasify the oil.

Admixing other hydrocarbons reduces the explosion potential of acetylene, effectively stabilizing it, although this technique may not always be practicable[10].

Acetylene-air or acetylene-oxygen mixtures in pipes very easily transition from deflagration to detonation, and millimeter lengths (unlike the meters normally required for pure acetylene) may be sufficient for this transition to occur[12].

Detonations in acetylene pipelines can pass through closed valves[16]. Experience indicated that they can pass through any bronze valves, even high-pressure rated ones. Detonations are likely to be stopped by a forged steel valve if the detonation comes from the bonnet side, but not from the under-seat side. Properly installed acetylene plant piping can withstand detonation pressures, but extremely high specification piping is needed.

For a *hot surface* to ignite acetylene, a rather low temperature suffices. Using a brass plate of 1770 mm^2 area, it was found that ignition occurs at 383ºC[17]. Only mixtures within the range of 3 – 40% can be ignited by mechanical sparks[8]. For electric spark ignition, mixtures over 70% acetylene require very large energies—joules, rather than millijoules. At the 100% acetylene limit, about 100 J is needed for ignition.

During the 19th century, acetylene was shipped as a gas, at pressures of 30 – 50 atm. The consequent losses due to explosions proved heavy, and it was soon learnt that acetylene dissolved in acetone is not as sensitive. Thus, it became mandatory that acetylene be shipped in cylinders which are unique in two respects: (1) the volume inside is filled with a porous flame-arrester mass; and (2) the acetylene is dissolved in acetone and not just compressed by itself. In the industry, acetylene shipped this way is known as *dissolved acetylene* (DA). The porous mass traditionally was charcoal and diatomaceous earth. Later, the porous mass used to be a cementitious substance which was reinforced with asbestos and baked in place to provide 90% porosity. This was supplanted by a charcoal-cement matrix, and then by calcium silicate fibers in the cement. Acetone is used because it has the desired properties—acetylene is highly soluble in it at high pressures, but poorly so at ≈ 3 atm (the normal 'empty' pressure of a cylinder). This means that the acetylene can be put solution at the manufacturer, and then obtained in gas form by user. The pressure gage reading of an acetylene tank indicates the actual solution pressure and will change drastically with temperature; the partial pressure of acetylene in a fully-charged tank is around 15 atm.

When an acetylene cylinder is heated externally by a fire or a flame, an explosion may occur. Fatalities have been recorded[18] from explosions that have occurred from modest external flaming impinging upon a cylinder. Heating can also occur due to flashback into the cylinder due to a faulty welding rig or due to improper operation. A standard recommendation[3] states that heating as little as 1 in^2 (6 cm^2) to 185ºC can suffice to start decomposition reactions, which may result in an explosion some hours later; however, it is not clear what quantitative data there may exist to support these values. If the heating is limited, then the hydrogen gas that is evolved from decomposition serves to act as a low thermal conductivity barrier to fresh reactants entering the areas. Thus, curiously, if a partial-pressure relief occurs during an incident like this, a much more disastrous outcome can follow than if the cylinder retains pressure[16]. Bursting discs and fusible plugs are commonly fitted to acetylene cylinders for the purpose of mitigating hazards in such occurrences. But recent HSE experimental studies[19] showed that they may not accomplish their intended purpose and may even make matters worse. Unless a full, early release is obtained, then the partial-release scenario mentioned above comes into play. An undesirable consequence of the operation of a fusible plug may be the overheating of an adjacent acetylene cylinder. Fusible plugs are sometimes mounted in a way as to make them susceptible to mechanical damage in handling the cylinder. In those cases, a leak may occur at the plug and this may be hard to notice.

Fire service operations when acetylene cylinders have been exposed to fire (or localized heating) can become dangerous. The common advice given to alleviate this potential of explosion when heating has taken place is to apply copious cooling water. However, tests have indicated that even cylinders which have been visibly and palpably cooled down can subsequently self-heat and explode up to 24 h later[19-21]. The best advice for situations where an ongoing fire is threatening acetylene cylinders appears to be one offered by the Swedish fire services: When circumstances permit, a sharpshooter is to shoot holes in the cylinder with tracer bullets at top, middle, and bottom. This causes an immediate discharge and ignition of the outflowing gas, eliminating the danger of an unexpected explosion.

Welding torches are designed so that acetylene and oxygen only come together at the torch. Flashback of a flame into an acetylene cylinder is not rare, but generally without serious consequences, due to the design of dissolved acetylene cylinders. But accidents have been reported where flashback followed the hoses into the cylinder and the cylinder exploded[22]. Some accidents have been caused by welders carelessly leaving a torch burning and hanging it over a cylinder; a hole is then burned in the cylinder by the flame[26]. The acetylene in cylinders occasionally undergoes spontaneous decomposition, but the overpressure created normally does not lead to an explosion[26].

Current US practice involves using color-coded and sized check valves in the system to prevent oxygen from being pushed back into the acetylene hose and torch. These check valves can be placed on the inlet to the torch, at every hose connection and at the regulator. Normal acetylene pressures for welding and cutting range from 35 to 50 kPa, but oxygen pressures are generally set relative to the thickness of metal being cut. For torch welding, pressures range from 25 to 175 kPa, but pressures over 700 kPa are not uncommon when cutting steel over 50 mm thick. Even higher pressures may be required if the cutting is conducted underwater. Because of the difference in pressure between the two gasses, it is readily apparent that the high pressure oxygen can easily flow back into the hose and cylinder in the event of a plugged tip and a damaged or missing check valve. Another problem that can occur is when a plugged tip forces the combustion inside the tip which can result in rapid damage to the torch components.

In general, acetylene cylinders can sustain a huge amount of mechanical abuse without exploding. Cylinders have been documented to be crushed into an hourglass shape or have wrinkles in the steel and yet survive[16]. Nonetheless, explosions have occurred in the course of what would appear to be modest mistreatment[23]. It is generally unwise to attempt to cut up acetylene cylinders for scrap, and fatalities have been recorded among individuals doing this[16]. A case has been reported[24] where two individuals filled a plastic bag with a mixture of acetylene and oxygen; the bag exploded while they were transporting it in their car. When the valve of an acetylene tank is opened and a jet of gas is discharged into the air, ignitions have occurred upon the jet impacting a person's hand[26]. The mechanism is electrostatic charging and is made possible by the entrainment of minute acetone droplets into the acetylene stream.

Vinylacetylene (C_4H_4) is the dimer of acetylene:

$$2\ HC{\equiv}CH \rightarrow HC{\equiv}CCH{=}CH_2$$

It has a wide variety of industrial uses and has similar stability problems to those of acetylene[11]. Explosive decomposition can occur in both liquid and vapor phases. This problem has also been studied in certain mixtures which include vinylacetylene[25]. For a given diameter, the pressure required to explode vinylacetylene is somewhat lower than for acetylene[11].

A variety of other *acetylenic compounds* (having the bond C≡C) exist and many are prone to explosive decomposition[3]. Methyl acetylene (propyne, $H_3C–C{\equiv}CH$) is commonly used in welding applications in the mixture MAPP, which is named after its two primary constituents, methyl acetylene and propadiene (allene, $H_2C{=}C{=}CH_2$), but also contains a variety of other hydrocarbons[*]. Diacetylene (1,3-butadiyne, $H–C{\equiv}C–C{\equiv}C–H$) and 1,3,5-hexatriyne ($H–C{\equiv}C–C{\equiv}C–C{\equiv}C–H$) are exceptionally unstable compounds, but without commercial applications. Also unstable are the haloacetylenic compounds, which have the structure $–C{\equiv}CX$, for instance, chloroacetylene ($H–C{\equiv}C–Cl$) and dibromoacetylene ($Br–C{\equiv}C–Br$). Chloroacetylene is a notably unstable compound, with a pressure limit[26] of 0.0065 atm.

Aerosol cans

The compressed gas propellant for aerosol cans used to be Freon or other halogenated gases which were, roughly speaking, fire extinguishants. With the environmental issue of eliminating use of ozone-destroying halogenated chemicals, the Freon propellants have been replaced with highly flammable gases, typically, propane, *iso*-butane, or dimethyl ether. The consequence has been a number of unanticipated accidents; DeHaan and Howard[27] have reviewed some of those. In several cases, houses have been destroyed when excessive numbers of aerosol flea foggers were discharged and the vapors explosively ignited. In another case, a room freshener can fell into a washing machine, the contents discharged and an explosion resulted when the vapors were ignited by a spark. An explosion demolished a 27,000 m^2 warehouse when the operator of a forklift truck ran over an aerosol can[22]. As is general practice in the industry, the truck was not designed for use in flammable atmospheres and could readily present ignition sources once a flammable atmosphere was created. A factory explosion took place when equipment filling spray cans with powdered shampoo and a butane propellant failed and two cans were acci-

[*] One typical analysis gave 37.8% methyl acetylene, 26.1% propadiene, 18% propane, 10% *n*-butane, 7.4% propylene, with minor amounts of other hydrocarbons.

dentally discharged[28]. The investigation revealed that the two-phase flow (solid particles + propellant) is particularly susceptible to electrostatic charging, but that the accident only occurred because the cans were very well electrically insulated and could be charged up to 35 kV. If a can were held by a person, a charging voltage of only about 2.7 kV could be achieved and this would not be incendive. A study concluded that serious accidents involving aerosol cans in Europe have been exceedingly rare[29].

A number of burn injuries have occurred due to aerosol cans failing. In some instances, the discharge occurs due to a valve failure, but a case is also reported[30] where a metallurgical failure caused a can's bottom to separate simply upon manually shaking an aerosol paint can. Aerosol cans should never be heated, but a case is reported where a woman was badly burned in attempting to heat an aerosol can in a microwave oven[31]. An aerosol can which is apparently 'empty' may contain sufficient flammable gas to explode, if it is heated or thrown into a fire[32]. Many explosions have occurred when cans of lubricant spray were used around electrical equipment, dropped and ignited by the arcing. This can occur with a car battery or around energized equipment in buildings.

Aerosol can fires and explosions can have significant consequences in aircraft. To minimize the consequences, improved can designs have been explored[33]. These showed delays in the time needed for a fireball to develop, but the safety implications of this delay is not necessarily clear.

Agricultural products

SELF-HEATING

A wide variety of agricultural products are susceptible to self-heating. These include clover, fishmeal, hay, malt, peat, starch, straw, tobacco, and various types of seed, grain, fodder, fertilizers, yeasts, soybeans and soybean products[34]. The exothermicity can involve any or all of:

- oxidation;
- oxidative polymerization of unsaturated oils;
- fungal (microflora) or bacterial action;
- fermentation (of sugars); and
- moisture (this is not sufficient as a sole cause, but can interact with the other sources of exothermicity).

Specific sections in this Chapter are devoted to *Bagasse; Cotton*; *Feedstuffs*; *Forest materials, vegetation, and hay*; *Hops*; *Jute*; *Marijuana and hemp*; *Peat*; *Rice husks*; *Soybeans*; *Sugar*; and *Wool*.

Some of the very earliest experiments in self-heating and spontaneous combustion are those that were done on grains. Medem[35] reports on studies in this area that an apothecary named Rüde was doing in 1782. Quantitative modeling has occasionally been attempted on agricultural products of various sorts, but the potential of deriving meaningful data is generally limited. Studies have typically been undertaken only on dry, clean, pure substances, but spontaneous combustion problems are the most likely to occur when none of these three conditions hold.

Rail-car loads of wheat being shipped will sometimes self-heat and smolder. In an early study, Bailey[36,37] investigated such occurrences and concluded that moisture was an important factor. He concluded that only wheat with a moisture content over 14.5% will show self-heating.

In general, self-heating in agricultural products has three main causes: (1) cell respiration; (2) thermogenic microflora; and (3) oxidation. Of these, cell respiration is considered to be only a minor contributor[38]. Microflora need a moist environment to flourish; for RH below 74% in the interstitial air space, self-heating due to microflora is unlikely[39].

Self-heating stemming from bacterial and mold growth can be reduced by the use of agents which inhibit such growth. These include acetic, ascorbic, and propionic acids. The latter also arrests biological functions of grain cells, reducing another source of heat generation.

Nut shells, copra, and olive oil presscake residues self-heat readily[40]. Seeds self-heat more slowly than other types of agricultural products, because nature has designed them to oxidize very slowly in order to survive prolonged periods prior to germination[41]. Case histories involving self-heating of corn, fishmeal, fodder, palm products, rapeseed flour, starch, sunflower seeds, wheat bran, and yeast have been reviewed[42]. A fire due to self-heating of bagged rapeseed has been reported[445], but the quantity involved was immense, around 400×10^3 kg, so this is not surprising. An extensive study of palm kernels was one of the earliest investigations in which scientific theory was applied to making practical predictions of self-heating[43]. Spent brewing grains, that is, barley from which malt has been extracted are known to have caused spontaneous combustion fires; their common use is as an animal feedstuff. Walker[44] has studied the self-heating behavior in laboratory tests. His data indicate E = 54 kJ mol^{-1}, P = 33.7. Extrapolation from these values indicate that at room temperature a pile of a couple meters in size would undergo thermal runaway. Bowes[445] reported data on a similar substance, distillers' dark grains, which gave E = 66.9 kJ mol^{-1}, P = 39.1. Self-heating tendency in seeds and seed meals is usually proportional to their fat content[34], but for a given fraction of fats, self-heating must also be considered as proportional to the degree of unsaturation (see *Oils*).

Yeast dusts accumulating in a spray-drying facility have led to self-heating and fire. In one case[45], a layer 40 mm thick at a temperature of 120ºC was the cause. Laboratory tests on 100 mm cubes showed thermal runaway at 165ºC.

A highly detailed manual by Mills[46] gives operators of agricultural facilities guidance for avoiding spontaneous combustion and for firefighting in case of fire.

ELECTROSTATIC PROPERTIES

Solids moved through pipes or tubes can pick up an electric charge. As early as 1919, the US Dept. of Agriculture issued an advisory[47] explaining that the then-rampant fires in cotton gins could be largely prevented by proper grounding of metal machine parts. Electrostatic charging of grains conveyed along metal or polyethylene surfaces was studied by Dahn[48]. Charge accumulation, expressed in units of energy/mass was 0.4 mJ kg^{-1} or less when using a steel surface, but up to 2 – 6 mJ kg^{-1} along the plastic surface. The dielectric constant was typically 4 – 12, but varied greatly with moisture, as lower moisture levels gave lower dielectric constants. The resistivity, measured at 6 kV, was commonly 10^7 – 10^9 Ω-m. In some cases, moisture had a profound effect, with wheat at 11.6% moisture being 4×10^8 Ω-m, while at 13.8% the resistivity dropped to 2×10^7 Ω-m. A typical charge[49] obtained from pouring corn down metal tubes is 2.5×10^{-9} C kg^{-1}.

Air compressors and compressed air systems

Fires and explosions of air compressors occasionally occur, with the combustible being the oil used for lubrication or cooling. Details on a number of incidents have been published[50]. Oil-flooded rotary screw compressors, such as are used in heavy industry, are particularly prone to accidental fire/explosion events[51]. Fowle[52] reported one explosion with 19 fatalities and another with seven. Three main causes have been found to be:

(1) shocks;
(2) excessive temperatures; Fowle suggested that temperatures over 250ºC are excessive, but extensive research studies and accident analyses[59] indicate that temperature over 135ºC are notably hazardous;
(3) sudden pressurization of piping.

Explosions of reciprocating type compressors having oil-lubricated cylinders commonly show the following traits[53]:

(a) the compressor itself is undamaged;
(b) carbonaceous residues are found in the vicinity and immediately downstream of the final stage outlet valves;
(c) faulty operation of the compressor was noted for some time, with high final-stage outlet temperatures (over 135ºC) observed;
(d) the pipe system is blown open at discrete points, separated by unshattered portions.

Empirically, multi-stage reciprocating compressors are safer than single stage. Explosions in turbine compressors are rare, since these do not introduce oil into the working volume. Compressing air to very high pressures in the presence of lubricating oil appears to be an intrinsically unsafe operation, even at low temperatures, as shown by one six-fatality accident[54] in which the explosion occurred on the return side piping of an air compressor where the temperature was only 29ºC. 'Shock' sometimes involves a small explosion which then sets off a more serious one. The Bureau of Mines reviewed several studies on this ignition mechanism[55].

Films of lubricating oils have been shown to ignite at a temperature of 120ºC under a compression of 31:1 and at 160ºC under a compression of 18:1. In rotary compressors, self-heating due to oxidation of oil-soaked reclaimer pads is another cause. Oxidation of mineral oils is generally moderate, but ignitions have been observed when the oil cooling system fails and temperatures rise over 300ºC. Some explosions in various types of compressors are attributed to buildups of oil films that progressively oxidize to a carbonaceous semi-solid mass. Buildup is especially a problem if SAE 10 weight or more viscous oils are used. The buildup level in cases where fires have occurred has typically been extreme—10 mm or more. The area most prone to buildup is the piping between the compressor outlet and the receiver. Rust is considered to catalytically promote the oxidation of lubricating oils. In general, some malfunctions of valves or cooling system, or blocked air filters, or other faults that serve to raise temperature in certain areas of the system are common causes of compressor explosions or fires. In one specific case, operation of a portable compressor in extremely cold weather caused the cooling oil (ATF) to jell and an explosion occurred in the receiver. Loss of cooling oil leads to two forms of overheating: (a) it is not longer possible to remove the heat of compression being produced by the unit; and (b) oil is used to create a seal at the rotor interface; if this seal is lost, then air is internally recirculated and this process can lead to a buildup of high temperatures. This scenario was recreated in a laboratory experiment[56].

Chase[57] studied some of the details of the process and concluded that compression serves to create high gas velocities across the face of the oil film. This causes much more rapid evaporation than would be possible otherwise. The oil film also receives heating from the hot compressed air adjacent to it. With the temperature raised and vaporization mechanism greatly enhanced, sufficient oil can be vaporized to create a flammable mixture. Chase also conducted experimental studies and found that the initial equivalence ratio (representing the vapor in the air prior to compression) along with the compression ratio served to characterize the ignitability of the oil (Figure 3). For an explosion to occur, sufficient oil vapor has to be present to reach the LFL. If the system (and the oil) are initially at a low enough temperature, the LFL will not be attained. But Chase found experimentally[58] that rather modest initial temperatures, on the order of 150ºC for common lubricating oils, suffice to cause the LFL to be exceeded. Even under conditions where sufficient oil cannot be vaporized, it may be put into a mist by the effect of vibrations[59]. Explosions originating in an oil film are likely to be detonations[53].

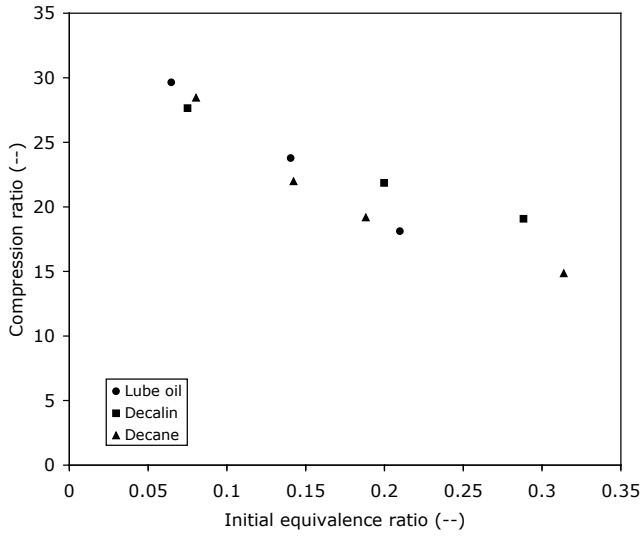

Figure 3 Relation between minimum compression ratio and minimum initial equivalence ratio necessary for compression ignition of several substances

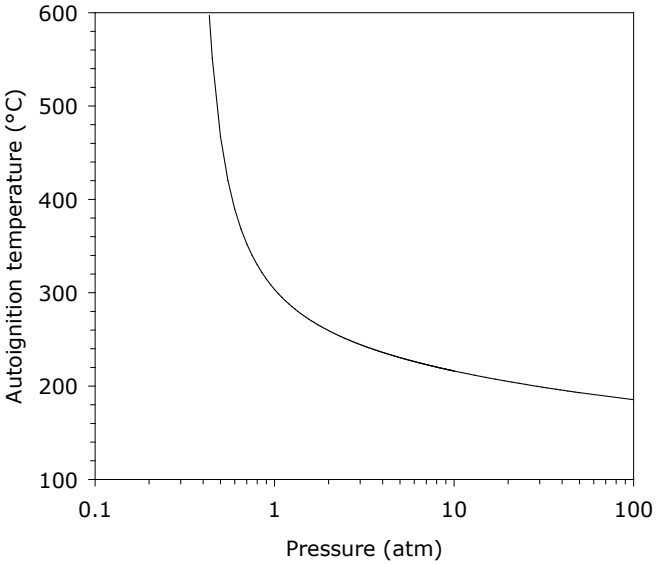

Figure 4 Effect of pressure on the AIT of compressor oil

The major mechanism for explosions however is considered to be not oil film detonations but ignition of carbonaceous residues built up on internal surfaces of a compressor. The Bureau of Mines[60] investigated these carbon formations and found that they are susceptible to exothermic reactions if heated over about 150ºC. Chemical analysis of soots removed from air compressors showed high percentages (15 – 34%, by mass) of oxygen in the soot and this was taken to suggest that an oxygen chemisorption mechanism may be involved. The authors also noted that some incidents of carbon monoxide poisoning have been occurred when breathing air was supplied from an air compressor. This, they concluded, was most likely due to partial combustion within the air compressor, so that an explosion did not result, but CO was generated. High flash-point oils are no longer felt desirable, since these do not reduce the detonation potential, yet lead to greater carbon buildup[53]. Naphthenic mineral oils are safer than paraffinic, since they produce softer residues that are less likely to interfere with outlet valve operation[53]. Narrow-cut fractions are preferred, since these leave fewer residues. Phosphate ester oils can provide enhanced safety, but should only be used on compressors designed for their use.

Laing and Russell[61] conducted experiments which led them to conclude that with oil-flooded rotary-screw compressors, the dominant cause of explosion is failure of oil supply, with an explosion typically occurring when the oil has reached its AIT (Figure 4), which for a compressor delivering air at 8 atm (absolute) is about 220ºC. In their experiments, they noted that the explosion typically originated in the separator and that 15 – 16 atm was commonly the peak pressure attained. For an unexplained reason, it was found that fresh oil was somewhat more prone to explosion than well-used oil.

Another explanation was provided by Loison[62], who considers that the catalytic effect of iron rust is highly dangerous. In the course of investigating some explosions in large-diameter (250 mm) compressed-air piping, he conducted a series of laboratory experiments. In an initial trial, oxygen was flowed through a pipe which was coated with a film of lubricating oil. Ignition occurred when the system reached 300ºC. But when a layer of rust was introduced into the pipe, the ignition temperature dropped to 160ºC, and dropped further to 150ºC when ferric hydrate, $Fe(OH)_3$ was used instead of actual rust. Further experiments were conducted with air. The most dangerous condition found was one where air flow was stopped and then re-started. Under that condition, an ignition temperature of 207ºC was found with iron rust and 151 – 157ºC with ferric hydrate. Loison points out that his experimental arrangement in the second series was a bit unrealistic in that the oil was applied as plug within the pipe and not as a film, nonetheless, he felt that prudent operation should consider ignition likely if temperatures in the vicinity of 150ºC are reached. These temperatures, unfortunately, are readily reached in high-capacity air compressors if they are not clean and scrupulously maintained. In some further experiments, he prepared pipes with various amounts of oil film and initiated an explosion via a frangible membrane connecting to an explosion initiation chamber where a flammable mixture was ignited. The violence of the destruction of the oil-coated pipe proved to be proportional to the amount of oil contained, with about 0.3 mm film thickness being the minimum. It was also observed that after the explosion the oil film was gone and was replaced by a coating of soot. The violent explosions had a detonation character, with velocities up to 1200 m s^{-1} being recorded. In the original accident

investigation, it had been speculated that the pipe explosion possibly was because an explosive was inadvertently set off in the vicinity of the pipe. To test this theory, Loison filled pipes with hydrogen/air mixtures and detonated explosives close by. Small explosions could be produced, but these only yielded one crack per pipe, not the extensive fracturing found in the real accident and in the oil-film experiments. Japanese investigators[63] found that a soot film itself can be detonated and concluded that this can explain certain explosions in compressed-air pipelines.

Apart from autoignition, piloted ignition can occur due to frictional sparks. But unexpected temperature increases, sufficient for autoignition, have been found in connection with malfunctioning valves[59].

Fires involving air compressor lubrication oil may also be externally ignited, for example, a detailed case history is presented of a fire which followed mechanical failure that led to rupture of an oil line and spraying of oil from it[64]. Vibration of fabric or rubber materials in a compressed air system can lead to sufficient heating so as to ignite the material. This was found in accidents and reproduced in the laboratory[26,65]. The materials can be located in flexible couplings, patches, etc. Luzik[66] has provided a check list of maintenance items to check to prevent explosions of oil-flooded rotary screw compressors.

When a valve is rapidly opened from a compressor to an air line, it is common to see a shower of sparks, created by frictional heating of rust and other debris in the air line. But, if upon opening an air valve, an explosion of a dust cloud takes place, the incandescent particles have been found not to be the cause. Instead, it is due to static charging of the dust[67]; experiments[68] indicated that incandescent particles ejected from compressors are of too low temperature/too small size to ignite methane/air atmospheres. Flammable gas atmospheres have also been ignited in the absence of dust clouds, simple by static charging of small debris moving in the air line. If high-pressure air is quickly admitted into a pipeline containing lubricating oil, an explosion is quite possible, due to adiabatic compression. One experimental study[69] showed that temperatures up to 650ºC were easily created by rapid valve operation. Because of the decrease in AIT of lubricating oils with increasing pressure, this mode of ignition presents a severe hazard.

Some large internal combustion engines are started by supplying air pressure to the cylinders from an air compressor. A check valve is used at the cylinder to prevent reverse flow of combustion products into the compressed air line. A number of explosions have occurred upon starting such engines, and Ridgway[70] hypothesized that these normally originate at the engine, not at the air compressor. If the check valve fails to operate properly, then a combustible mixture can be injected backwards into the compressed air line, thereby causing an explosion within the piping.

Aircraft cabin wall panels

Commercial aircraft have cabin walls constructed of a honeycomb composite which comprises fiber/resin face panels and a Nomex honeycomb structure. Harkleroad[71] tested the ignition performance of some commercial and developmental panels. Conventional epoxy/fiberglass/Nomex composites required 20 kW m^{-2} for radiant piloted ignition. Substituting Kevlar for fiberglass raised this value to 23 kW m^{-2}. Panels where phenolic was used instead of graphite required 34 – 36 kW m^{-2}.

Airplanes

Airplanes in flight can become charged to an extremely high potential of ca. 500 kV due to frictional contact with atmospheric particles[72]. Frictional charging is speed dependent, and varies roughly as the third power of velocity. Frictional charging is the strongest from dry particulate matter (e.g., ice crystals or dust); charging due to wet snowflakes is small[73]. The majority of discharges involving airplanes are corona or brush discharges (commonly referred to as St. Elmo's fire) and do not lead to significant damage.

But fires and explosions can occur due to lightning strikes of airplanes. Pilots may not be able to avoid lightning activity, since, according to one study[73], in over 50% of the cases where a strike was reported, there was no lightning activity visible to pilot, and in 11% of the cases there was no precipitation at all. Furthermore, theoretical considerations indicate that the mere entry of the aircraft into a zone of high electric field will increase the potential gradient and this may be sufficient to lead to breakdown and discharge.

Lightning strikes to aircraft are normally innocuous, but on some occasions can puncture fuel tanks and lead to tank explosions. Robb et al.[74] conducted laboratory simulations of lightning strikes to fuel tanks holding aviation gasoline and JP-5 fuel. For strikes that punctured the tank wall, they found that explosions did not occur when the mixture was above the UFL. Explosions did occur in mixtures significantly below the LFL, and this was seen to start with a local ignition by a spark shower from the puncture, escalating to a full explosion of the ullage space. A puncture can also lead to an external fire, but these generally have much less severe consequences and sometimes are even self-extinguished by wind velocity. The authors also noted that lightning-caused explosions of tanks holding aviation gasoline would be extremely uncommon, since the mixture will generally be highly over-rich in flight. By contrast, the temperature range at which most lightning strikes have been recorded, –10 to +10ºC, is within the flammability temperature limits of JP-4, which is thus seen as the most susceptible aviation fuel. Oh and Schneider[75] conducted another series of experiments simulating lightning strikes to airplane skin. The discharge conditions needed to puncture aluminum skin and titanium skin of various thicknesses were characterized. A lightning discharge that transferred about 10 coulombs of charge was found sufficient—in

worst-case circumstances—to cause a puncture (and a likely ignition of fuel) of a 2 mm thick aluminum skin. This is an extreme case and general guidance[76] is that it would take 200 C to puncture 2 mm skin.

See also: *Aviation fuels*.

Alcoholic beverages

Tests have indicated that alcoholic beverages of over 100 proof (US)* can be ignited directly by a match[77]. For such high-proof beverages, one specific hazard can be propagating of fire back into a bottle, whereby the bottle then becomes an effective flame thrower. Plastic inserts are now provided on some bottles that deflect the jet of liquid. Beverages below 100 proof require a wick to be ignited. Flash points[78] for beverages of various concentrations are shown in Figure 5.

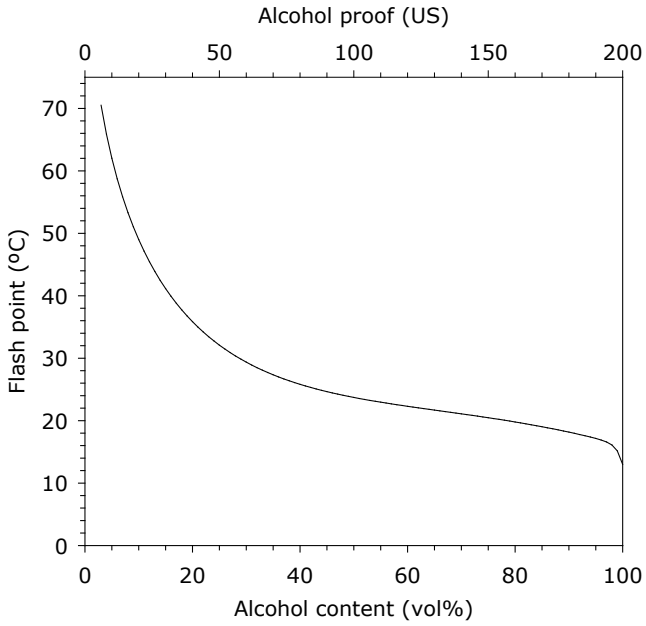

Figure 5 Flash point of alcoholic beverages

Aldehydes

Aldehydes are organic substances having a –CHO group and a number of them are highly reactive and, under certain circumstances, prone to explosion. Britton[79] examined a number of ignition-related features for several aldehydes. The minimum oxygen concentration for combustion of propionaldehyde was found to be 7%, which is unusually low. The AIT for propionaldehyde and butyraldehyde was found to be strongly influenced by pressure, dropping from 185ºC at 1 atm to 90ºC at 9.5 atm. Iron rust was also found to act catalytically towards promoting ignition of aldehydes.

* Proof of alcoholic beverages is defined as proof = 2× alcohol content in the US and as proof = 1.75× alcohol content in the UK.

Ammonia

Anhydrous ammonia (NH_3) is one of the oldest refrigerants and is commonly used in industrial refrigeration facilities. It does not show a flash point in standard flash point testing, consequently, it is sometimes erroneously described as "non-flammable." In fact, ammonia has flammability limits[80] of approximately 15 – 28%, and a high, but a readily measurable AIT of 651ºC. The pressure limit is 9.6 kPa; in other words, ammonia/air mixtures will not sustain flame propagation (at any ammonia concentration) if the total system pressure is lowered below this value. Decomposition begins at 450 – 500ºC. The MOC is around 17% at room temperature decreasing to ca. 11% at 400ºC. The MIE value is usually taken as 680 mJ, although there is a very wide spread of data in the literature[80], all the way down to 8 mJ. At elevated temperatures, ammonia decomposes into nitrogen and hydrogen; the hydrogen then becomes available for burning with oxygen. Not only can ammonia burn, but also detonate[81]. As Urben[3] puts it, "There is a long history of violent [ammonia] gas-air explosions in refrigeration practice." These have continued into modern times[82-86]. In one of the cases[84], the explosion was initiated from the hot filament of an incandescent lamp when cold ammonia gas reached a 300 W lamp and broke the glass envelope. Explosions have also occurred associated with deliveries of the bulk material. If liquid ammonia is accidentally mixed with refrigerant R-22, the tank will overpressurize and a solid residue will be formed in the reaction. Médard[26] claims that explosions inevitably require a confined atmosphere and that ignition is not possible in open air, but it is not clear whether this can always be relied upon. AIChE holds an annual symposium, *Ammonia Plant Safety*, the proceedings of which are published.

Ammonium nitrate and ANFO

Ammonium nitrate, NH_4NO_3, is a white crystalline solid which is widely used as an ingredient of fertilizer mixes. It can also act as an explosive. Its behavior is complicated by the fact that 5 different crystalline forms are found within different temperature ranges at ambient pressure, with a sixth found at high pressures. An additional complication is that it is a strongly hygroscopic material. Pure ammonium nitrate (AN) is stable at room temperature. In his review, Médard[26] concluded that not a single case could be found of an accidental explosion of pure, unheated AN. At elevated temperatures AN can thermally decompose in a variety of different ways, with the two most common ones being:

$$NH_4NO_3 \rightarrow N_2O + 2H_2O$$
$$2NH_4NO_3 \rightarrow 2N_2 + 4H_2O + O_2$$

The first reaction occurs during slow heating, while second reaction is the one which predominates in an explosion. AN has a melting point of 170ºC. In tests on small quantities, it is unstable above 200ºC and shows explosive decomposition[97] at 260 – 300ºC. But since—in at least some of its decomposition pathways—it is an exothermically decomposing material, critical temperatures can progressively drop with increasing sample mass. At about 100ºC, AN

starts reacting directly with organic materials[26] and the process may lead to ignition.

Since the elevated-temperature decomposition reaction produces oxygen, reaction is more potent if a fuel molecule is present. Thus, ammonium nitrate is normally combined with a fuel in order to give a commercially useful explosive. The explosive mixture ANFO is made combining prilled ammonium nitrate (AN), and fuel oil (FO). The amount of fuel oil added is about 6% of the mass of the ammonium nitrate, the amount necessary to make the mixture oxygen-balanced. Such an ANFO mixture is classified as a 'blasting agent,' since it cannot be detonated with a blasting cap. Not all grades of AN can make suitable ANFO. Three grades are commercially available:

(1) Explosive grade. This has a bulk density around 1050 kg m^{-3} and a particle size of 0.15 mm or less. The material is nearly pure, with few if any additives.
(2) Fertilizer grade. This has a bulk density around 1050 kg m^{-3}, a particle size around 2 mm, and includes anti-caking agents such as kaolin or diatomaceous earth. The type of anti-caking agent used has a definite effect on the suitability of the material for use as ANFO.
(3) Porous grade. This has a bulk density of 650 – 800 kg m^{-3} and particle size around 2 mm, with <1% anticaking agents included.

The porosity of the porous prills allows intimate absorption of fuel oil and is needed to produce a good quality explosive. The confusing nomenclature predates the commercialization of ANFO, which occurred during the mid-1950s; explosives based on non-porous AN were used in the 1930s but are not in use today.

For pure ammonium nitrate to explode requires confinement and extreme heating or else the use of a priming charge much more powerful than a blasting cap. It was known in 1835 that AN[87] can detonate, but subsequently many individuals dismissed the possibility. It was very graphically confirmed during an explosion at the BASF factory in Oppau, Germany in 1921 that when blasted with another explosive, ammonium nitrate indeed detonates. The Oppau factory manufactured an ammonium nitrate/ammonium sulfate fertilizer and workers regularly dislodged caked fertilizer with explosives, until the accident that claimed 509 lives. The explosion was 'imperfect,' in that only about 10% of a 4500 tonne cache actually exploded. An essentially identical procedure being performed on 99.5% pure AN in another German town, Kriewald, two months earlier led to only 19 fatalities; consequently its lessons were not learnt. Even after the Oppau disaster, an almost repeat incident cost several hundred lives at Tessenderloo, Belgium in 1942.

The 1947 Texas City disaster proved that large amounts and high heat can detonate ammonium nitrate and initiation with a priming charge is not required. The incident started when S.S. GRANDCAMP, a ship carrying ammonium nitrate fertilizer caught fire[88]. As a consequence, multiple fires were ignited, S.S. HIGH FLYER, a nearby ship with the same cargo also detonated, and 552 lives were lost. The original fire occurred during loading of the ship, so it was not attributable to self-heating; most probable cause was judged to be discarded smoker's materials. A nearby warehouse containing the same fertilizer as loaded on board the ships ignited during the incident, but only burned and did not explode. In 1948, the tragedy was repeated in another AN fertilizer explosion, destroying the ship OCEAN LIBERTY in the harbor of Brest, France, where 21 lives were lost. In 1952, AN exploded in a factory in Nagoya, Japan, killing 22. As recently as September 2001, an AN explosion in Toulouse, France, caused 29 fatalities.

In 1988 an incendiary fire involving a trailer where ANFO was stored led to a massive explosion and firefighter fatalities. The explosive potential of ammonium nitrate was again illustrated on 19 April 1995, when terrorists partly demolished the Alfred P. Murrah Federal Building in Oklahoma City by filling a truck with about 2 tons of ammonium nitrate and nitromethane. The priming charge used was probably a detonating cord. The explosion when using nitromethane is more potent than with fuel oil, since nitromethane is an explosive substance in its own right. Numerous other case histories of accidental AN explosions have been published[87,89]. While accidental detonations certainly have occurred, the record indicates that fires have been more common than detonations. A number of these have been caused by self-heating of impure AN. Scott and Grant[87] published an extensive review of the chemical and explosive properties of AN (but not ANFO) and also provided a number of case histories. Other collections of case histories have been compiled by Médard[26] and by Fedoroff et al.[90]

Van Dolah et al.[91] showed that the sensitivity of AN increases with temperature; results from testing in a card gap test indicated that above 130ºC, AN becomes much more sensitive. There is a strong diameter effect in this relation, with large diameters (greater than about 0.15 – 0.30 m) were found to be detonable at room temperature using a pipe-bomb geometry. When heated to elevated temperatures (as could happen in ship's fire), an 0.075 m diameter pipe bomb detonated in another Bureau of Mines test[97]. In attempting to recreate an AN detonation which occurred in a train wreck, Van Dolah found that a detonation created when fuming nitric acid was poured onto a pool of burning gasoline could sympathetically detonate adjacent AN, provided the latter was present in sizes greater than the critical diameter. AN was found to be detonable by high-velocity rifle bullets, but, unlike the real-life Kriewald incident, preheating was required in the experiments. Shock waves from detonations of gas/air mixtures were found not to detonate AN. A number of unconfined burning experiments, including ones of almost real-scale, were conducted with AN, but none of these resulted in detonations. Another part of the research of Van Dolah was addressed towards attempting to

explain a detonation which leveled a factory where ANFO was being prepared. On the basis of the fire tests conducted, he was not able elucidate the mechanism. In a British study cited by Médard[26], piles of 45 – 70 tonnes of AN were burned but did not explode. The AN was in paper sacks or paper-lined drums, but unconfined in those tests. Médard also collected a number of other research studies which gave negative findings on the explosibility of AN. There is some evidence in small-scale tests that confinement has to permit pressures over 100 atm to be developed for detonation to occur with pure AN, but this is scarcely pertinent to accidental explosions, most of which involved ANFO or AN with another contaminant. In general, it should be noted that very few tests exist where the properties of ANFO would have been explored in realistic scenarios.

A study of AN and ANFO in 1 × 1 m cylinders showed that sympathetic detonations[92] can be occur as far away as 16 m, although most trials gave detonations out to only about 4 m.

At a density of 650 kg m^{-3}, the critical diameter for detonation of pure AN without confinement was found to be 100 mm[26]. At a density of 520 kg m^{-3}, the critical diameter is less than 40 mm. At a density of 1000 kg m^{-3}, the critical diameter surpasses 320 mm. In general, as the density decreases, detonation becomes easier. ANFO is easier to detonate, and the critical diameter even at a high density of 1000 kg m^{-3} was found to be less than 30 mm when tested in a thin metal tube. In tests by Arai et al.[93], steel tubes of 36 mm diameter were found to be sufficient for the detonation of ANFO at a density of 860 kg m^{-3}. When confined in plastic tubes of 40 – 41 mm diameter, the results depended on the type of plastic and the wall thickness. PMMA tubes 2 mm thick sufficed, but PE tubes even of 3.5 mm thickness did not. No detonation was obtained in Pyrex glass tubes of 2.4 mm thickness and 40 mm diameter. The failure of detonation for PE was due to a large deformation that the material could successfully sustain. For Pyrex, the reason was the opposite—the tube fractured so quickly that effective containment was lost. About 0.2% fuel oil is the minimum organic content which causes a detectable increase in the explosibility of AN. Another study[94] found for pure AN a critical diameter of 125 mm at 1020 kg m^{-3} and 200 mm at 880 kg m^{-3}, while ANFO showed 100 mm at 820 – 880 kg m^{-3}. The Bureau of Mines[95] was readily able to detonate most fertilizer-grade AN samples by electrically heating a cylindrical steel bomb having a 75 mm I.D; the temperature of the AN at the time of explosion was typically 300ºC but the density of the tested specimens was not reported.

It is interesting to note that while the ship detonation disasters did not explicitly involve a fuel component, a fuel was in fact present in the form of an anticaking wax applied to the AN in the amount of 0.75% – 1% . Without this adventitious fuel, the explosions might have been much less severe, since even this small amount of wax substantially sensitizes the AN. The sensitization of AN by organic coatings was known as early as 1921, but evidently failed to be appreciated until after the Texas City disaster. Subsequently, in commercial fertilizer production, the wax was replaced by a diatomaceous earth coating, which does not act as fuel. Another factor helping create the large explosions was the reactivity between the paper bags and the AN[96].

Zinc has been found to be a synergist for ANFO[97]. Apart from deliberate introduction in powdered form, zinc could also be available from the coating on galvanized pipes, in the case of pipe bombs. The explosion of the S.S. HIGH FLYER was likely exacerbated by the presence of sulfur. The ship was also hauling a cargo of sulfur and cross-contamination was found. Testing[88] indicated that sulfur-contaminated AN can explode under conditions in which uncontaminated AN will not. An investigation after the Oppau explosion[26] examined the effect of mixture fraction on explosibility of AN/ammonium sulfate mixtures. It was found that results were very sensitive to the ratio and that mixtures with AN at less than 40% were vastly safer than ones with AN > 60%.

For commercial blasting applications in the US, ANFO is currently by far the most common explosive, and its production volume is about 50 times greater than all other explosives combined. Curiously, it does not head the list of favorites for criminal bombers, who vastly prefer black powder, fireworks powders, or dynamite[98].

Watson et al.[99] published data on 16 different ANFO-based explosives tested according to four sensitivity tests: the Koenen/BAM friction test, the Bureau of Mines friction test, a drop-hammer test, and a No. 8 blasting cap. The results showed that generally the mixtures were insensitive, with the exception of ammonium nitrate/nitromethane compositions, which were detonable from a No. 8 blasting cap and showed elevated sensitivity in some of the other tests.

Nabiullah et al.[100] determined the ignition temperature for ANFO as being 260ºC by use of an electric furnace with ramped heating. On the basis of DTA tests, they obtained the kinetic parameters E = 120 kJ mol^{-1} and $A = 8.3\times10^{8}$ s^{-1}. Rogers et al.[101] measured the critical temperature for thermal runaway in 1 mm thick slabs of AN and found T_c = 324ºC for reagent-grade AN and 230ºC for a prilled sample.

Hainer[102] evaluated a number of studies on the self-heating due to decomposition of ammonium nitrate. From his graph, the following values can be obtained. Chemically pure AN: E = 224 kJ mol^{-1}, P = 74. Fertilizer grade AN: E = 149 kJ mol^{-1}, P = 57. Fertilizer grade AN with 7% additional fuel added: E = 135 kJ mol^{-1}, P = 56. The heat of reaction for chemically pure AN is about 60 kJ mol^{-1} at 170ºC, increasing to 68 kJ mol^{-1} at 300ºC. Hainer also determined that pressure plays an important role in self-heating caused explosions of AN. He considers that decomposition in-

volves the simultaneous occurrence of the exothermic reaction:

$$NH_4NO_3 \rightarrow N_2O + 2H_2O$$

(which is then followed by exothermic decomposition of N_2O) and the endothermic reaction:

$$NH_4NO_3 \rightarrow NH_3 + HNO_3$$

A thermal balance between the endothermicity of one and the exothermicity of the other is possible only if significant pressure rise does not occur. If the pressure rises, however, the endothermic reaction is suppressed, temperature begins to rise, and an explosion can follow. This explains why most AN disasters have occurred on board ships and not in warehouses. In ships, the steel hull can allow pressure to build up, but for storage in warehouses, pressure buildup is unlikely. In a contrasting opinion, Scott and Grant[87] consider that self-heating hazards of pure AN are very limited, and that accidents have inevitably involved the presence of impurities. The effect of impurities is attributed to the fact AN is an oxidizing agent and exothermic reactions can occur with oxidizable substances, especially organic ones. Under rapid initiation conditions, it is considered[103] that the reaction of AN goes as:

$$NH_4NO_3 \rightarrow N_2 + 2H_2O + O$$

The oxygen is then available as oxidizer for the fuel oil portion.

ANFO as such cannot be used in wet environments. But it was discovered already in the 1950s that, contrary to the old adage "Keep your powder dry," AN-based explosives can be made that incorporate water into the formulation itself[104]. Initially, this took the form of *slurries*, more currently as *emulsions*, whereby ANFO is dissolved in water, then the liquid is dispersed into the oil and the emulsion is made stable by including an emulsifier (e.g., sorbitan mono-oleate, stearic acid, etc.). A commercial emulsion may contain around 10 – 15% water and can be successfully used in wet applications, but since it is intrinsically insensitive, a sensitizer must be added. For this purpose, air-containing microballoons may be used, or air bubbles introduced by another means. Aluminum may also be added to this emulsion to increase the energy content. Nitro explosives and organic amine nitrates also find some use as sensitizers.

Ammonium nitrate in paper bags should be kept at storage temperatures below 70ºC, since at this temperature acid vapors begin to be released which cause a partial nitration of cellulosic substances and nitrated paper is more flammable[26]. NFPA has a standard (NFPA 490[105]) on the storage of ammonium nitrate; ANFO is also covered in NFPA 495[106].

Ammonium perchlorate

Ammonium perchlorate, NH_4ClO_4, is an inorganic oxidizer used as a component of rocket propellants (but can also be used as a monopropellant) and in pyrotechnic mixtures. The commercial product is a granular solid (commonly 100 – 200 μm), generally coated with an anticaking agent such as tricalcium phosphate. As part of preparation of a rocket propellant, the material is ground to 2 – 5 μm. Unlike the coarse product, the finely-ground material becomes quite sensitive. AP is considered stable at room temperature, but decomposition begins to be detectable at about 150ºC. Early studies of AP decomposition and combustion were reviewed by Jacobs and Whitehead[107]. When heated, ammonium perchlorate does not melt but sublimes and dissociates; the latter takes place by two different reaction pathways, depending on the temperature of exposure:

at ca. 325ºC :

$$2NH_4ClO_4 \rightarrow Cl_2 + 4H_2O + N_2O + 1.5O_2$$

at 380 – 400ºC :

$$2NH_4ClO_4 \rightarrow Cl_2 + 4H_2O + (O_2, N_2, NO, NO_2)$$

where the latter reaction does not include N_2O production[26]. In addition, there are various further reactions among the reaction products. When detonated, the composition of the reaction products is approximately:

$$4NH_4ClO_4 \rightarrow 6H_2O + O_2 + 4HCl + 2N_2$$

The ignition temperature[108] of small, pressed pellets of ammonium perchlorate, NH_4ClO_4, has been reported as 440ºC. DTA measurements[116] gave ignition temperatures of 540ºC for a 15 mg sample, 500ºC for 30 mg, and < 400ºC for 125 mg. Elevated pressures reduce the ignition temperature; in a closed-vessel ignition study, raising the pressure from 1 atm to 50 atm lowered the ignition temperature from 460ºC to 310ºC. In the presence of catalytic compounds[26], ignition can occur at temperatures as low as 225ºC. For pure AP at room temperature to undergo self-sustained burning in a nitrogen atmosphere[116], it must be subjected to a large pressure of over 20 atm; however, in a methane atmosphere burning can take place at ambient pressure. Aging at temperatures substantially below the ignition temperature does not appreciably change the properties of AP[116]. The vapors emitting from the decomposition of AP can be ignited. In a glass cylinder test using 200 g of AP heated to 254ºC it was possible to ignite the vapors by use of either a hot wire or a gas pilot; however the reaction was only "mild burning." A large number of compounds, many of them metallic, act as catalysts for the decomposition or ignition of ammonium perchlorate. In one review[107], ignition temperatures around 400ºC were typically found for pure AP, but dropping to ca. 250 – 300ºC in the presence of C, CdO, Cr_2O_2,CuO, CuCl, ZnO, etc.

Self-heating data based on a small-specimen study in an adiabatic furnace were obtained by Gross and Robertson[109], giving E = 172 kJ mol^{-1}; $QA = 5.6\times10^{19}$ W kg^{-1}; ρ = 910 kg m^{-3}; C = 1500 J kg^{-1} K^{-1}. Later studies indicated that the actual value of E is much lower and the decomposition of AP is possibly autocatalytic. Jacobs and Russell-Jones[110] reported that E = 130 kJ mol^{-1}, and that the reaction is autocatalytic. Bogg[116] found E = 95.8 kJ mol^{-1} and $A = 3.7\times10^4$ for the low temperature regime and E = 117.6 kJ mol^{-1} and $A = 6.0\times10^7$ for the high temperature. Powling[111] correlated a large amount of literature data and concluded that E = 126

kJ mol^{-1}, but without much evidence of autocatalytic behavior.

Pure AP can be detonated at modest heights in a drop-hammer test, but the explosion is notably mild and the explosive has a large critical diameter. The crystal density of AP is 1950 kg m^{-3}. The critical diameter for detonation has been reported as 150 mm for 1050 kg m^{-3} density and 220 mm for 1200 kg m^{-3}. When confined within a strong steel tube, a critical diameter of 35 mm was found for 1200 kg m^{-3} material[26]. For densities greater than 1365 kg m^{-3} of a 95% AP/5% aluminum powder composition, a critical diameter of 70 mm was found. In another study using 200 µm AP particles packed to a density of 1200 kg m^{-3}, a critical diameter of 93 – 100 mm was found[116]. AP becomes much more sensitive when combined with a hydrocarbon; when 1 – 8% oil or grease is added the lowest impact energy for ignition is required[116]. Combining AP with magnesium can lead to spontaneous combustion[1436]. If chlorates (e.g., $KClO_3$) are added to AP propellants, formation of ammonium chlorate will greatly increase the sensitivity of the propellant.

When subjected to radiant heating at 1 atm, pure ammonium perchlorate[112] shows a minimum flux for ignition of ≈ 400 kW m^{-2}. Small amounts of catalyst, however, lower the minimum drastically. For example, with 0.5% copper chromite, the minimum flux drops to ≈ 80 kW m^{-2}. Radiant ignition tests on AP-based rocket propellants typically[107] show ignition temperatures of 350 – 400ºC, but since each investigator generally used both a different experimental technique and a different formulation, wide variations in reported results are seen. The US Army[113] conducted on single steel drums filled with 113 kg of ammonium perchlorate. In one test series, various igniters were placed in the center of the drum; in another test, the drum was placed on, and surrounded by, a burning wood pyre (UN 6c Bonfire Test[550]). In no case did the material explode or detonate. In some cases, AP can sustain a large fire without detonating. Médard[26] reports a case where 5500 kg of AP in a rail shipment burned fiercely, but without explosion. The cause was surmised to be due to friction.

Despite benign results of drum-scale testing, a major US facility producing AP was destroyed by a series of explosions[114,115]. The accident at the production facility of Pacific Engineering Production Co. (PEPCON) in Henderson, Nevada on 4 May 1988 started as a small fire in a dryer building and spread to a large area of 55 gallon (208 L) plastic drums holding AP. The plastic drums tended to burn incompletely, without detonation, and it appeared that the polyethylene played a larger role in the combustion than did the AP. There was also a number of aluminum shipping containers holding AP. Detonations originated at these containers, even though many of them were not pressure-sealed. The particle diameter of the product was > 90 µm, which, according to then-current US Dept. of Transportation advice, was considered to be less hazardous than < 45 µm material. The event was slow-developing, with some 10 – 20 minutes between the start of the fire and the first of 7 explosions. The accident caused a US military committee to be formed to investigate the hazards of AP which prepared an encyclopedic report on AP hazards[116]. A natural gas pipeline traversed the property and was involved in the fires, thus the investigation included the possibility that natural gas played a role. But by conducting tests in a detonation tube, the committee rejected the proposed hypothesis that the event was particularly violent because it entailed the formation and subsequent detonation of an AP/natural gas/air cloud acting as a 'fuel-air explosive.' The factors that led to the PEPCON detonations have not been fully understood. But since the facility and its contents were demolished, the benign results of single-drum testing were demonstrated to be misleading. A paper has been published giving the views on the incident of an engineer retained during the course of litigation by the utility company whose pipeline traversed the site[117].

On 15 October 2001, a much smaller explosion leveled an AP facility, AeroTech Inc., located in Las Vegas, Nevada.

Antifreeze

Automotive antifreeze normally consists of a 50:50 mixture of ethylene glycol and water. Numerous fires have occurred when antifreeze boils over. The typical fire situation involves a discharge of antifreeze onto hot engine surfaces, where the water component, which has a lower boiling point, preferentially boils away. Ethylene glycol is then readily ignitable by a sufficiently hot surface. Cole[118] reports that the flashpoint of the 50:50 mixture is 132ºC, but the conditions of the test, of course, do not simulate these actual occurrences.

Arsenic compounds

A number of fully-alkylated arsenic compounds are pyrophoric, for example, cacodyl (tetramethyldiarsane, $C_4H_{12}As_2$). Urben[3] provides listings along with literature references.

Ashes

Ashes have a low thermal conductivity, consequently it is not rare for an individual to believe that ashes are 'dead,' while in reality hot or smoldering embers are still contained therein. No study has established the maximum limits, but one case history has been published[119] where an individual collected and placed ashes in a plastic bucket upon a wood floor. Seven hours afterwards, flaming erupted. Another

* one outlier was at 63ºC		

investigator[120] reported examining with an infrared camera a container of ashes four days after the ashes were deposited in the container and still finding high temperatures.

Asphalt

The minimum flux for ignition of asphalt* has been measured[121] to be in the range of 15 – 20 kW m^{-2}. It was also found that exothermic reactions occur between asphalt and various sodium salts, indicating a potential for runaway self-heating. Franke et al.[45] reported on a fire where cardboard drums filled with 90 kg of an asphaltic adhesive at an initial temperature of 160 – 200ºC self-heated to ignition. See also: *Tanks*

Automatic transmission fluid

An extensive discussion of physical and chemical properties of automatic transmission fluids has been presented by Kemp and Linden[122]. Ohlemiller and Cleary[123] investigated the effect on the flash point and fire point of ATF when contaminated with gasoline. Using a non-standard open-cup test apparatus, they found that the flash point dropped from 185ºC for pure ATF to room temperature (22ºC) when 15 – 20 vol% of the mixture was gasoline. The fire point dropped from 200ºC for pure ATF to 22ºC for a mixture with 25 vol% gasoline. Fitz[124] measured the AIT of ATF using a heated, 0.5 L pressure vessel. At 1 atm, he obtained 255ºC, which dropped slightly to 244ºC at 9.5 atm pressure (absolute). ATF fires are likely to occur when a transmission has been overfilled, if the vehicle is operating under overload conditions, or both[125]. In those cases, fluid can be ejected from filler or vent openings and ignite upon hitting hot exhaust components. While rare, fires that occur in this way have been documented as being potentially very violent[126].

Aviation fuels

Aviation fuels contain an enormous variety of hydrocarbons. Av gas may contain 300 compounds, while JP-4 some 5000 – 10,000. The composition of Jet A is typically[128]: 29% isoparaffins, 28% *n*-paraffins, 20% cycloparaffins, 18% alkylbenzenes, 2% naphthenes, and 3% other. The molar mass[129,130,140] of various aviation fuels is shown in Table 5; other tabulated properties are given in Chapter 15. In the US, aviation fuels for civilian uses are governed by ASTM D 910[131] and ASTM D 1655[132]. Jet fuels are divided into low volatility and high volatility grades.

- High volatility (flash point < –18ºC): JP-4, Jet B
- Low volatility; sometimes referred to as aviation kerosenes (flash point > 38ºC): JP-5, JP-7, JP-8, Jet A.

JP-1 and JP-3 are obsolete, while JP-2 was never designated. The primary fuel used in civil jet aircraft is Jet A, while the military uses mainly JP-8, along with some JP-5. JP-8 differs from Jet A mainly in that it contains anti-icing, anti-corrosion, and antistatic agents. The predominant compounds in the aviation-kerosene type fuels are C_8 to C_{15} hydrocarbons. Vapor pressure curves for a variety of aviation fuels are shown in Figure 6. Jet B, which is uncommon, is the civilian equivalent to JP-4. Occasionally, aviation fuels are referred to by their NATO designations, e.g. F34 (JP-8), F40 (JP-4), F44 (JP-5).

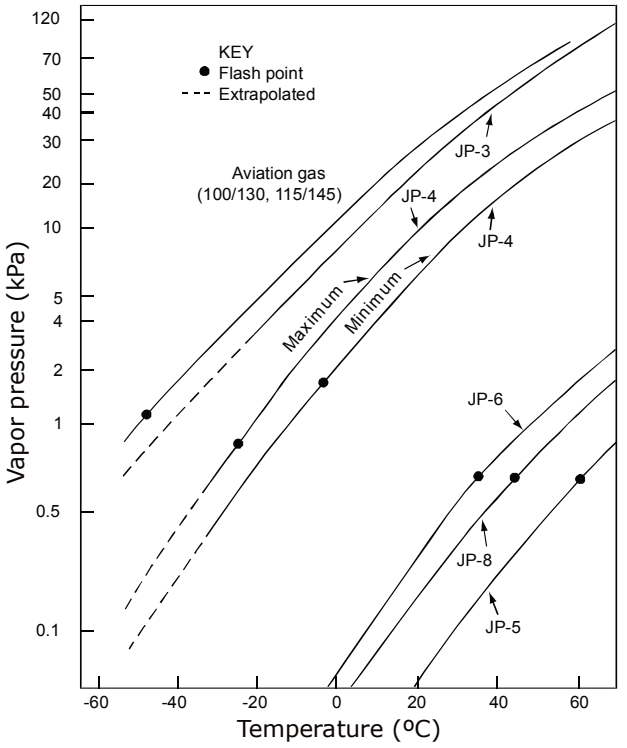

Figure 6 Reid vapor pressure curves for aviation fuels[127] (values are indicative only; actual commercial product can show wide variations)

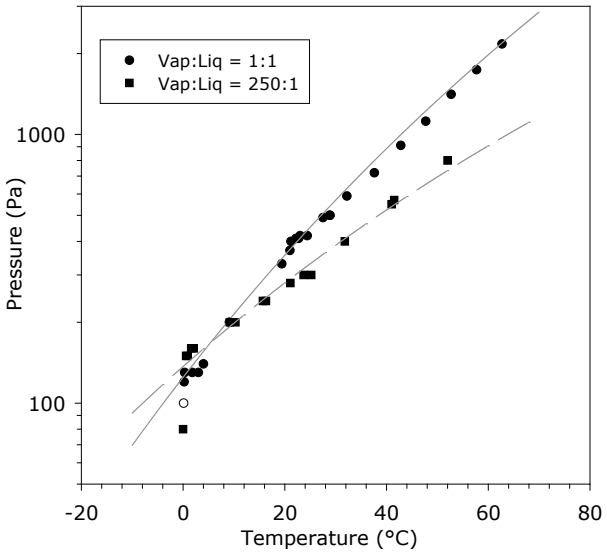

Figure 7 Vapor pressure for Jet A fuel under two different vapor/liquid test ratios

* In the US, asphalt, bitumen, pitch, and tar are considered synonymous terms. However, in some industries and in some countries, distinctions are made.

Table 4 Fractional distillation features of aviation fuels

Fuel	Temperature (°C) at which given % has evaporated		
	0%	50%	100%
Avgas	33	98	210
JP-4	65	160	250
JP-5	180	220	265

For the 'high flash point' fuels, Sochet and Gillard[133] conducted a literature survey and found the results shown in Table 3.

Being blends, aviation fuels do not have a boiling point, but rather show a temperature range over which distillation occurs. Table 4 shows typical properties for avgas and for two jet fuels[134]. Anti-static agents were introduced into military jet fuels and non-US civil aviation fuels around 1970. Subsequently, fires due to static electricity, which were common previously, dropped to low levels[135]. The agents were not seen as necessary for US civil aviation fuels, since electrostatic problems have not been serious in that sector. The agents mainly serve to raise the conductivity of the fuel, shifting the fuel's conductivity out of the region where static discharge susceptibility is the highest. Thus, they can be counter-productive if added to a fuel which has a very low conductivity.

The vapor pressure curve for Jet A was recently measured by Shepherd et al.[136] While Reid vapor pressure is reported using a standard vapor : liquid volume ratio of 4:1, the results are sensitive to this ratio, thus Figure 7 shows it for two different ratios. The authors provided the following data fits:

$$P = 5.75 \times 10^8 \exp(-4191/T) \qquad \text{ratio } 1:1$$

$$P = 4.971 \times 10^6 \exp(-2868/T) \qquad \text{ratio } 250:1$$

with P = pressure (Pa), and T = temperature (K). These results will be reflected in the flash point, which will be lower for the 1 : 1 ratio than for the 250 : 1. This is an example of the effect of liquid/vapor volume ratio for certain complex mixtures, as discussed in Chapter 6.

The flammability of fuel inside airplane tanks is difficult to assess accurately. Four factors are involved:

Table 6 Effect of pressure on aviation fuels

Fuel	Press. (atm)	Flamm. limits (vol%)		MOC (vol%) with diluent:	
		LFL	UFL	N_2	CO_2
Avgas 100/130	1.0	1.3	7.15	11.9	14.8
	0.53	1.25	6.75	11.2	14.1
	0.27	1.3	6.85	11.6	14.1
	0.13	1.4	7.6	11.9	14.8
Avgas 115/145	1.0	1.2	7.1	11.9	14.6
	0.53	1.25	6.9	11.6	14.6
	0.27	1.25	7.0	11.6	14.8
	0.13	1.5	7.85	12.0	14.9
JP-4	1.0	1.3	8.2	11.5	14.3
	0.5	1.3	7.85	11.4	14.5
	0.27	1.35	8.05	11.7	14.6
	0.13	1.35	8.1	12.4	14.9

- pressure
- temperature
- slosh
- oxygen enrichment.

The pressure and temperature effects exist in general for any flammable liquids, as discussed in Chapter 6, but for aviation fuels the pressure effect on LFL and UFL (but not on LTL and UTL) can be ignored, as shown in Table 6[142]. The LTL and UTL are strongly affected by altitude, since they directly decrease with decreasing total pressure.

But temperature limits only pertain to vapors that are vaporized from a liquid under still-air, equilibrium conditions. If significant generation of an aerosol occurs, for instance, due to motion, filling, or agitation, then a flammable aerosol may be created, and this will effectively bring down the lower temperature limit. In flight, if significant non-vertical accelerations are present, then fuel will slosh around and create an aerosol in the tank. As discussed in Chapter 6, the vapor pressure is higher at a curved surface than at a plane surface, thus the fuel's vapor pressure rises due to slosh.

An oxygen enrichment effect occurs since oxygen is more soluble than nitrogen in jet fuel[137]. When an aircraft climbs, oxygen and nitrogen both are de-gassed from the liquid and enter the vapor space, but since a disproportionately higher amount of oxygen was present in the fuel, the vapor space becomes oxygen enriched. In addition, this outgassing cre-

Table 5 Current types of aviation fuels

Fuel	Type	Molar mass (g mol^{-1})	Use

JP-8	kerosene; sim. to Jet A-1, but has anti-static and other additives	162 – 167	military

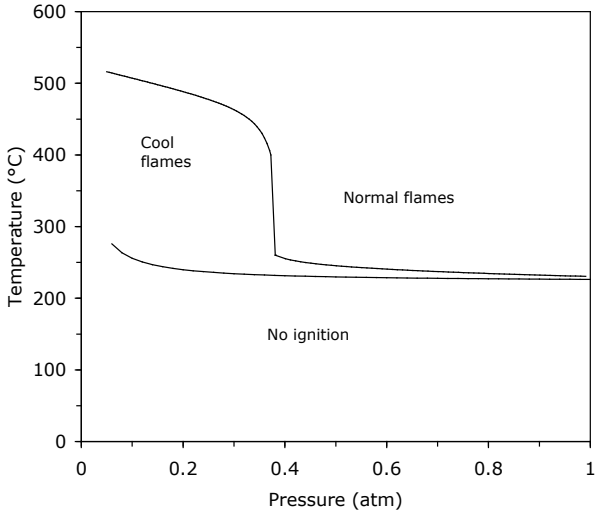

Figure 8 Autoignition regimes for JP-5 fuel

ates a foam at the surface of the liquid[138] and the foam may have different ignition properties than the vapor.

JP-5 fuel has an AIT of approximately 250ºC. But at sub-ambient pressures a substantial cool-flame regime is found[139], as shown in Figure 8. By contrast, JP-4 and JP-8 do not exhibit cool-flame ignition[140]. Figure 8 also shows that at elevated pressures, the AIT of JP-5 falls slightly with pressure, decreasing to 210ºC at 9 atm; similar results have been obtained[141] for JP-1 and JP-4.

For some aspects of jet fuel flammability, it is necessary to know the atmospheric pressure at above-ground elevations. An approximate expression is[142]:

$$P = \exp\left(-1.2\times10^{-4} H - 1.3\times10^{-9} H^2\right)$$

where P = pressure (atm) and H = altitude (m). The MIE increases at higher altitudes, due to decreasing atmospheric pressure. The FAA has suggested[143], based on very limited experimental data, that the effect for Jet A can be approximated as:

$$MIE = \exp\left[\frac{0.207H - 1.395}{\sqrt{1 - 0.049H}}\right]$$

where MIE = minimum ignition energy (mJ), and H = height above mean sea level (km). The dependence of the actual ignition energy E (mJ) on the fuel temperature T (ºC) and the fuel flash point T_{FP} (ºC) was then given as:

$$E = MIE \cdot \exp\left\{\left[9.22\times10^{-4} H + 0.0218\right]\left[T - T_{FP} - 12.2 + 2.73H\right]^2\right\}$$

Contour plots of the above equation are shown in Figure 9. Ignition due to static electricity in a fuel tank, for example, will be limited to certain maximum discharge energy, thus constant-energy contours can be used to distinguish flammable from non-flammable regions. It is reported that many incidents of ignition within airplane fuel tanks have occurred and that most of them involved fueling on the ground[144]. Figure 9 shows that, at ground level, the fuel

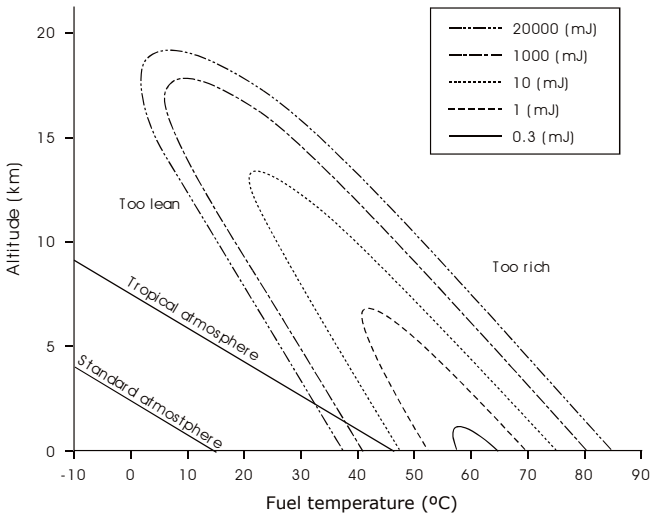

Figure 9 Estimated ignition energy needed for Jet A fuel at various altitudes and fuel temperatures. The large change with altitude is due to effect of total pressure on the LTL and UTL.

tank would be expected to be below the LFL. But this is based on average conditions within a quiescent volume and does not take into account splashing or spraying. Laboratory experiments to reproduce the fuel-tank ignitions have been attempted but have thus far been unsuccessful[144]. Extensive discussions of fuel-tank ignition scenarios are given in an FAA study[143].

Atkinson and Eklund[145] endeavored to find out if a lower temperature limit could be reached with regard to ignitability of jet fuels in mist form from a heated wire. At the lowest fuel temperature they were able to achieve, –40ºC, both JP-4 and JP-5 ignited readily.

Jet A aviation fuel can regularly pick up a charge of up to 4000 μC m^{-3} in handling operations at commercial airports[146] and values up to 5800 μC m^{-3} have been measured on JP-4 fuel[147]. Average charge densities of 30 – 50 μC m^{-3} have been found in airport tests[148]. To place these values in context, general guidance on petroleum-based liquids, given in Chapter 11, indicates that charge concentrations as small as 20 μC m^{-3} can lead to incendive discharges during tank-loading operations. Thus, it is perhaps surprising that so few aircraft fueling explosions have been recorded, even in the absence of antistatic agents.

A number of corrosion inhibitor agents can cause even greater charges to be picked up, but these have a benign effect, since the same agents have been found invariably to raise the conductivity of the fuel to a safe value (> 50 pS m^{-1}). Jet A with no additives of any kind has a conductivity of about 0.1 – 0.3 pS m^{-1}; commercial fuels show about 0.5 – 5.0 pS m^{-1}. JP-4 fuels show typically 1 – 10 pS m^{-1}, but values of 0.7 – 34 pS m^{-1} have been measured. Water was found to be a particularly undesirable component in jet fuel,

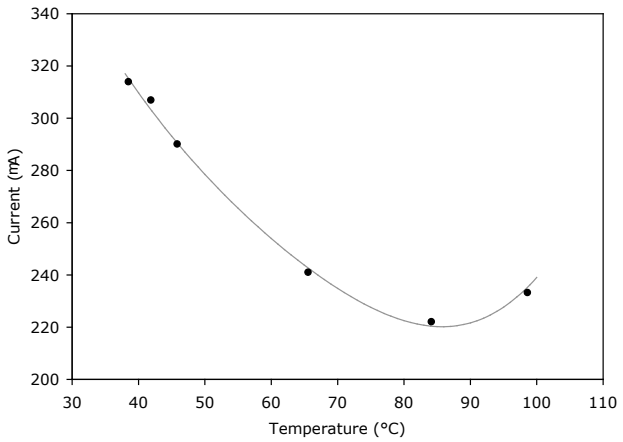

Figure 10 Minimum current needed for ignition of JP-5 in a fuel tank by means of corona discharge

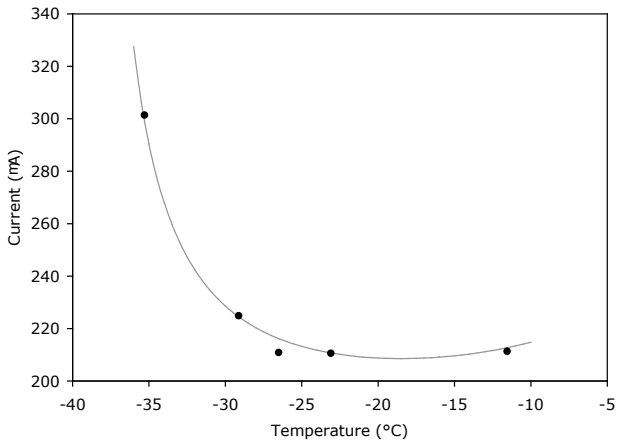

Figure 11 Minimum current needed for ignition of aviation gasoline in a fuel tank by means of corona discharge

since it drastically increased the maximum electrostatic charge, which was not compensated by any increase in the conductivity. The role of water is complex, since its effect of increasing the charge is not intrinsic, and only occurs when the fuel is pumped through filters[149].

Leonard and Carhart[150] noted that ignitions of jet fuel due to electrostatic charging from fuel flow are rare, and determined to find out the detailed reasons. They set up a polyethylene tank with JP-5 jet fuel where the fuel was continuously recirculated and charged by passing through a fiberglass filter. Various grounded electrodes were studied, placed at varying heights above the fuel surface. A parallel series of experiments was conducted where the second electrode was a metal plate, instead of the surface of the fuel. The results are summarized in Table 7 and Table 8. For the two-metal-electrode experiments, the most common result was a spark, especially with larger diameter of grounded electrodes. For discharge to the liquid surface, only a single spark discharge was obtained, the remaining 23 experiments showed either corona or brush discharge. The latter was a form described by the authors as a "pre-breakdown streamer." The brush discharges started out as a single-electrode discharge, but eventually a main stroke spanning to the other electrode was generally attained. The amount of energy available for this main stroke was small, however. Both the corona and the brush discharges were repetitive, with as many as 100 events per minute. For the discharges to the liquid surface, only gaps of 25 mm and greater were used, since it was found that for smaller spacings electrostatic attraction of the charged liquid to the grounded electrode would cause the liquid to rise and come into contact with the electrode, precluding the possibility of a discharge. For a 25 mm sphere, the energy of discharge available at a comparable gap size was about 30× greater for the discharge to the metal plate than to the fuel surface. The authors went on to attempt to ignite mixtures to actually test the incendivity of the discharges. In these tests, they switched to JP-4 fuel, for which a flammable mixture could be created. No successful ignitions could be obtained, but details of the trials were not documented.

Table 7 Summary of experimental results when discharge was to a metal plate

Grounded electrode	Gap (mm)	Discharge obtained	Charge transf. (nC)	Energy of discharge (mJ)
needle	10 – 30	corona	< 1	< 0.001
60º point	2.5	spark	90	0.17
	10 – 80	corona	0.9 – 1.3	0.004 – 0.011
6 mm sphere	2.4 – 8.7	spark	165 – 330	0.68 – 2.64
	9.5 – 12.7	brush discharge	33 – 49	0.27 – 0.49
13 mm sphere	0.24 – 9.5	spark	154 – 443	0.77 – 4.70
25 mm sphere	2.0 – 16.0	spark	128 – 575	0.44 – 12.0

Successful ignitions from a corona discharge were obtained by Newman and Robb[72]. In connection with studies to examine the potential for ignition of fuel tanks by discharges entering the fuel tank through the vent, they conducted experiments on the minimum current needed for ignition of aviation fuel tanks from a corona discharge. The results are shown in Figure 10 for JP-5 and Figure 11 for aviation gasoline; they also obtained data for JP-4, a ramjet fuel, and 'RVP special fuel.' The findings were seen as providing some cause for concern, since corona currents of several hundred microamps were plausible for aircraft in flight.

In the aircraft industry, it is common to use 200ºC as a notional hot-surface ignition temperature for all aviation fuels. This is highly conservative and one maker of aircraft engines, Rolls-Royce[141], found that no ignitions could be obtained below 400ºC.

Table 8 Summary of experimental results when discharge was to a liquid surface

Grounded electrode	Gap (mm)	Discharge obtained	Charge transf. (nC)	Energy of discharge (mJ)
needle	10 – 50	corona	< 1	< 0.001
60º point	25	spark	28	0.27
	10 – 150	corona	0.5 – 0.9	0.003 – 0.012
6 mm sphere	25 – 125	corona	2.0 – 4.0	0.2 – 0.4
13 mm sphere	25 – 125	brush discharge	24 – 97	0.34 – 0.91
25 mm sphere	25 – 125	brush discharge	49 – 84	0.43 – 2.33

Azides

A number of azides, especially silver azide, AgN_3, and lead azide, $Pb(N_3)_2$, are primary explosives which are very sensitive to friction or impact ignition. As little as 4 mg of lead azide has been known to detonate[151]. Hydrazoic acid, HN_3, can explode in either the gas or the liquid phase[151]. Inadvertent reactions producing azide-caused explosions also have been known to occur. In two cases[323], explosions occurred in hospital drain systems, where a saline solution containing 0.1% sodium azide was flushed down. The sodium azide reacted with the copper pipe, producing explosible copper azide. Older automotive air bag inflators used to contain sodium azide (see *Motor vehicles*). See also: *Explosives*.

Bagasse and bagasse products

Bagasse, which is the crushed, juiceless remains after sugar cane is milled, comprises largely cellulosic matter. It typically emerges from the mill[152] having around 50% water by mass and is then stored into piles while still at around 48 – 60ºC. Bagasse is subject to self-heating and, if stored improperly, can lead to spontaneous combustion. A certain amount of self-heating, however, is beneficial, since it allows moisture to be driven off, without needing an external energy source. The moisture is so dominant in determining the self-heating of bagasse, that this is a product where use of the standard oven-basket testing procedure would not only give substantially erroneous large-scale extrapolations, but would produce errors on the unconservative side. Gray and coworkers found that use of self-heating theory based on a dry material undergoing a single chemical reaction grossly overestimates the safe size of stored piles of bagasse[153]. To approximate a correct prediction, they determined that the theoretical formulation must explicitly include water vaporization/condensation and also moisture-dependent chemical reactions[154,155]. In highly wet systems, the major constituent of bagasse, cellulose, has been found to undergo two different reactions, a 'dry' oxidation and a 'wet' reaction which is probably a form of hydrolysis and whose rate is proportional to the liquid-phase water concentration in the material. Their theory involves solving a system of three partial differential equations, representing conservation of energy, liquid water, and water vapor.

In contrast to the simple theory delineated in Chapter 9, numerical solutions of the theoretical model showed three different cases are possible: (1) a rapid decrease in temperature from the original hot-work temperature to a slightly above-ambient equilibrium value; (2) a small initial rise in temperature, followed by a long near-steady plateau at around 60ºC, then a sudden drop of temperature down to a plateau value slightly above ambient (Figure 12); and (3) a runaway behavior with rapid heating at first, then a time when temperature growth tapers off, and finally a steep rise leading to runaway temperatures. This series of behaviors, especially the intermediate-cooling one (#2), is distinctly more complex than that shown by dry materials that are governed by simple kinetics. In practical storage of bagasse, case #2 is preferred, since it allows moisture to be driven

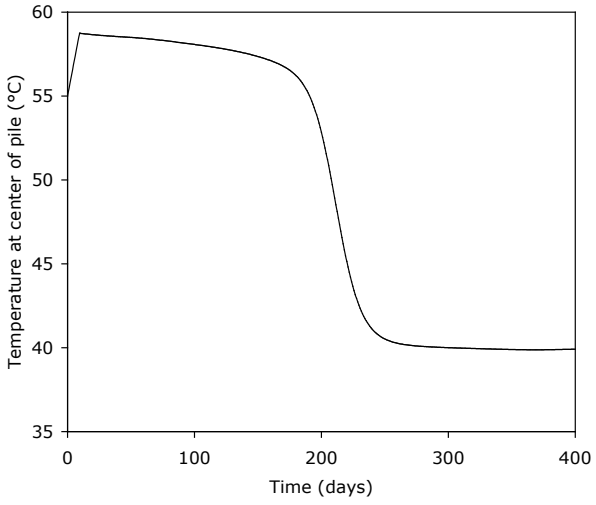

Figure 12 Example temperature history of pile for case #2

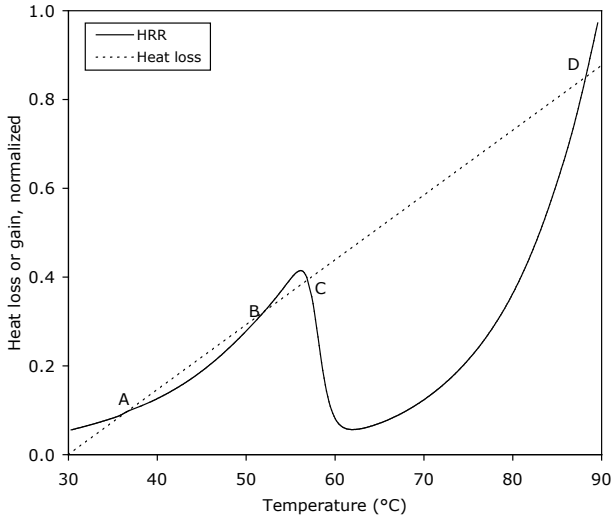

Figure 13 Self-heating curves for bagasse

off. Case #1, by contrast, cools so rapidly that water is not driven off.

Not unexpectedly the energy gain/loss diagram for bagasse looks more complex than for the simple Semenov case. Figure 13 shows an example[154], computed for an ambient temperature of 30ºC. Compared to Figure 2 in Chapter 9, it can be seen that the HRR curve is more complex and that it shows a local maximum and a local minimum. Point C is a quasi-steady equilibrium state which comes about due to the wet reaction term. This point corresponds to the long period of elevated, nearly-steady temperatures observed in a bagasse pile. After sufficient moisture is exhausted, the system drops down to point A. If the original temperature at which the pile was stored were more than 88ºC, then immediate runaway (Case #3) would ensue. The analysis of this problem requires a substantial mathematical effort and does not readily lead to engineering simplifications such as developed in Chapter 9. For a sense of magnitude, given reasonable physical property assumptions, quasi-steady Case #2 solutions were found in the range of 2 – 4.5 m pile size. The plateau in the vicinity of 60ºC can last for a half year, before the rapid drop begins. Piles smaller than 2 m did not show a significant rise in temperature, while piles greater than 4.5 m led to runaway conditions. As for any agricultural product, contribution to self-heating from microbial activity must be considered. But tests[152] where bagasse piles were treated with a biocidal agent showed essentially no difference in self-heating from untreated piles, indicating that for practical purposes this factor might be ignored.

In addition to serving as fuel, bagasse fibers are often used in the manufacture of lightweight fiberboard. The manufactured product is very similar to that which is produced from wood fibers. The AIT of fiber boards derived from bagasse[443] was reported by NIST in 1947 as being 240ºC, but the test method used was only described very sketchily; see *Wood* for details. Mitchell[156] conducted self-heating tests on bagasse fiberboards and found trends similar to wood fiberboard, although the bagasse material was slightly worse. See also: *Wood and related products: Wood fiberboard*.

Boranes

The borane family includes $(BH)_n$, BH_3, B_2H_6 (diborane), B_4H_{10} (tetraborane), B_5H_9 and B_5H_{11} (pentaboranes), B_6H_{10} (hexaborane), and others. Diborane is one of the most hazardous known substances, igniting in ambient air, unless dry and free from impurities[157]. The ignition may take 3 – 5 days, instead of being instant[3]. Diborane also reacts hypergolically with alcohol. Its flammability limits are 0.84 – 93.3%, with combustion possible down to an oxygen content of 1.3%. Polyborane, $(BH)_n$, is similarly reactive. Borane, BH_3, does not exist as a pure substance, since, on formation, it immediately polymerizes into one of the higher boranes. Tetraborane and the higher boranes are reactive similarly to diborane. Additional guidance is given by DOE[158].

Boron

Boron has been proposed as a rocket and ramjet fuel due to its high volumetric heat of combustion, 135,000 MJ m^{-3} (liquid fuels are generally < 35,000 MJ m^{-3}). A common pyrotechnic mixture for igniters (electric matches, squibs) contains potassium nitrate and boron. Boron particles normally contain an oxidized outer layer, and when the particles are heated, their oxide coats tend to stick together, resulting in clustering or agglomeration. In an early study, Talley[159] determined boron to ignite in O_2 at around 1960ºC. Maček and Semple[160] compared several later studies and concluded that, for small particles of about 50 μm, a temperature of around 1630ºC is the ignition temperature in air at room temperature, with the value dropping to ca. 1230ºC when under 15 atm of pressure. In a later paper, Maček concluded[161] that the ignition temperature can be anywhere between 1230ºC and the boiling point of B_2O_3, which is 2043ºC at 1 atm. Moisture affects the ignition process, and ignition temperatures are about 50ºC lower in moist atmospheres than in dry. Unlike some other elements, boron does not burn in low-O_2 environments, with ca. 10% being required for combustion[161]. Yeh and Kuo have reviewed other experimental ignition studies[162].

Boron is understood to ignite by a two-stage process[163]. In the first stage, the oxide layer is removed from the metal, followed by a second stage where oxidation can occur on the metallic surface. Further details of the reactions involved in ignition have been outlined by Li and Williams[164]. Most researchers consider that, due to its low volatility, boron burns heterogeneously, without gas-phase reactions. On the other hand, Yuasa et al.[165] heated small (10 – 13 mg) lumps of boron and concluded that ignition could be either homogeneous or heterogeneous, with homogeneous combustion showing a green-white flame. Glassman[166] challenged this conclusion and suggested that the observed luminosity is from B_2O_3 decomposition products. At the minimum heat flux, Yuasa found that the specimen temperature at ignition was 1400ºC, irrespective of supposed mode of ignition. Commercial boron tends to contain impurities of oxygen and magnesium and this makes the material substantially easier to ignite than the high-purity form.

Mohan and Williams[167] provided an early theoretical model of boron ignition. This indicates that for $1 < d < 50$ μm, diameter makes little difference. But for larger diameters, increasingly higher ignition temperatures are expected. They also pointed out that many of the unique features of boron ignition can be attributed to its highly unusual thermal conductivity properties. Glassman et al.[168] developed a later theory, where they proposed that elemental boron becomes available for combustion by diffusing outward across the oxide coating; most previous theories assumed that oxygen diffuses inward, instead. A recent theory was

published by Zhou et al.[169] They note that the measured ignition time corresponds roughly to the time required to remove the oxide layer, since active combustion is seen very soon thereafter. While the study did not produce closed-form expressions for prediction, the effect of oxide layer thickness was characterized. When all other conditions are held constant, the ignition time equals a constant, plus a term proportional to the oxide layer thickness. The constant represents the heat-up time, while the second term represents the time needed to remove the oxide film, once thermal equilibrium has been reached. The theory also indicates that there is a maximum oxide layer thickness, beyond which ignition will not occur. Their theory states that a layer which is 6.8% of the radius represents this limiting condition.

Clouds of boron particles ignite at lower temperatures than what is needed for single-particle ignition. The minimum ignition temperature decreases with (a) increasing cloud radius, (b) decreasing particle radius, (c) increasing particle concentration, (d) decreasing particle velocity, and (e) decreasing atmospheric pressure. Particles with a radius of 3 μm forming a cloud with a radius of 0.6 m at a mass fraction loading of 5% ignite at an atmospheric temperature of about 1030ºC under zero-velocity conditions[163]. If the mass loading is increased to 25%, ignition becomes possible at 630ºC. A minimum temperature for ignition of boron dusts in air[170] is reported to be 730ºC. Dust clouds with about 12% of magnesium added to the boron show ignition temperatures about 150ºC lower than for boron particles alone[171]. In a CO_2 atmosphere, boron powder (ultra fine, 0.05 μm size) was found not to be ignitable up to the maximum temperature tested, 960ºC[1396].

Brake fluid

Ohlemiller and Cleary[123] investigated the effect on the flash point and fire point of brake fluid when contaminated with gasoline. Using a non-standard open-cup test apparatus, they found that the flash point dropped from 100ºC for pure brake fluid to room temperature (22ºC) when 10 vol% of the mixture was gasoline. The fire point dropped from 130ºC for pure brake fluid to 22ºC for a mixture with 15 vol% gasoline.

Calcium resinate

Used in various paints, leather processing, and cosmetics, calcium resinate ($C_{40}H_{58}CaO_4$) is reported to be a self-heating substance[1542].

Camping fuel

According to DeHaan[172], a typical camping fuel has a Reid vapor pressure of 43.3 kPa at 38ºC. Camping fuel is a complex mixture of hydrocarbons, but dominated by hexane and related compounds. Its flash point is not fixed, but may be around –33ºC. See also: *Gasoline* (white gasoline).

Candles

Candles are one of the oldest forms of open-flame devices in a home, but in a modern residence candles involve some unique ignition hazards. Factors to consider are:

- the combustion is not confined to an engineered combustion device; some candleholders are grossly inappropriate for the application (e.g., they are combustible or are unstable and can be tipped over);
- the open flame has no protection or shielding and candles are often burning while unattended;
- unlike matches and lighters, a candle flame can burn for hours, thus items that take fairly long to ignite can be threatened.
- attempting to extinguish a candle fire with small amounts of water available to a householder is likely to exacerbate the fire in a manner similar to pouring water of burning liquid fires.

Sanderson has documented additional aspects of candle fires[173]. Candle flames were studied very early by Michael Faraday, and his classic 1861 textbook still makes worthwhile reading[174].

Candle fires in the US, while still a small fraction of all residential fires[175], have experienced a significant upsurge in recent years (Figure 14). In response to this, in 2002 ASTM issued a specification, ASTM PS 59[176], establishing safety requirements for candles.

CPSC[177] has compiled US statistics on the general nature of candle fires, see Table 9. NFPA published detailed statistics[175] on US fires for the years 1994-1998, as shown in Table 9 through Table 11. Over the years, CPSC has issued a number of recalls for products that are a combined candle/candleholder due to improper designs where either the candleholder was made from a combustible material and tended to catch fire, or else there was a propensity (typical-

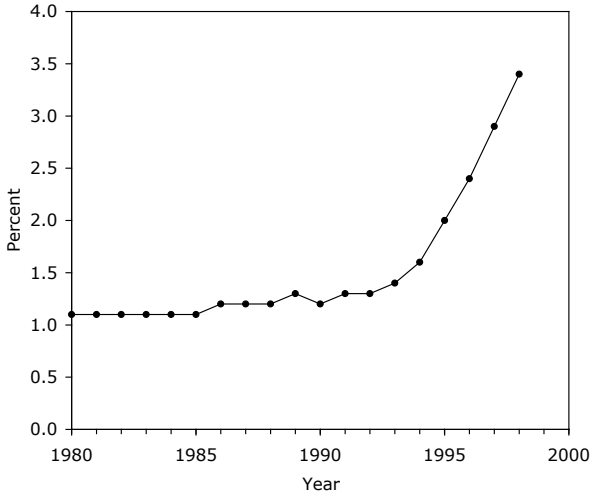

Figure 14 Candle fires in the US, as a percent of total residential fires

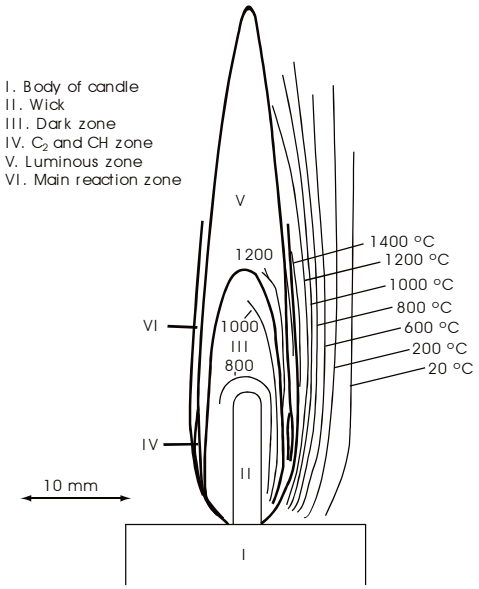

Figure 15 Temperatures in a candle flame, as determined by Gaydon and Wolfhard

ly with a glass or ceramic construction) for the candleholder to shatter and spill out burning material.

Some very high temperatures are found in a candle flame. Gaydon and Wolfhard[170] measured a peak temperature of 1400ºC (Figure 15). Note however that the size of the flame zone is relatively small. Peak temperatures measured in flashed-over room fires are typically around 1000ºC and only rarely reach 1200ºC. Thus, the peak measured temperature in a candle is higher than in a room fire (the candle is not unique in this; other small laminar flames show very similar temperature distributions). The high temperatures in a room fire, of course, encompass a vastly greater area, thus, ignitability comparisons cannot be made solely on values of the temperature peak. A German study[178] reported temperature measurements *above* the tip of visible candle flames (Table 12). The flash points of waxes from various candles were measured by the Cleveland open cup method[179]; three different products showed values of 196, 216, and 236ºC.

Yallop[180] reports that the minimum oxygen concentration needed to sustain a candle flame is typically 10%. Dillon[181] measured heat fluxes above the flame of a 21 mm diameter paraffin-wax candle. He found 50 – 70 kW m^{-2} at the flame tip, dropping to about 20 kW m^{-2} at 200 mm above the flame tip. Less than 10% of the heat was due to radiation. Flame height was 40 – 45 mm.

It is reported[182] that even an overt failure within the candle may not be necessary, if the candle is separated from an ignitable surface only by a relatively modest thickness of metal (e.g., copper, brass). Since metals are substances of high thermal conductivity, in such cases, sufficient heat can pass through the metal to ignite the substrate.

Table 9 Types of candle fire accidents, US statistics (1985-1997)

Type of fire	Percent
ignition, other combustible	49
tipover	19

Table 12 Temperatures measured at various heights above the tip of visible candle flames

Ht. (mm)	ºC	Ht. (mm)	ºC
20	488	100	280
40	453	120	213
50	400	140	163
80	372	160	89

Candles are sometimes used as incendiary timing devices. A common rate of burning of candles is 25 mm per hour, although larger candles will burn more slowly; candles less than about 20 mm diameter, on the other hand, burn up rapidly. In any case, this is easy to determine experimentally

for a candle of a known type. For common candle types, the heat output is 50 – 100 W.

TEA CANDLES

Tea candles (also called tealights) are small candles self-contained in an aluminum dish and often used without an additional candleholder. A number of fires have been reported where tea candles have ignited combustible surfaces that they were sitting on. These have included European-style, non-FR television cabinets, polystyrene compact disc cases and plastic toilet tank lids[183]. An investigation[184] has revealed that the mode is normally one whereby flaming takes place over the whole top surface since it has reached its fire point temperature. The fire point of wax is fairly high (although it does not appear to have been studied), so the question becomes what raises the wax to its fire point. The investigation determined that several different mechanisms can occur:

- Placing of a spent match in the candle. This is commonly done by users, but it was found that the match sometimes ignites much later and serves as a 'second wick.' The combined effect of two wicks in a small area suffices to heat up the entire wax surface to its fire point.
- Contamination in the wax, leading to 'flaring.'
- Other contaminants (e.g., decorations) that cause multiple-wicking when the candle is nearly regressed to the base.
- Improper wick size; or formation of a lump in the wick, effectively creating an extra-large wick.
- A detached wick that floats up to the surface and causes flaring.

Daéid and Thain[185] measured the temperatures of tea candles at the base of the aluminum dish. Under still-air conditions, they found a peak temperature of 52 – 67ºC, but providing a modest air flow of 0.4 m s^{-1} gave a peak of 89ºC. For such 'normal usage' conditions, the wax did not reach its fire point. Dropping a spent wooden or paper match into the candle led to a gross change in burning—at a certain point the wax ignited and burned as a pool fire. The base temperature at the moment of this ignition was 126 – 182ºC, depending on whether the match was wooden or paper, and whether or not there was an air flow; the actual fire point temperature of the wax itself was not recorded. The peak temperatures at the base under such conditions were 287 – 324ºC. When these candles were placed atop TV cabinets (of unidentified plastic), the cabinet locally melted and the candles fell in once a base temperature of 155 – 226ºC was reached.

GEL CANDLES

Gel candles are made from mineral oil which has been gelled by incorporation of a small amount of a polymer; fragrances, colorings, and other additives are also often added. The resulting substance behaves differently from wax in that it can melt and flow more readily. In case of breakage of container, the burning material may be easier to spread around and harder to extinguish. A comprehensive study of the product category is not available, however. The basic fire performance, in brief, is intermediate between a wax candle and an oil lamp. According to a manufacturer of the raw materials, the open-cup flash point of gel candles is approximately 226ºC, while the fire point is 260ºC.

Carbon disulfide

A versatile solvent, but one of the most hazardous of common industrial chemicals, carbon disulfide, CS_2, has a flash point of –30º, a boiling point of 46ºC, and burns with a nearly colorless flame. It also has an exceptionally low AIT (100ºC) and very wide flammability limits (1.3 – 50%). Carbon disulfide spilled on steam pipes has caused ignitions, especially if the pipes are rusted, and various fires with carbon disulfide have occurred in laboratories. Carbon disulfide was involved in one of the most famous tunnel fires, the Holland Tunnel fire of 13 May 1949[186]. The fire was severe enough to demolish some 180 m of concrete tunnel lining. For a hot surface to ignite carbon disulfide, a rather low temperature suffices. Using a brass plate of 1770 mm^2 area, it was found that ignition occurs at 150ºC[17].

Carbon monoxide

As explained in Chapter 4, the combustion of CO is strongly affected by the presence of moisture, with truly-dry CO being harder to ignite. This also affects the flammability limits, as shown in Table 13. In these tests, 'dry atmosphere' had 15 ppm moisture, while 'normal air' had 0.1 – 0.5%. The tests[187] were run in a rig similar, but not identical, to the one with which standard tabulated values for CO have been reported (the BM values are 12.5 and 74%, respectively).

Table 13 Effect of moisture on flammability limits of CO

Atmosphere conditions	LFL (vol%)	UFL (vol%)
dry atmosphere	18	54
normal air	14	67

Cellulose

Cellulose is one of the three main ingredients of wood, the other two being hemicellulose and lignin. It is found in nearly pure form in laboratory filter paper, and in various purities in commercial papers. The thermal conductivity (W m^{-1} K^{-1}) of cellulose at room temperature can be expressed as[188]:

$$\lambda = \exp\left(1.45 \times 10^{-3}\, \rho - 3.39\right)$$

where ρ = density (kg m^{-3}). In an early study, Brown[189] found an autoignition temperature of 239 – 254ºC. Holm[190] reported in 1913 that cellulose shows a glowing ignition at ca. 360ºC. NBS conducted autoignition tests on 3.3 g of filter paper using a small tube furnace where the air flow rate was said to have been optimized[191] (Table 14). The specimens ignited by a glowing ignition and it was not re-

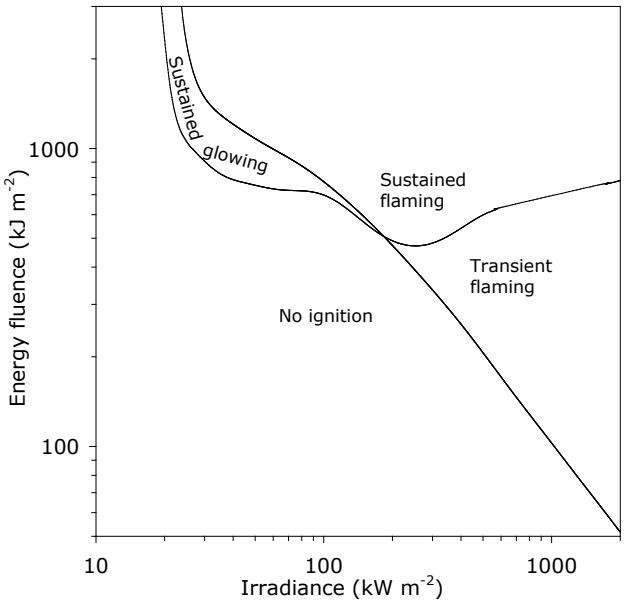

Figure 16 Regimes of ignition for 0.05 mm thick blackened cellulose paper exposed to tungsten lamp radiation

ported whether flaming subsequently ensued. Note that the minimum ignition temperature found for wood is 250ºC (see: *Wood*) and cellulose is one of the main components of wood, so the ignition temperature would be expected to be roughly similar.

Shivadev and Emmons[192] used a radiant heater to ignite Whatman No. 2 white filter paper of 0.18 mm thickness and 85 g m^{-2} basis weight. They found that $\dot{q}''_{min}$ = 42 kW m^{-2} was needed for autoignition. At lower irradiances, the material charred and fell apart, but did not begin flaming. At ignition, they found an average specimen temperature of 350ºC. They concluded that, as far as Arrhenius kinetics was concerned, there were two temperature regimes. For temperatures in the range 260 – 382ºC, E = 109 kJ mol^{-1}, A = 5.9×10^6 s^{-1}, and Q = –368 kJ kg^{-1} (endothermic). For temperatures above 382ºC, E = 226 kJ mol^{-1}, A = 1.9×10^{16} s^{-1}, and Q = +1860 kJ kg^{-1} They also suggested that, throughout the temperature range, the two Arrhenius expressions should be viewed as additive, rather than exclusionary. Martin et al.[1615] conducted experiments where blackened filter paper was exposed to a tungsten lamp source. For

Table 14 Tube furnace tests for the AIT of cellulose filter paper

Furnace temp. (ºC)	Heating time (h)	Ignition
228	70	no
230	45	no
232	7 – 9	yes
246	3	yes
253	2	yes
280	0.5	yes

various types and thicknesses, $\dot{q}''_{min}$ values in the range 20 to 29 kW m^{-2} were found. For these samples, surface absorptivity with respect to the tungsten lamp radiation source was determined to be 0.92. They also assessed ignition by two different means—first observation of surface glow, and first observation of flaming. The values of $\dot{q}''_{min}$ determined at the glowing threshold were about 10% lower than the values cited above for flaming. Martin and Alvares[193] summarized their results in the form of a graph of irradiance versus energy fluence (irradiance × exposure time), and this is shown in Figure 16.

In comparing the results of Martin and Alvares to those of Shivadev, it is not clear why Shivadev's minimum heat flux was so high. A value of around twice the black-material value would be expected for white specimens if a tungsten lamp source were used by Shivadev, but he used a low-temperature coiled-wire heater. For specimens exposed to enormous heat fluxes (180 – 1900 kW m^{-2}), Martin[194] found that the surface temperature at ignition was 600 – 650ºC. This is in line with studies on other substances which show that T_{ig} rises significantly if huge heat fluxes are involved, but a factor also to be considered is that Martin irradiated fairly small areas. Weatherford and Valtierra[195] claimed to have achieved piloted ignition of cellulose sheets using a convective heat flux of only 2.5 kW m^{-2}, but their numbers are inconsistent and it appears that their calibrations were erroneous.

Hinkley et al.[196] conducted experiments on vertically-oriented filter paper (87 g m^{-2}) by impinging an air stream from a hot-air blower onto the paper. Their results are given in Table 15. Air flow velocities were not measured.

Table 15 Autoignition of filter paper from hot-air blower

Distance from outlet (mm)	Hot air temp. (ºC)	Ignition time (s)
25	876	3.8
51	849	3.7
76	705	5.3
102	545	10.5
127	413	N.I.

Walker et al.[197] studied self-heating of cellulose and concluded that the exothermic reaction is of the autocatalytic type. However, Vovelle et al.[198] determined that cellulose oxidation can be represented as a first-order reaction, with E = 250 kJ mol^{-1} and $A \approx 10^{19}$ s^{-1}. Davies et al.[199] examined cellulose in a thermal analysis apparatus at a heating rate of 20ºC min^{-1} and found that autoignition occurs at 350ºC if flowing air conditions are maintained. If the specimen is exposed in stagnant air, an exotherm was found at 341ºC, but no overt ignition. As the heating rate was lowered, the ignition temperature dropped, going down to 283ºC at 1ºC min^{-1}. For oxidation in atmospheres of 21% oxygen, the

same workers[200] concluded that E = 155 kJ mol^{-1}, but noted that the value rises with increasing oxygen concentration.

Cellulose insulation

'Cellulose' insulation is made from ground-up newspaper, which of course, is a wood-pulp product and not wholly just cellulose (it can also occasionally be made from cardboard or wood stock material). Loose-fill cellulose insulation is blown into place using a mechanical blower, and is blown in to a density of 28 – 35 kg m^{-3}. With time, the insulation settles, and a settled density of 50 kg m^{-3} is typical. In making the insulation, FR agents must be added if the product is to pass fire tests required by US Federal regulations mandated by CPSC since 1978: the critical radiant panel test ASTM E 970[201], and a separate smoldering test described in ASTM C 739[202]. Kokkala has provided details for a variety of other test methods designed for cellulose insulation that are occasionally used[203].

Commonly borax (sodium tetraborate, $Na_2B_4O_7 \cdot 5H_2O$) is used to retard flaming ignition and flame spread, while boric acid (H_3BO_3) is added to limit the smoldering potential. These FR agents are added as dry powders. The total amount of retardants added on is about 15 – 25 pph (parts per hundred parts of cellulose insulation, by mass), since attempting higher loadings yields segregation. Siddiqui et al.[204] recommended that about 2 pph borax is needed to pass the critical radiant panel test, and about 18 pph boric acid to pass the smoldering test. In another paper, the same author[205] suggested that the loading be no less than 2 pph borax and 12 pph boric acid. Commercial formulations vary widely, but 4 pph borax and 14 pph boric acid would be fairly typical. In some formulations, another powder, ammonium sulfate is used, but this can show corrosion problems. A liquid FR agent, ammoniated polyphosphoric acid, has occasionally been used.

To pass the required tests, the material must not show a critical flux for 'creeping' flame spread of less than 1.2 kW m^{-2} nor a mass loss over 15% in the smoldering test, which uses a cigarette for the ignition. A cigarette is a very small hot body and, for a successful smolder-retardant formulation, self-sustained smoldering does not occur. However, if a larger-area hot body does cause smoldering to be initiated and the insulation layer depth is greater than about 60 – 100 mm, even large loading (25%) of boric acid will only reduce the velocity of smolder, but not stop smoldering[206]. Gustin reported that a 75 W light lamp placed on a variety of commercial FR-treated cellulose insulation resulted in smolder being initiated in 100% of the trials[207]. Boric acid acts to extinguish the high-temperature afterglow that follows the smolder front; thus, it can help reduce the tendency for a smolder-to-flaming transition to occur. Under conditions of no external wind, the peak temperatures in a smolder front are about 500ºC.

For a given level of FR treatment, the ignition resistance of cellulose insulation increases with fiber diameter. Additionally, larger particle sizes require less FR treatment to achieve the same resistance to smoldering. Some experimental work[208] with an FR system comprising boric acid, borax, and aluminum sulfate in the ratio 2:1:2 showed that increasing the particle diameter from 0.2 to 2.0 mm was equivalent to increasing FR agent loading by about 5 percentage points. The mixture used by the researchers, however, does not represent a common commercial formulation.

Grand[209] conducted a survey where he examined 73 fire incidents involving cellulose insulation. He observed that ignitions of this material are hard to isolate in US statistical fire data bases, due to coding problems. From the actual cases examined, he concluded that the major factors leading to the ignition of cellulose insulation were overheating at an electrical fixture; electric wiring problems; and heating from furnace or flue installations. In addition, he noted that some incidents were due to unobserved ignition of cellulose attic insulation when a fire in another space had occurred and been extinguished. Later, smoldering transitions into flaming. Gustin[207] reported that in one case cellulose insulation ignited simply from heat created by a ceiling-mounted room fan. A large fire occurred when cellulose insulation ignited from mechanical sparks that were emitted by a circular saw used to cut through metal roofing[210].

Belles[211] studied the performance of cellulose insulation and reported a number of problems. He concluded that even properly treated insulation can smolder. As with any porous, smoldering material, extinguishment is very difficult and rekindling can be expected. Belles also reported that the fraction of products in the marketplace not complying with the mandatory regulations was found by CPSC in one study to be 65%. Furthermore, several studies have found that aged, in-place material, when tested, failed the flammability tests, although it is not clear that the material would have passed when new. In one field study[212], only 8 out of 133 samples passed both the ASTM E 970 and the smoldering tests. According to Davie[213], fires occur most commonly when ceiling light fixtures are improperly installed, and adequate clearances do not exist. In a large-scale mockup experiment, he found that, after smoldering for 10.5 h, cellulose insulation then ignited wood joists. He also reports that after extinguishment with water, smoldering was not completely stopped, and resulted in a rekindle 2 days later. Thus, evidence exists that smoldering of cellulose insulation can persist for at least 2 days.

Laboratory studies have confirmed the progressive worsening of performance with age. A NIST study[214] noted that fire retardants may be lost by mechanical settling out, by subliming, or due to moisture effects. After conducting environmental cycling tests, the author concluded that "the long term fire protection provided by fire retardant com-

Table 16 Critical hotplate temperature needed for ignition of 300 m thick layer of cellulose insulation

Condition	Critical hotplate temp. (ºC)
non-FR, ambient = 22ºC	212
treated with 20% boric acid, ambient = 22ºC	232
treated with 20% boric acid, ambient = 80ºC	222

pounds may be limited." Without effective fire retardants, of course, cellulose insulation is just shredded paper, with ignition properties identical to shredded paper. One laboratory study[215] documented that thermal aging of the material may make it more prone to fail the radiant panel test. In an extensive California study[216] using three different manufacturers' products, it was found that after a 3-year exposure all specimens no longer passed the ASTM E 970 test. In the California study, the material was simply stored in a warehouse and was not subjected to either mechanical forces that could cause FR agents to settle out, nor to any accidental wetting which could leach them. Thus, the authors of the study concluded that the diminishing performance is probably due to acidic components being produced by the cellulose itself, which react with, and neutralize the borax. They also pointed that boric acid may slowly be sublimed out of the material. Another possible reason may be that when crude (rather than pure) boric acid is used, the residual sulfuric acid which is contained in crude boric acid reacts to convert borax into boric acid, diminishing the flaming-ignition performance[217].

As discussed in Chapters 7 and 9, smoldering ignition cannot be characterized by a fixed ignition temperature. In testing with hot bodies, the area of the hot body is an essential variable. Issen measured the self-heating parameters of unretarded cellulose[218] and applied standard self-heating theory. Using several different methods, he got substantially scattered data, but his results using an adiabatic furnace are probably most relevant: E = 110 kJ mol^{-1}, QA = 1.7×10^{13} W kg^{-1}, and P = 46.6. In a more extensive study, Ohlemiller[206] found that hot body temperatures of 380 – 385ºC were needed when using a wire of 4.8 mm diameter, but only 255 to 266ºC for an 0.2 × 0.2 m hot plate. For modeling purposes, he concluded that the oxidation chemistry could be represented by a reaction with E = 174 kJ mol^{-1}, λ = 0.053 W m^{-1} K^{-1}, A = 1.17×10^{13} s^{-1}, and Q = 4.2 kJ kg^{-1}, with P = 41.0 being derivable from his given data. These values were obtained from thermal analysis studies[219]. In studies with a hotplate method[220], however, he obtained E = 113 kJ mol^{-1}, QA = 3.7×10^{13} W kg^{-1} and giving P = 40.3 for unretarded insulation of 34 kg m^{-3} density. For insulation retarded with 20% boric acid, the hotplate results were E = 132 kJ mol^{-1}, QA = 9.0×10^{14} W kg^{-1}, and P = 43.9 at a density of 41 kg m^{-3}. These results are perhaps most clear if illustrated for the case of a 300 mm layer, a common insulation depth in attics (Table 16). Over a moderate range of practical densities, Ohlemiller also showed that variations in *density* do not affect the critical conditions[221]. While he discusses the application of the first-order theory to predictions of self-heating, Ohlemiller cautions that no study exists where behavior of cellulose insulation exposed to moderately elevated temperatures over the course of months or years was examined. Cellulose insulation fires are known to have occurred months-to-years after original installation. For example, a CPSC study[222] documented a number of cases where the time between the installation of insulation and a fire originating at a light fixture (not overlamped) was recorded. These times were: 1 day; 4 and 9 months; and 1, 8, and 10 years.

Yereance[223] claims that attic fires have been identified where cellulose insulation self-heated without the presence of any external sources of heat. Using an ambient temperature of 330 K and values of E = 110 kJ mol^{-1} and P = 46.6 gives a critical layer height of 24 m. This is vastly in excess of the 0.3 m or so of attic floor insulation that is typically provided, and—if theoretical extrapolations are justified—indicates that ignition will not occur due to self-heating. However, as further considered in connection with self-heating of wood (see: *Wood*), there must be a general *caveat* applied to using chemical reaction data obtained from short-term experiments to thermal degradation occurring over long time periods.

UK tests[224] on cellulose insulation showed that products treated to pass the cigarette test will not ignite from a lighted match nor from a small wood crib, but can go into smolder from (1) an electric wire drawing excessive current; or (2) from contact with an already smoldering object larger than a cigarette. If smoldering is initiated, it typically proceeds at about 180 mm h^{-1} in unretarded material and 115 – 130 mm h^{-1} in material with insufficient FR agent[203].

Cellulose nitrate, Celluloid, pyroxylin

Cellulose nitrate (also called *nitrocellulose*) is made by the nitration of cellulose. Cellulose belongs to the general chemical family of polysaccharides. It is a major constituent of living plants and is a natural polymer comprising repeating units of a hexagonal structure. Its ultimate formula is $(C_6H_{10}O_5)_n$. Cellulose nitrate is produced by reaction with a mixture of nitric and sulfuric acids. This esterification process, whereby hydroxyl (OH) groups are replaced by ONO_2 groups, is called nitration. The end product consists of high-molecular-mass polymer chains composed of anhydroglucose units, with each unit containing up to 3

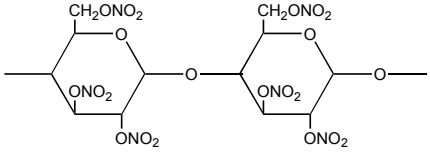

Figure 17 Structure of fully-nitrated cellulose nitrate (OH, instead of ONO_2, groups are present to the extent that the substance is not fully nitrated)

nitrate groups (Figure 17). The general formula is $C_6H_7O_2(OH)_x(ONO_2)_y$, where x+y = 3. Thus, if y = 1, then the formula is $C_6H_9O_7N$ and N content is 6.75 mass%; if y = 2, then the composition is $C_6H_8O_8N_2$ and the N content = 11.11 mass%; while if y = 3, then the formula is $C_6H_7O_{11}N_3$ and the N content is 14.14%. Although maximum nitration corresponding to y = 3 is not practically achievable, nitrocelluloses with the highest practical amounts of nitrogen (13 – 13.5%) are called *guncotton*. The commercial form of the product can be fibers, films, or powders. The end use applications include explosives, Celluloid, lacquers, inks, adhesives, and nail polish. A variety of 'double-base' explosives are prepared by combining nitrocellulose with nitroglycerin. Single-base explosives which do not use nitroglycerin are also made. Celluloid contains 10.5 to 12.2% nitrogen (typ., 11%), material going into lacquers and other coating products 11 – 12%, while material for explosives manufacture ranges from 11.8% to 13.5%. The term *nitrocellulose* is chemically misleading, since the nitrogen-containing groups are nitrate (ONO_2), not nitro (NO_2).

Celluloid, a thermoplastic material, was invented in 1862 and comprises cellulose nitrate, camphor and castor oil, prepared with alcohol solvent. The camphor (typ. 25 – 30%) acts as a gelatinizer and larger amounts increase the flexibility of the product. Castor oil also increases the flexibility of the product, but its softener action is because it is miscible with nitrocellulose, rather than being due to a direct chemical reaction. Celluloid film was the first flexible, transparent material successfully commercialized for use as photographic and movie film. A nitrocellulose 'leathercloth' was another early consumer product used as automobile seat upholstery and in other applications. It is a cotton cloth treated with nitrocellulose, which imparts it an impervious film coating. *Pyroxylin* is a term sometimes used for commercial nitrocellulose-based products.

When cellulose nitrate is detonated, the products are primarily CO_2, CO, H_2O, N_2, and solid C. Nitrocellulose is subject to a slow, spontaneous decomposition, and the products of decomposition are quite different from those of detonation. The decomposition process, sometimes referred to as *denitration*, involves the oxidization of unreacted cellulose by the nitrate group, producing nitrogen oxides which have an autocatalytic effect[225]. It is thought that decomposition begins by cleavage of the O–NO_2 bond, with subsequent interaction occurring between the liberated NO_2 and the bulk material. The decomposition products include nitrogen dioxide (NO_2), nitric acid (HNO_3), and nitrous acid (HNO_2). The nitrogen dioxide which is initially formed then continues to react, undergoing secondary reactions with both the solid material and its decomposition products. The exact mechanism of autocatalysis is not clear. Since the nitrate groups have a destabilizing effect on each other, nitrocellulose compositions with a higher percent of nitrogen are less stable than ones which have a lower nitration level. Some of the decomposition is attributed to hydrolysis, caused by residual sulfuric acid which cannot be fully removed by boiling the nitrocellulose during its manufacture. The gaseous products of thermal decomposition primarily comprise NO, NO_2, and N_2O_4. A reddish-brown color seen in decomposition gases is due to NO_2; NO, N_2O_4 (and N_2O) are colorless. In studying milligram-size samples of nitrocellulose exposed to slow heating[226], it was found that rapid burning or detonation was preceded by liquefaction, which begins slightly above 180ºC. Thus, any visible liquefaction should be taken as a sign of onset of instability. The addition of camphor (as in Celluloid) increases the thermal stability of the product. Decomposition of cellulose nitrate does not require oxygen, thus excluding oxygen is not a viable safety measure. The presence of moisture accelerates the decomposition[227].

Cellulose nitrate is subject to photochemical decomposition by ultraviolet radiation. Stabilizers, e.g., sodium carbonate, can be added to nitrocellulose products to reduce the tendency to decomposition. Cellulose nitrate films have ignited when exposed to direct sunlight, and a Celluloid comb was reported to ignite in a lady's hair[242]. A shoemaker's material called "toe puffs," comprised of cotton or wool cloth impregnated with cellulose nitrate, solvent, rosin, and dye, is associated with a significant danger of spontaneous combustion. Several disastrous fires on ships carrying this material have been described[228]. Gamble[229] provided an extensive listing of fires attributed to ignition of Celluloid.

The cellulose nitrate contained in smokeless powder explosives was traditionally treated with about 1% diphenylamine as a stabilizer[230], later, diethyldiphenylurea also came into use. Stabilizers work in a sacrificial manner, by reacting with the NO_2 that is liberated and forming various nitro- and nitroso derivatives. The stability of cellulose nitrate was in recent years found to depend on the position in the carbon ring which is esterified, with the C_6 position being fully stable, the C_3 intermediate, and the C_2 highly unstable[231]. Since moisture promotes decomposition of smokeless powder, careful drying of the product is necessary.

It is considered[943] that decomposition and instability of cellulose nitrate can first be detected at around 100ºC. A number of empirical tests have been developed specifically for testing the stability of cellulose nitrate materials[225]. At 50ºC, the rate of decomposition is about 4.5×10^{-6} % h^{-1}, and this increases by about 3.5 times for each 10ºC rise in temperature[232]. Gross and Robertson[109] made some of the earliest studies to determine the self-heating data for nitrocellulose. Their results are shown in Table 17, along with later, mostly Russian, determinations. The Gross study has been criticized for being performed in an open-vessel arrangement, so that reaction products could escape. Since it is known that autocatalytic effects exist, this arrangement under-represents the heating that may actually occur if the products are not freely vented[233]. Russian research[234] has indicated that the actual decomposition proceeds as two

parallel reactions, a first-order reaction and an autocatalytic reaction. They concluded, however, that for practical purposes, a zeroth order representation does not lead to large numerical errors, provided that the fraction of substance reacted is not large. Fifer[235] and Brill[236] provided more extensive reviews of the literature and discuss the proposed kinetic mechanisms in some detail. Brill pointed out that data in the range 100 – 200ºC show two parallel reactions, and that widely scattered E and A measurements can be reconciled by plotting ln(A) as a function of E. Two different, straight lines emerge, depending on whether autocatalysis or first-order reaction dominated in the particular experiment.

The sensitivity of various cellulose nitrate products depends highly on chemical and physical details and general guidelines are not possible. Nitrocellulose propellant powder, even if stabilized and in good condition, can be highly sensitive to detonation from electrostatic sparks, as was determined after an explosion in the Netherlands[237]. The ignition of cellulose nitrate from impact by heated small particles was studied by Grossmann and Rele[238]. They concluded that, for particles of 5 mm diameter, ignition will occur even at negligible kinetic energy, if the particle temperature exceeds 300ºC. Conversely, even unheated particles will cause ignition at velocities over 150 m s^{-1}. The radiant ignition of thin (10 μm) films of cellulose nitrate (12.5% N content) was studied by Lenchitz et al.[239] They found that an energy fluence of 14.6 kJ m^{-2} was needed for ignition of film that had its surface blackened. Clear films required about 5× greater energy fluence than did blackened ones. The computed T_{ig} was 270±10ºC. For other thicknesses, the energy fluence required for ignition was related to film thickness as:

$$E'' \propto d^n$$

where d = thickness and $n \approx 0.72$. In addition, they concluded that films thicker than about 20 μm could not be analyzed as thermally thin, since a substantial temperature gradient started to be present. Their study also demonstrated that radiant ignition of cellulose nitrate is a pure-decomposition event which does not require oxygen from the atmosphere—comparative tests run in an N_2 atmosphere yielded essentially identical results.

Numerous fires with X-ray film occurred in the early decades of the 20th century. These have typically involved ignitions from incandescent lamps or from steam pipes. If not extinguished very early, the fires typically lead to forceful explosions. The most systematic investigation of the ignitability of cellulose nitrate film occurred in the aftermath of a fire at the Cleveland Hospital Clinic in 1929[242] which claimed 125 lives. The base stock for the X-ray films of the era comprised cellulose nitrate with 12% nitrogen content, 9% camphor, and a small amount of solvents. The coating on the base stock was gelatin, amounting to 12% of the total weight. The stability of cellulose nitrate film stock is considered intermediate between Celluloid grades and explosives grades. This is attributed to the intermediate level of camphor, typically 9% and much lower than found in Celluloid materials. The camphor component has a tendency to vaporize away in prolonged storage; this, along with the autocatalytic nature of the decomposition, makes aged film more hazardous.

Experimental work in connection with the above investigation involved examining small, 1 g amounts of films in a constant-temperature oven. During a 24 h exposure, no decomposition was seen at 100ºC. For exposure at 120ºC, rapid decomposition occurred at about 12 h. For exposure at 140ºC, rapid decomposition occurred at 5 min and flaming at 15 min. Using 500 g samples at 100ºC, decomposition started at 40 min; at 120ºC, it started at 7 min. However, at 80ºC, a 500 g sample remained undecomposed for 24 h. All experiments, even ones where decomposition was not seen, indicated that the material readily lost 2 – 3% of the mass; this is probably largely solvents, but also some camphor.

Another series of experiments was done exposing film to direct contact with frosted 100 W lamps. Naked film ignited in 310 s. When the film was enclosed in paper envelopes a longer ignition time of 420 s was seen. A wire lamp guard holding the lamp about 8 mm away from the films proved to be of no value in forestalling ignition. Further studies examined the milder exposure of film placed in paper envelopes and exposed only edge-on to the lamps. In these tests, 100 W lamps also caused ignition, and even 60 W lamps were able to start significant decomposition. Companion tests with cellulose acetate safety films showed no ignitions.

The value of 149ºC has been cited as the ignition temperature for nitrate film[250]; the same reference cites data that fresh nitrate film exposed in air at 163ºC ignite in 80 s; at 204ºC in 10 s; and at 260ºC in 3 s. But other studies showed lower values. In experiments on steam pipe contact with cellulose nitrate films in connection with the Cleveland

Table 17 The self-heating chemical kinetic properties of cellulose nitrate

Test method	Temp. range (ºC)	E (kJ mol^{-1})	QA (W kg^{-1})
oven heating in glass tube (Taliani test)[240]	90 – 140	128	NA
radiative ignition[234]	233 – 286	174	2.0×10^{23}
radiative ignition[234]	227 – 268	211	3.2×10^{27}
convective ignition[234]	210 – 250	187	2.1×10^{25}
convective ignition[234]	210 – 220	201	1.5×10^{25}
conduction ignition[234]	211 – 241	185	2.5×10^{24}
conduction ignition[234]	185 – 225	200	9.6×10^{25}
self heating[234]	225 – 255	209	2.1×10^{26}
self heating[241]	--	204	2.0×10^{25}

isothermal calorimeter[234]	140 – 165	197	3.1×10^{25}
adiabatic calorimeter[234]	135 – 170	176	1.2×10^{23}

disaster, when temperatures on the outside of the pipe were ca. 145ºC, ignition generally took place in 15 – 30 min, depending on details of the arrangement. For temperatures of ca. 155ºC, ignition took place in 2 min. NBS[243] ran tests on tiny (2 – 5 g) samples and found that, if stored at 135ºC, ignition typically took place in around 2 h. Slightly larger (5 – 10 g) specimens stored at 110ºC typically lost about 25% of their mass in 8 days, but did not ignite. Using large 300 g samples subjected to 100ºC, explosions occurred in about 8.5 h. A Japanese study[244] found an AIT of 167ºC when testing 1 g quantities in a test tube.

The high hazard of cellulose nitrate products, however, comes not from rapid ignition when exposed to high sources of external heat. Rather, the problem is due to the unstable nature of the material and its innate self-heating propensity. Even storage in film vaults under common summertime conditions of 38ºC is believed to have been the cause of nitrate film fires[250]. A study by NBS[245] identified the crucial role of deterioration in determining the self-heating propensity of nitrate films. In their tests, film cans were wrapped with thermal insulation and stored at elevated ambient temperatures of 41 – 49ºC. Films which were visibly deteriorated prior to testing went to thermal runaway, but non-deteriorated films did not.

Some large-scale burning experiments have been reported on cellulose nitrate packed in steel or in cardboard drums[246]. The measurements include emissive power and radiant fraction, and are intended to enable estimations of ignitions of targets from a burning stack of packaged nitrocellulose. Ryan et al.[247] reported results of large-scale fire tests on nitrocellulose storage vaults, but this study did not examine ignition aspects.

In addition to the Cleveland disaster, photographic, radiographic (X-ray), and movie 'nitrate' film has been responsible for other catastrophic fires, but in this use it has been replaced by 'safety film' (generally based on cellulose acetate) for the last half-century. However, stocks of old nitrocellulose films may still exist in archives. Because of the inevitable degradation, cold storage warehouses are used for safety and for preservation. A violent explosion occurred when a pipe containing cellulose nitrate residues was being cut by a hacksaw[248].

Water is often ineffective in extinguishing burning cellulose nitrate, since the material is self-oxidizing and does need access to air; large amounts of water, however, can cool the reaction down. NFPA 40E[249] is a standard describing requirements for warehouses and facilities storing nitrocellulose materials, except those used as motion picture film or in lacquer manufacturing. NFPA 40[250] treats nitrocellulose motion picture film. It is especially intended that film be regularly examined for signs of decomposition (discoloration, blistering, tackiness) and destroyed or segregated if such are found. This is an essential precaution due to the catalytic effect of the decomposition products upon further degradation. NFPA 35[251] describes the safety precautions to be used in the lacquer industry.

Charcoal, coke, and related products

CHARCOAL

Charcoal is produced by the destructive distillation of carbonaceous material. The most common source of carbonaceous material is hardwood. The composition of charcoal depends strongly on the temperature of carbonization (the temperature at which it was produced)[252], as shown in Figure 18. For temperatures exceeding 900ºC, the carbon content exceeds 95%, but commercial charcoal is normally not carbonized at such high temperatures. In general, charcoal made by the traditional process of pit-burning is carbonized at a higher temperature than is charcoal produced in a wood distillation plant, using retorts or ovens. In the absence of measured data, it is often estimated that the mass percent carbon is about 67 – 80%; hydrogen 2 – 3.5%; oxygen 13 – 17%, nitrogen 0.2 – 0.6%, sulfur 0 – 0.04%; and ash 3 – 13%. For many purposes, it is adequate to express it as having a simplified formula of $C_{16}H_{10}O_2$. The gross heat of combustion is 25 – 31 MJ kg^{-1}. Charcoal is largely amorphous, but contains a small amount of ordered, graphitic crystallinity.

In 1816 Sir Davy[253] reported that charcoal heated to the "strongest red heat" would not ignite a methane/air mixture. This is not surprising, since his "strongest red heat" was surely less than the minimum 1000 – 1200ºC which later investigators found a hot object must be heated to in order to ignite methane/air mixtures.

Using a convective heating apparatus, Hill[254] measured the ignition temperature of charcoal to be 403 – 408ºC. Fons[255]

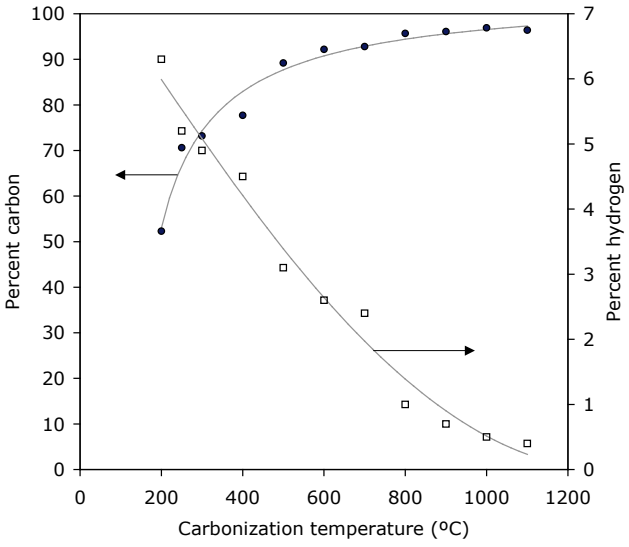

Figure 18 Effect of carbonization temperature on composition of charcoal

reported that 232ºC is the minimum temperature to which charcoal must be raised for glowing ignition to occur, but the experimental basis for his conclusion is unclear. Furthermore, such data would not be of much value, since studies have shown that the ignition temperature of charcoal is strongly dependent on its carbonization temperature. Violette's test results of 1848, as given by Urbański[256], are shown in Table 18. Burgoyne and Richardson[257] performed ignition tests on charcoal in oxygen, not air, and obtained the results in Table 19. Bergström[258,259] also found a dependence on the carbonization temperature, but in his case, lowest ignition temperatures were found for charcoal carbonized at 425ºC, with higher or lower carbonization temperatures both serving to raise the ignition temperature. His lowest reported autoignition temperature was 100ºC, with charcoals carbonized at other temperatures igniting at 110 – 140ºC. These are very low values and are presumably because the material was tested in a finely-ground state. His apparatus was a vertical test tube inserted in a constant-temperature bath, with air being pumped through the test tube. Bergström's data are rather hard to interpret, but Violette's and Burgoyne's results both imply a clear increase of AIT with increasing carbon content of the material. A similar dependence of AIT on carbon content was also found for another carbonaceous material, coal, and those results are given in Chapter 8.

Table 18 Ignition temperatures of charcoal, as reported by Violette

Temp. of carbonization (ºC)	Color of charcoal	Ignition temp. (ºC)
260 – 280	brown	340 – 360
290 – 350	brown	360 – 370
432	black	400
1000 – 1500	black	600 – 800

Table 19 Ignition temperatures of charcoal when ignited in oxygen, as determined by Burgoyne and Richardson

Temp. of carbonization (ºC)	Ignition temp. (ºC)
350	236
450	248
550	268

It has been claimed that the reason why charcoal carbonized at a higher temperature has a higher AIT value is because such charcoal has a lesser ability to adsorb oxygen[260]. However, no reliable experimental studies exist on this point. The heat of adsorption of oxygen onto charcoal was studied to a limited extent by Blench and Garner[261], who showed that it varied with temperature and with the fraction of surface sites already occupied by oxygen. One set of results showed the value rising from 218 J mol^{-1} at 18ºC to 937 J mol^{-1} at 450ºC.

Lumps of charcoal can be highly susceptible to spontaneous combustion, as indicated by this incident[262] described by 19th century Harvard University professor Charles T. Jackson: "While at work in my laboratory, I had occasion to use a piece of charcoal for blow-pipe experiments. I went down to my cellar and brought up a piece of light, fine, round charcoal, suited for that purpose. It was damp. I laid it on the top of a column stove to dry, directly beside a tin pan containing water which was not boiling, and never did boil there. I took the charcoal off the stove and laid it on my table. A short time afterward, I discovered that it was on fire through the piece. I laid it aside, and it burned entirely to ashes. The theory of the ignition of the charcoal under these circumstances struck me at once. Charcoal has wonderful porosity: it has the power of analyzing air, and adsorbing oxygen with comparatively little of its nitrogen. The pores of the charcoal were previously filled with moisture. Drying expelled this moisture. The oxygen of the air was condensed in the charcoal, taking the place of the moisture. The condensation of the oxygen produced enough heat to ignite the charcoal. I repeated this experiment again intentionally, watching it carefully, and with the same result." This incident is especially interesting, since Jackson demonstrated the repeatability of spontaneous combustion at a sub-100ºC external temperature. A moisture effect was again found by Bixel and Moore[263], who reported that in their tests dry charcoal ignited at 216ºC, but moist charcoal at 159ºC. Lucas[449] mentioned an incident of spontaneous combustion of small pieces of freshly-made charcoal, but gave no details.

In 1913, Rosenhain and Gemmell[264] conducted an experiment where they filled a cubical basket (0.35 m on a side, made of perforated brass) with flake charcoal and placed it in an oven. If air supply was restricted to the oven, only modest self-heating was found, but for a larger air supply (but still limited) they found that if the oven temperature was set at 96ºC or higher, spontaneous combustion took place. They then repeated the experiments using air containing 5% SO_2 (used as a fumigating agent on ships). In that case, they found that spontaneous combustion would take place without heating the oven, starting from a room temperature of 16ºC.

Laupper[265] reported in 1926 on sketchily-described experiments where he showed that small amounts of iron strongly catalyze the self-heating of charcoal. He also documented[266] that explosions occur when liquid oxygen is introduced into iron-contaminated charcoal, but do not occur if the charcoal is iron-free. In 1943, Blayden et al.[267] provided quantitative data to demonstrate that quite a few, primarily inorganic compounds (e.g., sodium, potassium or lead carbonate; lead or sodium acetate; vanadium pentoxide, etc.) act as catalysts and reduce the ignition temperature of charcoal by 100 to 230ºC.

Ground charcoal can act similarly to textile fibers in providing a large surface area for oxidation to take place on. Thus,

self-heating fires have been found due to cod-liver oil applied to granulated charcoal[268].

CHARCOAL BRIQUETTES

Commercial charcoal briquettes are comprised of ground charcoal which is combined with a starch paste. The commercial product may also contain additives such as sawdust, coal, limestone, sodium nitrate, and borax[269] to improve the physical characteristics and to achieve a more uniform combustion. Although this has not been studied formally, it is reasonable to assume that these commercial products ignite and burn rather similarly to pure charcoal. Some thermocouple data on commercial briquettes burning meat in a barbecue show peak temperatures of 410 to 470ºC, but with an average temperature around 380ºC during the first 2 to 3 hours of active combustion[269]. Results from seven tests indicated that temperatures dropped to 100ºC in 8 – 13 h after ignition and ashes had returned to room temperature in all cases by 15 h. In another series of tests[270], charcoal briquettes were tested two ways—(1) piled as a pyramid of 2.3 kg (5 lb) on the grill and not disturbed; and (2) spread around the grill after the initial combustion period. When burned untouched, a peak temperature of 1075ºC was recorded and combustion lasted over 26 h, although it is not clear what criterion was used to declare end of test. When spread around, a peak temperature of 600ºC was found with the lid open and 425ºC with the lid and ventilation holes shut. In that case, combustion lasted only 12 – 15 h. The author conducted additional tests demonstrating that slightly burned and extinguished briquettes could cool down to ambient temperature on the exterior, but retain enough heat inside to erupt in fire when placed in a bed of cold ashes at a windy outdoors location. The outcome of this experiment was consistent with situations where a fire is caused by a person attempting to re-use partly burned briquettes by dousing them with water and packing them back in the original bags when they appeared to be cold[271]. See also: *Ashes*.

Wolters et al.[275] conducted oven-basket tests and analyzed the results according self-heating theory to quantify the self-heating behavior of briquettes. Extrapolating from the laboratory results, they concluded that the largest common bag size, 9 kg (20 lb), would require a minimum ambient temperature of 121ºC for critical conditions to occur. At normal room temperature, the amount of briquettes required to reach thermal runaway was computed to be 800,000 kg. For their tested specimens, if the first-order theory encompassed by the testing and analysis is appropriate, then spontaneous combustion cannot occur from one or even a modest collection of 9 kg bags. The authors also examined the effect of high moisture by conditioning some specimens at 32ºC and 85% RH. The critical temperature for those specimens increased about 3ºC over the controls. Advice has occasionally been published that wetting and drying charcoal will lead to spontaneous combustion. To examine this point, the same authors, in another series of experiments[272], took briquettes originally at 4.5% moisture, watered them to reach 30% moisture, then dried them for 4 days until the moisture dropped again to 4.5%. The moisture-cycled specimens showed a critical temperature about 5ºC lower than the controls. This value was just barely statistically significant in the experiments conducted. Aging the briquettes[275] for one year (under unspecified conditions) raised the critical temperature by about 10ºC. Compared to normal production, lignite-based charcoal showed higher critical temperatures.

Despite oven-basket test results which suggest that enormous piles would be needed for spontaneous combustion to occur, fire incidents[273,274] continue to be attributed the self-heating of consumer-size bags of charcoal briquettes. In some cases, it could be that investigations were sloppy and other ignition sources (e.g., discarded cigarettes or ashes) were involved. But if the investigation was done properly, the cause can be attributed to contamination. The section on *Paper* in this Chapter describes a well-documented case where a roll of sealed paper towels was found smoldering on a storeroom shelf. In this Federal laboratory incident, the investigating scientists concluded that the product became contaminated either during manufacture or during packaging. A similar effect may be involved with charcoal briquettes.

Methods to prevent easy access of oxygen to the substance, such as polyethylene bags, were found to be useful to eliminate self-heating ignitions of charcoal[280]. This was confirmed by Wolters et al.[275] for charcoal briquettes. Interestingly, Wolters found that Kraft paper bags lowered the critical temperature. They explained that a Kraft paper bag allows oxygen transfer but inhibits convective cooling of the charcoal.

A very different commodity are 'self-lighting' briquettes which contain a solvent (around 10%) for easy ignition by the user. Tests indicated[275] that not only did the solvent not lower the critical temperature, but slightly raised it. Easier-to-ignite charcoal briquettes may also include paraffin wax, but its role has not been explored.

COKE

Coke is produced by carbonizing coal much in the same manner that charcoal is produced by carbonizing wood. Its self-heating properties can be expected to be broadly similar to those of charcoal, but few self-heating studies are available on coke. Shea and Hsu[276] conducted an interesting study using a 'semi-adiabatic' furnace where they examined the effect of atmosphere composition by passing various gases through the Dewar in which the sample was located. From an initial oven temperature of 66ºC, samples subjected to dry oxygen only showed a rise of 1.5ºC; samples subjected to oxygen which was saturated with water vapor showed a 25ºC rise; while samples subjected to water-vapor-saturated nitrogen or CO_2 showed a rise of 17ºC.

This indicates an extremely large effect of moisture on the self-heating process. In comparing various coke types, they found the highest self-heating propensity with semi-calcined coke; green coke showed a much smaller effect, while calcined* coke nearly nil. Coal itself showed a tendency somewhere between the green and the semi-calcined coke. Activated carbon was roughly similar to semi-calcined coke, while lignite showed the highest self-heating tendency of any substance tested.

ACTIVATED CHARCOAL

Activated charcoal denotes charcoal which has a highly porous structure, and is typically used as filtering and adsorption media. Once produced, charcoal can be activated by use of steam, in a reaction ('water-gas shift') where steam at 900 –1000ºC converts some of the carbon to CO according to:

$$C + H_2O \rightarrow CO + H_2$$

and thereby opens up the pore structure. Or, it can be activated by chemical activation, using phosphoric acid or zinc chloride to swell the wood and open the capillary structure. The substances created are not identical. The oxygen content of steam activated charcoal is less than 2%, while the oxygen content of chemically activated charcoal can exceed 10%. Typical activated charcoal[277] may have a bulk density of 370 kg m^{-3} and an internal surface area of 10^6 m^2 kg^{-1}.

'Weathering' is known to affect the thermal stability of all types of charcoal. It is simply storage of the material in small piles in a place where it can acclimate to the ambient moisture. Typically, about 8 days are allowed for this process. During this time, moisture is adsorbed onto the freshly made charcoal†. For a very long time it has been known that this procedure reduces the later risk of self-heating in shipping or in storage of large quantities. Since adsorption is exothermic, a limited amount of self-heating takes place during the weathering procedure. But since weathered charcoal has already undergone the low-temperature self-heating due to sorption of moisture, if it has been cooled down to ambient temperature after this weathering, the remaining hazard is only from oxidative reactions, and not compounded by water sorption exothermicity. Bags holding 25 kg of activated charcoal sustain a temperature rise of about 37ºC during the peak of this process[277].

Bowes and Cameron studied the problem of self-heating in activated charcoal from the point of view of hazards in ship transportation[277]. They conducted standard oven-test experiments on cubical specimens ranging from 25 to 610 mm and found an activation energy E of 97.4 kJ mol^{-1}. They also obtained some self-heating data on specimens which had first been weathered. Weathering for 7 days at 40ºC was found not to affect the critical temperature. Of course, it would not be expected to, since the oven tests are run at typically > 100ºC and the environmental process of moisture flow into a dry specimen is not replicated in such tests‡. They also conducted accelerated weathering experiments at a temperature of 100ºC. These thermally-treated specimens were found to be more resistant to self-heating than the fresh ones, but it would appear that such high-temperature treatment would also alter the chemical nature of the substance. The authors also undertook to compare the laboratory self-heating results to ship-fire incidents involving several tons of material. Based on approximate values of storage sizes and temperatures, they concluded that reasonable agreement exists.

Modern tests based on self-heating theory provide some additional support for the type of data presented by Violette, discussed above. Over the range 410 – 520ºC, the critical temperature in oven-basket tests using 25 mm cubes rose linearly with the carbonization temperature[277].

At one time, it was hypothesized that activated charcoal can act as a catalyst for the heterogeneous oxidation of some organic compounds. Boden et al.[278] conducted experiments using ethanol and benzene on activated charcoal and demonstrated that such catalysis does not occur and, therefore, that it could not be a contributing factor to the self-heating of activated charcoal. Even in the presence of organic solvents, the self-heating was found to occur due to direct oxidation of carbon. Once this self-heating was occurring, however, the elevated temperatures were able to cause some homogeneous oxidation of the solvents' vapor. Another heating mechanism that can also take place in solvent-soaked beds. The heat of adsorption of ethanol onto carbon is much smaller than that of oxygen. Thus, if oxygen is passed over an ethanol-soaked carbon bed, the displacement of ethanol from the carbon surface will be an exothermic process and contribute to the heating. It was also found that when air is passed over an activated charcoal bed which is at 250ºC, there is no measurable amount of CO being produced, only CO_2. Fires in activated charcoal scrubbers are not uncommon[279] and are ascribed to the exothermic heat of adsorption.

Cameron and MacDowall[280] studied 10 charcoals produced by widely differing processes and conditions. For all except the three minimally-hazardous products, the slopes of the lines in the oven-cube test plots were identical, giving $E \approx$ 97.0 kJ mol^{-1}. The values of P ranged from 49.5 for the most self-heating-prone, to 42.0 for the least. These results implied that a single-size oven cube test (but hopefully with at least some replicates!) would be sufficient to classify the self-heating behavior of charcoal. Another important find-

* Calcined coke is produced by heating green coke to about 1300ºC until the remaining material is over 99% pure carbon.

† It is likely that certain chemical reactions (e.g., oxidation at some surface sites) also occur during the weathering process, but this has not been explored in detail.

‡ The weathered material entered the oven bearing moisture which the originally-dry samples did not. But this moisture was largely (endothermically) eliminated prior to the start of the main self-heating process, which does not begin for a 25 mm cube until ca. 143 C.

ing of this study was the performance of the two charcoal specimens which were unfinished products, not yet activated. Neither specimen was outside of the range of the results of the activated products: one of the specimens was about mid-scale in the test results, while the other one was the second-worst performer. This would imply that the massive increase in internal surface area occurring when the material is activated is not the dominant factor which governs the self-heating performance.

For ship transportation, the maximum expected temperature may be ca. 40ºC with a size of 3 m cube. Thus, Cameron and MacDowall suggested that a critical temperature ≈50ºC for a 3 m cube would be an adequate criterion of safety. A laboratory oven-cube test may conveniently be carried out in a size of 0.1 m. Since

$$\delta \propto \frac{r^2}{T_a^2} \exp\left(-\frac{E}{RT_a}\right)$$

with E = 99.0 kJ mol^{-1}, T_a = 323 K, and r = 1.5 m, the value of δ will the same if r = 0.05 m and T_a = 413 K (140ºC); it is not clear why the authors took E = 99.0 instead of 97.0, which represents their published data plot better. Thus, Cameron and MacDowall concluded that a satisfactory test would comprise a 100 mm cube tested at 140ºC. In their tests with 100 mm oven-cube samples they noted that the time to either a peak temperature or thermal runaway was always less than 7 h; on this basis they concluded that a prudent test time would be 12 h.

Cameron and McDowall concluded that the oxygen content of the original material is the dominant factor. The specimens which were chemically activated and had a high oxygen content were the worst performers, while the low-oxygen content steam-activated ones were the best.

The finding that all charcoals have the same E value was rather unexpected and proved not to be reproducible. Jones[281] studied 11 different activated charcoals and found that the values of E ranged from 88 to 110 kJ mol^{-1}, while the zeroth-order pre-exponential constant A varied between 2×10^5 and 2×10^9 s^{-1}. Jones recommends using a value of Q = 25 MJ kg^{-1} for all charcoal types. He also determined that critical temperatures for 100 mm cubes were 110 – 115ºC for the chemically-activated specimens and 250 – 260ºC for the steam-activated ones. Bowes[445] proposed that λ = 0.055 W m^{-1} K^{-1} is a suitable value for thermal conductivity to be used for activated charcoal, but Jones[282] argued, through some indirect findings, that the actual values are typically 0.15 – 0.27 W m^{-1} K^{-1}.

ACTIVATED CARBON

Activated carbon is a substance which is basically similar to activated charcoal, but is generally considered of higher purity, i.e., the components other than carbon are minor. Its uses are also primarily as filtering and adsorption media. Activated carbon (or finely divided forms of carbon) is an unusually active fuel which possesses adsorptive and catalytic properties to accelerate combustion reactions with virtually any oxidant. Ignition may occur upon intimate contact with oxygen, oxides, peroxides, oxosalts, halogens, interhalogens and other oxidizing species[3].

The autoignition temperature for the ignition of packed beds of activated carbon was studied by Bigg and Street[283] in an environment where hot gas at a specified temperature flowed upwards through the bed. Using 2 mm diameter particles with a large surface area of 8.8×10^8 m^2 kg^{-1}, they found a mild dependence of T_{ig} on the velocity. The lowest temperature, 295ºC, was found for a velocity of 0.1 m s^{-1}. For high velocities, the AIT reached an asymptote of 320ºC. For velocities lower than 0.1 m s^{-1}, there was an inversely relation of AIT on velocity, with a temperature of 370ºC found for near-zero velocity. The authors also developed a complex predictive model, based on Elovich kinetics, that showed good agreement, but required a fully numerical solution. Hardman et al.[284] also found an ignition temperature of 370ºC at zero velocity, but in their experiments the AIT rose monotonically with increase in air flow.

ASTM provides a test method, ASTM D 3466[285], for testing the ignition temperature of activated carbon under conditions where a steady stream of heated air is pumped through a bed of the activated carbon. This is intended to simulate adventitious ignitions in nuclear power plant filtration operations, not to identify storage hazards. The interest in use of the test method is because the activated carbon beds will contain high concentrations of impurities, and it is desired to characterize the ignition hazard of an actual bed containing impurities—the performance of pure activated carbon is not relevant to these applications. Use of the method has been described by Freeman et al.[286] Suzin et al.[287] studied three types of activated carbon and 3 additional types that were impregnated with metals. For the 'pure' carbons, they found AIT values of 365ºC for one type and "over 370ºC" for the other two. The impregnated types ignited at 365 – 300ºC. Using thermal analysis, they also determined temperatures where exothermicity was first detectable to be about 100 – 150ºC lower than the corresponding AIT values. The specific surface area, which spanned 10^3 – 10^6 m^2 kg^{-1}, did not affect the AIT, although the smaller granule size led to lower AIT values; the sizes ranged from 1.5 to 12 mm. Apart from the uses in the nuclear industry, activated carbon beds are also used in semiconductor manufacturing facilities as scrubbing media for oxidizing gases. In self-heating tests using the Accelerating Rate Calorimeter[288], it was found that activated carbon that had adsorbed NO_2 showed rapid exothermic activity at ca. 30ºC; by contrast, pure activated carbon showed exothermic activity starting at 105ºC.

Nelson[1597] conducted oven-cube tests on powdered activated carbon and obtained the following results over the range

50 – 190ºC: E = 83.2 kJ mol^{-1}, P = 42, λ = 0.16 W m^{-1} K^{-1}, C_p = 1.07 – 1.27 kJ kg^{-1} K^{-1}.

Chimneys and flues*

A large number of fires originate in chimneys, or are initiated by the heat of a chimney or flue pipe[289]. Two main modes of ignition are found:

- A chimney fire occurs because unburned and partially burned material builds up to sufficient depth on the walls that it can eventually be ignited. A chimney fire may (a) directly ignite nearby external combustibles; (b) release flaming material from the top of the chimney, which then falls upon and ignites a combustible roof; or (c) the chimney material may crack or warp due to the fire, so that subsequently a hole opens up and enclosing materials may become endangered.
- A single-layer metal flue pipe radiates at a high temperature if a hot fire is created in the heating appliance. If combustibles are inadequately separated or protected, they may become ignited. The NFPA Handbook[290] and NFPA 211[291] provide guidance on necessary clearances. To allow closer spacing of combustibles, flue pipes can be used that have 2 or 3 concentric metal layers, or else have two metal layers with thermal insulation filling the annulus. Fires involving multi-wall flue pipes typically occur when an improper installation creates a gap between two successive pipe sections.

There have been several experimental and theoretical studies[292- 296] on heat transfer from flue pipes, and advice on clearances to be used is derived from these studies. A 1963 report by Shoub surveyed much of the early literature[297]. In 1985, NIST conducted unpublished tests on factory-built insulated chimneys used with wood stoves and coal stoves[298]. Tests were run for roughly 1 – 2 months, with firing being done to simulate a normal winter-time cycle of usage. No chimney fires occurred with coal stoves, but creosote buildup in the wood stove led to a chimney fire which buckled the metal and caused gaps to open up. The study disproved the sometimes-given advice that creosote can be adequately removed "by having a little fire in the chimney once in a while." With a wood stove, flue gas temperatures were typically in the range of 170 – 250ºC, but under some conditions (excluding an active chimney fire) reached as high as 860ºC. By contrast, the highest flue gas temperature obtained in coal-burning tests was only around 380ºC.

Some triple-wall flue pipes are designed on a *thermal siphon* principle. In that type of design, the innermost space is used for the flow of combustion gases. The space between the inner and the middle tube may be filled with a non-combustible insulation, while the space between the middle and the outer tube acts as the thermal siphon. The principle involved is that if this flow path is open at the bottom and properly discharged at the top, room air gets entrained into it and the flow of this air helps keep both the fuel pipe and the heating appliance cooled. With this type of flue pipe, there is lessened danger of ignition from combustibles contacting the outer surface. However, a failure mode exists that is unique to this system. If the installation is improper, and the flow path in the outer annulus is blocked, then overheating of both the appliance and the flue pipe may be encountered. To mitigate these hazards, every installation must be in accordance with the manufacturer's listing and installation instructions. Some appliances are acceptable only when installed with a thermal siphon flue pipe, and any substitution may result in a fire. In a more general context, this *caveat* is very important with any fuel-burning appliances. Many appliances cannot pass safe-temperature requirements contained in UL and similar standards unless a very specific flue pipe installation is made exactly according to instructions.

Fires are sometimes encountered due to a non-obvious hazard created in a situation where a flue pipe was installed in a space that did not contain attic-floor or similar thermal insulation. If previously-empty space between the flue pipe and a nearby combustible member (floor joist, plywood, etc.) is subsequently filled with thermal insulation, the combustible member will become exposed to much higher temperatures than it would otherwise see. This situation is made clear by considering the geometry in Figure 19.

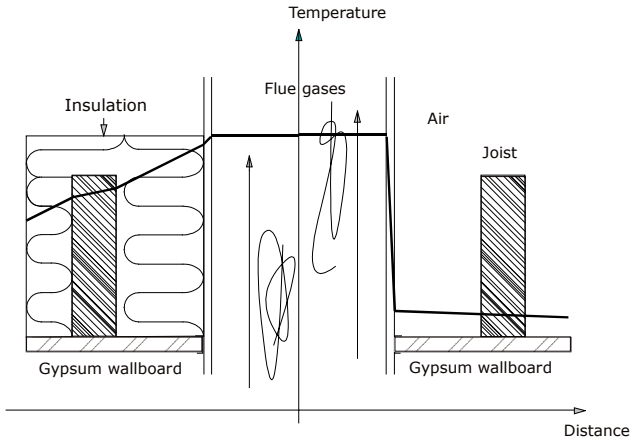

Figure 19 Effect of adding attic insulation on raising the temperature of joists near a flue pipe

Fires in older fireplaces that were site-built using firebricks often occur because there was not a sufficient thickness of brick separating the inside of the fireplace from wood framing members outside[299]. A course of bricks having a thickness around 100 mm is distinctly insufficient and NFPA 211 recommends 150 to 200 mm, depending on whether the fireplace is lined or unlined.

5-Chloro-1,2,3-thiadiazole

Yoshida[300] has reported that this chemical (C_2HClN_2S), an industrial intermediate, has caused two fatal explosions. Its special problem has been that thermal analysis and drop-

* Portions of this section were prepared by Michael M. Fitz.

weight testing failed to reveal the explosive tendencies. In fact, it readily ignites and explodes from friction or impact.

Christmas trees, artificial

The only US standard for testing artificial Christmas trees is UL 411[301]. This includes several tests intended for determining if branches can be directly ignited by faulty electrical lights or wiring, plus a full-scale fire test. It would take an exceptionally flammable plastic material to fail the test portions that simulate electric faults, but the full-scale fire test, on the other hand, is a reasonably tough test. In this test, 0.454 kg shredded newspaper is dispersed at the base of the tree in an 0.61 m circle and is ignited at 4 locations. Failure is declared if the specimen shows flames more than 0.91 m above the top of the tree, if later flame spread takes place in the tree, so that portions not directly over the ignition source catch fire, or if flaming molten drops continue flaming upon hitting the floor. This test simulates ignition from burning gift packages, decorations, or wrappings at the base of the tree. The test was withdrawn in 2002 due to non-use. Currently, artificial Christmas trees sold in the US are largely foreign-made, and these manufacturers have not been submitting products for UL listing, although some of them, in fact, can meet the UL 411 requirements.

Most artificial Christmas trees and properly moist natural ones will resist direct ignition from an electrical source. But ignitions from defective electrical lights or wiring do occur and these are understood to generally take place as a two-stage event. The initial electrical fault produces burning or hot material that drops onto combustibles under the tree. These combustibles, once ignited, then function much like the shredded newspaper source in the UL 411 test to ignite the tree itself. In general, a tree which would not ignite from flames applied onto branches can often ignite and burn vigorously when a burning object is placed underneath it.

Natural Christmas trees are covered under *Forest materials, vegetation, and hay*.

Cigarettes and cigars

Cigarettes are the most common form of ignition which occurs with upholstered furniture and beds; it is also a common source of ignition for a wide variety of other fires. A CPSC study[302] on residential fires initiated from cigarettes gave the results shown in Table 20. The products first ignited in cigarette fires were studied by NFPA[303], as shown in Table 21. The role of cigarettes as an ignition source has been reviewed by Holleyhead[304].

A commercial cigarette[305] typically weighs 0.6 – 1.1 g, is 7.8 to 8.1 mm in diameter, and has a length of 60 to 100 mm. In one series of tests[306] the burn times for 22 different cigarette packings were measured in the range of 11 – 18 min and, surprisingly, there was no relation to length of cigarette—the shortest cigarette (70 mm) burned longer than did any 100 mm cigarettes. In another study, however

Table 20 Materials first ignited in residential fires caused by cigarettes

Material first ignited	Percent
cotton, rayon, or cotton fabric or finished goods	54.3
man-made fabric or finished goods	13.7
untreated, uncoated paper	9.6
fabric, textile or fur, details unknown	3.7
sawn wood	3.2
polyurethane	1.6
tobacco	1.4
multiple items	1.4
PVC	1.2
plastic, unknown type	0.9
other (each less than 0.7%)	6.7
unknown material	2.3

Table 21 Product first ignited by cigarettes (data from 542 fires in 8 US cities during 1991-1992)

Product first ignited	Percent
mattress or bedding	45.4
upholstered furniture	25.4
trash	8.3
clothing	3.5
floor covering	2.5
papers	1.4
curtain or drapery	1.2
multiple items	1.2
structural element or framing	1.1
box or bag	1.1
other known products	7.8
unknown	1.1

burning times of 23 – 29 min were found for 100 mm cigarettes[307]; an extreme duration of 34 min has been reported[308]. The heat output of a cigarette that is not being actively puffed is 4 to 6 W. The autoignition temperature[1418] of tobacco subject to modest air flow velocities below 1 m s^{-1} has been found to be 210ºC. The peak gas temperature inside the cigarette is 800 – 850ºC, however values of 700 – 750ºC are more representative of larger portions of the combustion zone. When a cigarette is smoldering and is not being puffed, temperatures drop by about 100ºC[309]. The temperatures measured on the solids are higher than what is measured in the gas phase. For a puffed cigarette, temperatures of up to 850 – 950ºC are found on the solid 'coal'[309,310]. A temperature of 1110ºC has been reported at an unidentified measuring location[311]. By use of optical measurement techniques, extremely small zones of 1200ºC temperature have been found during puffing[312], the small size, however, makes it unlikely to be of importance in ignition problems. For a cigarette placed on a horizontal surface, the temperature recorded at the cigarette/substrate juncture is about 630 – 690ºC in the case of an insulating material such as upholstered furniture. In the case of a dense, hard surface, e.g., calcium silicate board, values of 370 – 470ºC are found. The peak heat flux[313] from a cigarette to that surface is about 50 – 60 kW m^{-2}. Users tend to

discard non-filter-tip cigarettes[314] when about 32 mm remain, with 95% of the discards ranging from 9 to 43 mm. Krasny has reviewed in more detail the combustion characteristics of cigarettes[1859].

Unlike cigarettes, cigars show much more brand variability. In general, it is considered that cigars do not continue burning to completion unless air is drawn through them, although this may not necessarily be true for all brands in the marketplace. The rate of burning[314] of cigars ranges between 1.8 and 3.8 mm min^{-1}. Left alone, a cigar will burn for 138 – 310 s before self-extinguishing. During that time, 5 – 11 mm will be burned. Some very old data on the temperatures measured in cigars[315] indicate values of 815 – 925ºC when not being puffed; these are indistinguishable from cigarettes.

It may be surprising to realize that cigarettes, puffed or smoldering, are unable to ignite most mixtures of flammable gases in air, at least in laboratory tests. Strese[316] measured a wide variety of gas/air mixtures to determine which ones could and which ones could not be ignited by cigarettes. Ignition was obtained for:

acetylene	hydrogen
carbon disulfide	hydrogen sulfide
ethylene oxide	phosphine
diethyl ether	

Ignition was not obtained for:

acetone	ethylene
acrolein	*n*-heptane
ammonia	*n*-hexane
benzene	methane
butadiene	methanol
butane	methyl amine
butyl acetate	methyl chloride
butylene	methylene chloride
chlorotrifluoroethylene	*n*-octane
cyclohexane	*n*-pentane
cyclopropane	propane
dimethyl ether	iso-propanol
dimethyl amine	propylene
dioxane	propylene oxide
ethyl acetate	town gas
ethanol	trimethyl amine
ethyl amine	vinyl chloride

Strese observed that the fuels which do ignite from cigarettes all have MIE values less than about 0.08 mJ, while most of the gases which do not ignite have values which are higher. Ethylene (which does not ignite) and vinyl acetylene (not tested), however have values which are barely higher than those of ethylene oxide and hydrogen sulfide, which do ignite. Toluene appears to be borderline ignitable. In one set of tests[317], a single ignition of toluene was obtained with a puffed cigarette, but further trials gave negative results. Hards[318] conducted tests where he was able to ignite diethyl ether from cigarettes, but not butane, pentane or propane. Nii[319] showed that diethyl ether and carbon disulfide vapors are readily ignited by cigarettes, especially if the burning end separates and falls into the flammable volume. For diethyl ether, the highest fraction of ignitions was achieved at a vapor concentration of ca. 12% and it proved impossible to ignite mixtures of 7% concentration or less.

Several papers report that gasoline vapors are not ignited in cigarette tests[310,317,320]. A number of theories have been proposed why ignitions do not take place when a cigarette is introduced into a flammable gasoline/air mixture. These include the highly oxygen-depleted conditions in the hot zone, and the 'flame arrester' action of the ash layer[310]. Perhaps most germane is the relation shown in Figure 71 in Chapter 4. In the cigarette, the zone where temperatures over, say 800ºC, exist is only about 2 mm in size. For such tiny heated areas, very high temperatures are required, more than 1000ºC, and these temperatures are more than can be achieved by glowing in the cigarette. For a puffed cigarette, the high temperatures are further counteracted by the very short time that the gases are in contact with the combustion area. If the residence times of the gases is estimated[310] as 1 ms, then only gas mixtures with an induction period (for the appropriate temperature) of less than 1 ms would be prone to ignition. A limited amount of testing indicates that cigars behave the same way as cigarettes with respect to ignition of gases. Neither cigarettes nor cigars are able to ignite dust cloud explosions[506].

Concerning 'non-ignition' results, it must be kept in mind that all of the laboratory tests have entailed only modest numbers of trials and were not set up to explore a wide range of conditions. The test results clearly indicate that ignition of gasoline vapors by a cigarette would be a rare event, but it would be imprudent to assume that the possibility is categorically disproved. As Hards[318] noted: "With negative evidence of this kind one cannot be sure without performing an infinite number of experiments!" Even though often-cited results are that natural gas (largely methane) does not ignite from cigarettes[321], Bureau of Mines tests[315] showed that a cigarette *can* ignite a methane/air mixture, if a velocity of 5 m s^{-1} is present. Combustion in a cigarette is a smoldering process and, presumably, ignition occurs because the imposed air velocity raises the temperature of the smolder front. As shown in Figure 68 in Chapter 4, methane is more difficult to ignite than gasoline, so if methane/air mixtures can be ignited, it would be unreasonable to consider vapors of gasoline and other more-readily ignitable gases to be non-ignitable.

It appears that when a cigarette is *thrown* onto a concrete surface the likelihood of ignition gasoline vapors may be higher. DeHaan[322] reports conducting some trials where such throwing did not result in ignition of gasoline vapors.

However, fire cases have been litigated where this precise scenario has been identified as the cause of the fire. A specific case has also been described by Yallop[323], where a fire was ignited when a man dropped a cigarette near a bowl in which he was using gasoline as a solvent. As with all ignition, a probabilistic aspect must be considered, and it does not appear that DeHaan was able to conduct a large number of trials. Clearly, several aspects of combustion favor ignition in such cases: (1) a large supply of fresh oxygen quickly enters the oxygen-depleted smoldering zone of a cigarette, thereby raising the temperature of the combustion area; (2) the protective ash layer is knocked off and the hot central core is directly exposed to the atmosphere; and (3) a shower of multiple burning fragments often results. What is not in doubt is that matches or cigarette lighters used to light a cigarette can ignite gasoline, methane, and a whole host of other gas mixtures. Thus, in practical cases where a cigarette is considered as a likely ignition cause, the means used to ignite the cigarette itself must be given consideration.

DeHaan[324] suggests that ignitions of gases/vapors from cigarettes that are otherwise identified as 'non-ignitable' may be due to flareups in burning, occasioned by foreign matter in the cigarette. There has not been any study attempting to examine this possibility. A study of smoking-caused methane explosions in coal mines[315] suggests that such incidents are generally due to striking a match in a methane/air atmosphere, not simply due to bringing in an already-lit cigarette. Yallop reports[323] the fascinating information that stubbing cigarettes out on a block of TNT does not cause ignition of the TNT.

With all other factors held constant, a filter-tip cigarette is less likely to ignite a substrate than is a plain-tip cigarette. This was determined in a study[325] which examined the propensity for cigarettes to ignite wood shavings with a cross-wind of 0.75 – 1.0 m s^{-1}. This was attributed to a pulse of high temperature which results when the smolder front in cigarette reaches the butt; the pulse does not occur when a filter is present. The probability of ignition was also found to be dependent on the wind velocity, but this was not studied in detail.

The effectiveness of cigarettes as ignition sources for wastepaper baskets has been examined[326]. For wastebaskets filled with papers, snack wrappers, fast-food bags and polystyrene foam coffee cups, ignitions were not observed. Oily paper towels turned out to be ignitable, but out of a total of 300 tests of dropping cigarettes into wastebaskets, flaming occurred in only 5 instances; the times to flaming ranged from 14 to 18 minutes. A German study[327] provided more comprehensive results (Table 22), but the results were based on only 12 – 15 trials[328]. In fact, much longer ignition times have been observed in real fires. Figure 20 shows documentation of a fire that occurred due to cigarette disposal in a rubbish container. The time between the last human activity at the place of origin and the eruption of flam-

Table 22 Experimental times for flaming ignition to take place after placing a cigarette on a given substrate

Substrate	Time for ignition (min)		
	Min.	Avg.	Max.
corrugated cardboard	12	20	50
cotton	9	16	19
hay, straw	8	15	30
leaves, forest litter	12	46	68
paper	8	17	40

ing was 192 minutes. Some additional research is discussed under *Paper products*.
In a study of comforters filled with feathers, down or polyester fibers, it was found that no ignitions from cigarettes occurred; in each case only local, non-progressive charring was found under the cigarette[329]. The covers tested included cellulosic, thermoplastic, and mixed-fiber fabrics. A computer model has been developed to simulate the ignition of soft furnishings by cigarettes[330]; however, it is a research tool and is not set up for the predictions of real-fire ignitions.

US Congress twice passed legislation to investigate the possibility of reducing cigarette ignitions of upholstered furniture and mattresses. Pursuant to this, NIST completed two major studies of test methods intended to qualify safer cigarettes; these are discussed under *Upholstered furniture*, as are other aspects of cigarette ignition of upholstered furniture and mattresses.

Burning of cigarettes is substantially more hazardous in oxygen-enriched atmospheres. Wharton[331] found that in atmospheres of 30% O_2 or higher, cigarettes flamed, not just smoldered, and burned up rapidly. At 40% O_2, it took only 8 to 9 s for a 50 mm length of cigarette to be consumed. When dipped in liquid oxygen, a cigarette burns like a flare.

Clothes irons

A clothes iron normally shows temperatures of 215ºC or lower on its baseplate if no faults are involved and it is not put down upon an insulating surface[332]. The heating element is typically rated at 1100 W and clothes irons are so designed—unlike many other heat producing devices—that a 100% duty cycle will rapidly destroy it. If for some reason the thermostat fails, then a molten base plate (melting temperature ca. 550ºC) can result[333]. The results of some simple testing on the propensity of clothes irons to set fire to clothing have been published[334]. The study examined the potential for ignition when an electric clothes iron (without an automatic shutoff feature) is placed face down on combustible clothing. A lightweight cotton fabric was used, placed over a cotton ironing-board cover, atop a foam pad. With an iron that had a properly functioning thermostat and thermal fuse protection, no fire resulted during a 168 h test, although substantial scorching resulted. When the thermostat and thermal fuse protection was bypassed, ignition occurred in about 16 min, with visible flaming first occurring on the bottom surface of the particle-board ironing board, then progressing upwards. Another study[335] found that, with a defective thermostat, a 1000 W iron reached a peak temperature of 740ºC in 20 minutes; this is above the melting point of aluminum and the aluminum soleplate did melt out. A different ignition mode is involved when the power cord is damaged by contact with a hot iron surface.

CO_2 extinguishers

When a carbon dioxide extinguisher is discharged, whether fixed or a portable unit, the discharge comprises gaseous CO_2, particles of frozen CO_2, and both condensed and frozen water droplets (from atmospheric moisture). Due to collisions, the stream easily picks up an electrostatic charge. Thus, in a flammable atmosphere, a hazard can be created if an electrostatic discharge occurs. In 1966, such an ignition was the cause of an explosion on the tanker ALVA CAPE which was on fire after a collision took place and CO_2 was discharged for extinguishment. CO_2 discharge was also the cause of several disastrous tank explosions in Germany[336], with one of the cases involving 29 deaths[26].

Leonard and Clark[337] discharged hand-held 6.8 kg (15 lb) CO_2 extinguishers into a flammable, heptane/air atmosphere and obtained explosions in 2 out of 6 trials; tests also showed that charging voltages of 10 – 40 kV were being obtained. Haessler[338] measured up to 50 kV and a typical capacitance of 600 pF; the latter value appears to be very high, but details of experimental arrangements were not given. Up to 20 kV was found near the nozzle of a fixed CO_2 extinguishment system[339]. Butterworth[340] examined the electrostatic charging occurring with fixed, total-flooding CO_2 installations. He concluded that charging rates could be reduced by a factor of 20 – 50 by the implementation of a special discharge nozzle. The two essential traits of the nozzle were (1) non-metallic material, and (2) a sharp-edged orifice at the discharge tip, with no further downstream surfaces available to the flow. Another study explored the electrostatic fields associated with portable CO_2 extinguishers[341]. Maximum field strengths of about 0.6 MV m^{-1} were found, substantially lower than the breakdown value of 3 MV m^{-1}. The authors believe that a shock hazard exists, however, and that electrostatic ignitions are not precluded. In opposite conclusion as for the fixed-installation nozzles, for portable units, the authors found that a metallic discharge horn was helpful, and that a grounding wire included with plastic horns had no beneficial effect.

Coal

PROPERTIES OF COAL

The chemical composition of coal varies widely. Very roughly, coal comprises, by mass, about 80 – 90% carbon, 4 – 5% hydrogen, 3 – 11% oxygen, 1 – 3% nitrogen, 0.5 – 1% sulfur, and much smaller quantities of other elements. For bituminous coals, the percent of hydrogen and oxygen are at the high end, while for anthracite coals they are at the low end of the range. For many purposes, it is adequate to represent the effective formula of coal as $CH_{1.4}O_{0.6}$. A typical value of heat of combustion is 22 MJ kg^{-1} (upper) and 21 MJ kg^{-1} (lower). Coal may appear to be a solid substance, but in fact it is referred to as a "solid colloid"[342]. Its density is typically in the range of 1300 – 1500 kg m^{-3}, although it can range from below 1000 kg m^{-3} to over 2000 kg

m^{-3}. The heat capacity of coal increases with temperature and moisture content and decreases with increasing carbon fraction. The typical range is 0.8 – 1.6 kJ kg^{-1} K^{-1}. A thermal conductivity of about 0.13 W m^{-1} K^{-1} is found. An extensive study on the thermal properties of coal has been published by the Bureau of Mines[343].

POROSITY AND SORPTION OF WATER

A number of studies have been done to elucidate the microstructure of coal, specifically the porosity, and to quantify its relation to the sorption of water. The heat of wetting is approximately 0.4 J per m^2 of internal surface area. To reduce this to a more convenient measure of heat per mass of substance, the internal surface area must be known. The pore structure of coal is complex and has two hierarchies of fine and ultra-fine pores; only small molecules can penetrate the latter. The internal surface area of the ultra-fine pores is in the range of 10 – 200 m^2 g^{-1} of coal. The porosity allows gas diffusion through coal, which, at room temperature, is slow but measurable. The surface area[344] of pores large enough to allow sorption of water is around 10 – 100 m^2 g^{-1}. Using a value of 100 m^2 g^{-1}, the per-mass heat of wetting becomes 40 J g^{-1}. Since the surface of coal is hydrophobic, water is initially adsorbed onto oxygen sites and then additional water molecules cluster due to intermolecular forces of water.

EXTERNAL IGNITION

The temperature needed for the autoignition of pulverized coal varies greatly according to rank, going from 200 – 300ºC for lignite to 450 – 600ºC for anthracite[345], but values in the range 350 – 450ºC are most frequently encountered. A Bureau of Mines study[346] using a vertical tube furnace gave AIT values for a number of coals, along with their chemical composition. For anthracite coals, increasing fraction of carbon gave an increasing AIT. But across the different families of coals, few general trends could be seen. The lowest temperatures (ca. 200ºC) were found for sub-bituminous coals, which had high ash contents (ca. 12%) and high oxygen contents (ca. 13%). It has also been reported that even small amounts of iron oxides lower the ignition temperature as does weathering of the coal, that is, simply letting it sit in air after being mined[355]. The latter effect is typically not large (a drop of 10 – 30ºC), but exact reasons for it have apparently not been elucidated. A number of detailed studies on individual small-particle ignition and on the ignition of coal dust clouds are reviewed in Chapter 8.

SELF-HEATING

When mined out of their original deposits, coals show a tendency for self-heating. In extreme cases, there are deposits of coal that cannot be safely mined, due to their excessive self-heating. Coal was the first self-heating substance of industrialized concern to have been extensively studied. It is reported[347] that in 1646 a scientist was already offering the theory that oxidation of iron pyrites was the cause. The earliest book on the topic of self-heating of coal was a British study by Thomas Rowan[348] on the spontaneous combustion of coal in ship holds, published in 1882. Rowan considered that there were two causes of self-heating: (1) the oxidation of some of the sulfur compounds (primarily iron pyrites) present in coal; and (2) oxidation of the coal itself from atmospheric oxygen. Rowan was also aware, but only in rough terms, that moisture increases the self-heating tendency. He was also aware that increasing the size of the pile will increase the tendency, as will decreasing the size of individual coal lumps.

A few years earlier, in 1876, a Royal Commission[349] appointed by the British Parliament to investigate spontaneous combustion of coal in ships made a number of recommendations, based largely on testimony, not on scientific research. Its primary findings were:

(1) That certain descriptions of coal are intrinsically dangerous for shipment on long voyages.
(2) That the breakage of coal in its transport from the pit to the ship's hold, the shipment of pyritic coal in a wet condition, and, especially, ventilation through the body of coal cargoes, conduce to spontaneous combustion, even though the coal may not be unfit for conveyance on long voyages.
(3) That spontaneous combustion in coal cargoes would be less frequent, if regard were had by shipowners and underwriters to these facts.
(4) That when coal is being carried on long voyages, the temperature in the various portions of the cargo should be tested periodically by thermometer, and registered in the log.
(5) That, with a view to guard against explosion, free and continuous egress to the open air, independently of the hatchways, should be provided for the explosive gases, by means of a system of surface ventilation, which would be effective in all circumstances of weather.

Other recommendations dealt with inspections and similar matters. In related technical findings, the Commission discovered a very strong correlation between the probability of a coal ship's loss due to spontaneous combustion versus the weight of the cargo. The Commission also rightly identified the quantitative importance of time. They studied the time after leaving port before fires broke out, and found that the median value was 60 days. The range for all the ship fires they studied was 37 to 190 days for fire to break out. In addition, testimony indicated that the time from mining to ship-loading ranged from a few hours to 10 days. The Commission also opined that "patent fuel" (fuel briquettes made from powdered, pressed coal) was never a self-heating problem, despite the fact these products were reported in the US to have regularly suffered spontaneous combustion[353].

In his study, Rowan tried to re-examine the Commission's conclusion that iron pyrites are the main cause of coal self-heating in light of more current research. Such newer re-

search, however, was not conclusive. He heartily approved of the Commission's emphasis on increasing the size of individual coal lumps as a preventive strategy. The effects of moisture were also not understood, since explanations were attempted which relate moisture directly to oxidation, instead of considering (as we know now) that the main effect is the heat of sorption. Rowan understood that self-heating is not a process whereby the bulk temperature of the substance rises uniformly, but he was not able to distinguish between hot-spot heating and the temperature distribution which occurs in a porous solid where the local heat generation is uniform, but the heat losses are not.

Self-heating ignitions in ships' holds were often energetic phenomena, and resulted in forcible explosions, some of which continued even after the first event blew hatches off. This, of course, is due to the confined nature of a hold. Rowan accurately noted the early period of slow self-heating, and he described a ship's hold fire as having four stages:

(1) Heat was observed, and this might cover a period of from 10 to 15 days or more. When the temperature increased beyond a certain point the next indication was,
(2) A slight smell of "gas" increasing in intensity, and accompanied by whitish smoke. This rapidly increased, and
(3) Smoke appeared in dense and increasing volume, with a pungent and suffocating small of "gas," which with great rapidity resulted in
(4) General conflagration, with more or less explosion. The occurrence and frequency of explosions being determined by the locality where ignition commenced. The nearer the surface the less likelihood of explosion.

Rowan was impressively perceptive about self-heating, given the limited chemistry knowledge of the era, and the nearly non-existent theory of heat transfer. Thus, he was able to debunk J. W. Thomas, an earlier author, who devoted a chapter in his textbook on coal to spontaneous combustion issues[350]. The latter, writing in 1878, considered that self-heating in charcoal was due to heat of friction caused by air passing through the pores of the substance! Thomas, however, considered that a good remedy would be a means of increasing ventilation to the coal. Rowan dismisses Thomas' suggestion on the basis that it is impractical, but offered a proprietary ventilation system of his own. Clearly, the time was not yet ripe for the realization that increasing the heat losses by "ventilation" can be accomplished by dividing the bulk store into smaller piles, not just by forced-air cooling.

Thomas also considered that "the moistening of coal by rain is very probable the prime mover or cause of the generation of heat." On this point, he was again contradicted by Rowan, who advocated a scheme whereby newly mined coal would be dried in a 150ºF atmosphere. He believed that such heated drying would exhaust the exothermicity of "carbonaceous oxidation of the coal," rather than simply drying the coal.

The first correct interpretation of the self-heating of coal is probably due to the Frenchman Henri Fayol[351,352] (he became famous for his theories of business management), who wrote a 260-page paper on the subject in 1879. He conducted experiments not too different from the sort of oven-basket tests used today and elucidated the effects of oxygen supply, coal rank, particle size, and pile size. During this era, the problem of self-heating was apparently much less for US coals. Hexamer reports[353]: "Fortunately for our country, our soft or bituminous coals are not as prone to ignite spontaneously as the English." Hexamer also reports that in the scientific circles of the time, there was much debate on whether oxidation of organic components of the coal, or oxidation of iron pyrites was the main culprit.

Despite the concerted study of the self-heating of coal, simple answers have not necessarily been produced, although today there is a reasonably good ability to model the self-heating of coal. Many of the practical and theoretical difficulties arise due to the wide-ranging chemical differences among coals of various types. A still-useful monograph on self-heating of coals was published by the Bureau of Mines in 1944[354]. A similar study[355] was produced in the UK in 1957 and serves as a comprehensive review of self-heating studies from the earliest times through the first half of the 20th century. In the modern era, Banerjee[356] reviewed self-heating studies up to 1980.

Coal does not self-heat unless it is exposed to oxygen. Such oxidation of coal is termed 'weathering.' According to Van Krevelen, self-heating proceeds in several sequential stages[342]:

(1) chemisorption of oxygen, with increase in weight (up to 70ºC)
(2) initial release of oxygenated reaction products, and of intrinsic water (70 –150ºC)
(3) production of more fully oxygenated reaction products (150 – 230ºC)
(4) rapid combustion, including the generation of soot (over 230º).

The chemical kinetics of these stages are difficult to unravel, since they overlap as the temperature is raised. The apparent activation energy, to the extent that it can be assigned in such a sequence, steadily increases from around 12 – 16 kJ mol^{-1} in the first stage, up to 100 – 150 kJ mol^{-1} in the fourth. In the first stage, the heat of chemisorption for oxygen has been estimated to be on the order of 400 kJ per mole O_2. If self-heating data are analyzed assuming only a single-step, first-order reaction, then an activation energy of around 120 kJ mol^{-1} is assigned. Braun[357] studied eight different US coals in an adiabatic calorimeter over the range 50 – 130ºC and for five of these coals found that there were two distinct activation energies in this interval. From 50 to

about 80ºC, $E \approx 50$ kJ mol^{-1} was found; from 80 to 130ºC, $E \approx 75$ kJ mol^{-1} was found. In a higher temperature regime of 130 – 170ºC, Jones and Vais[358] found $E \approx 90$ kJ mol^{-1} for several low-rank coals, although individual samples showed the broad range of 75 to 111 kJ mol^{-1}. For a pulverized specimen of low-rank (lignite) coal, Jones[359] obtained the values: $E = 94$ kJ mol^{-1}, $Q = 20$ MJ kg^{-1}, $A = 7\times10^5$ s^{-1}, $\rho = 556$ kg m^{-3}, $C = 1170$ J kg^{-1} K^{-1}, and $\lambda = 0.07$ W m^{-1} K^{-1}. For bituminous South African with a volatile content of 26%, Tognotti et al.[360] found that over the experimental range of 120 – 220ºC, $E = 70$ kJ mol^{-1}, $P = 38.8$. The authors sensibly pointed out that below ca. 125ºC, straight-line relationships no longer hold, and that extrapolations to real storage piles (where ambient temperatures << 100ºC are of concern) should be considered as only rough indications.

Despite the fact that a major contribution to self-heating of coal comes from the sorption of oxygen onto the surface, it turns out that self-heating tendency is increased when the fraction of oxygen that is already chemically incorporated into the coal's structure increases[361]. Highest fractions of oxygen are found in low-rank coals, e.g., lignite. There is a complex interaction between oxygen fraction and particle size, as factors that influence the self-heating propensity of coal. Nugroho et al.[362] showed that for low-rank coals the particle size effect is small, but for high-rank coals decreasing the particle size greatly lowers the temperature of thermal runaway. In addition, in running oven-basket tests they obtained typical self-heating parameter values for Indonesian coals. A high-rank coal with particle size of 0.18 mm and $\rho = 725$ kg m^{-3} gave $E = 90$ kJ mol^{-1}, $QA = 4.48\times10^{12}$ W kg^{-1}, $C = 1240$ J kg^{-1} K^{-1}, and $\lambda = 0.11$ W m^{-1} K^{-1} and the E and QA values are only valid for this specific particle size. At a particle size of 2.3 mm, the corresponding values were $E = 45$ kJ mol^{-1} and $QA = 3.11\times10^6$ W kg^{-1}. A low-rank coal with an 0.18 mm particle size and $\rho = 635$ kg m^{-3} gave $E = 96$ kJ mol^{-1}, $QA = 3.73\times10^{13}$ W kg^{-1}, $C = 1480$ J kg^{-1} K^{-1}, and $\lambda = 0.13$ W m^{-1} K^{-1}. Its variations of E and QA with particle size were much smaller.

As with any self-heating substance, times to criticality are hard to estimate accurately and are rarely examined in connection with case histories. Nonetheless, it has been reported that coal piles most commonly go into thermal runaway within three months of piling, but times as long as 2 years have been noted[354].

The critical temperature for self-heating of coal can be roughly correlated to percent volatile matter. Under one set of test conditions[342], coal with 15% volatile matter showed a critical temperature around 190ºC; for volatile matter of 40%, the temperature dropped to 150ºC.

Moisture is a factor which contributes to the self-heating of coal[363]. For initially-dry coal, Bhattacharyya[364] noted that, while adsorption of both oxygen and moisture are exothermic processes, heat generation due to moisture adsorption is the dominant effect. Matters are complicated because oxidation and moisture are coupled: initial oxidation tends to be inhibited unless there are at least traces of moisture present. There is an optimum level of moisture for maximum self-heating—for coal already holding a lot of water in the pore structure, increasing moisture correlates to a decreased oxidation rate due to flooding of the pore structure: pores which are water-filled cannot be oxidized[372]. In one study[365], the optimum level was identified as 7%. It has been demonstrated that if coal is pulverized and vacuum-dried, and then moisture-saturated oxygen passed through it, even very small amounts of susceptible coal types will reach thermal runaway starting from room temperature[366]. In air, the time scale is longer, but the effect is the same—a 3 kg sample will self-heat to ignition from room temperature[367]. While dramatic, these demonstrations do not seem to reflect on the actual hazard conditions. The oxygen/moisture relationship is complex, because it has been determined that the major portion of the oxygen reacts with coal after first going into solution in the moisture present[368]. The effect is further complicated since it appears to greatly depend on the coal type.

It is now understood that pyrites contribute to self-heating primarily by causing swelling and disintegration of the coal[369]. This disintegration opens up new surface area to oxidation, and the added oxidizable area becomes the ultimate contributing factor. The rate of self-heating is roughly proportional to the third root of the available surface area. The direct effect of heat from the oxidation of pyrites is negligible[376].

Pulverized coal shows the same response as charcoal to 'weathering.' That is, if freshly ground product is exposed to air in small batches before being aggregated into larger volumes, self-heating problems can be minimized, since

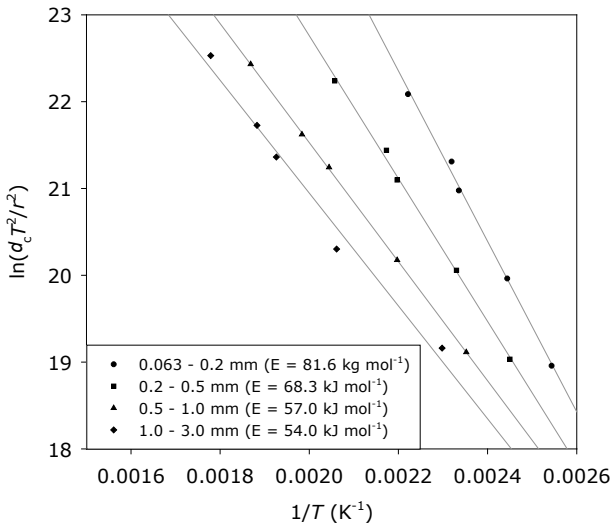

Figure 21 Effect of particle size on self-heating of Derne coal

exothermic sorption of oxygen onto the surface has already taken place[260].

Individual lumps of coal in coal pile can vary from large pieces to ones which are in the 75 µm range. Even though standard self-heating theory considers that there is no effect of *particle size*, researchers studying coal experimentally have generally come to the opposite conclusion. Hardy[370] found that for coal dust layers deposited on hot surfaces, an increase in particle size corresponded to an increased value of temperature needed for ignition. Hensel[371] studied the effect of particle size on self-heating of coal from Derne, Germany using the standard oven-basket method. His results are given in Figure 21 and show a sizeable effect, with larger particle sizes leading to lower values of activation energy and higher values of critical temperature. Hensel considered that this is because simple Arrhenius kinetics is not descriptive of the oxidation chemistry. In his view, latent heats of sorption of molecules at the surface account for the size effect and this effect cannot be represented in the Frank-Kamenetskii theory formulation, although its effect causes the apparent E to change in value. Changing the particle size does change both the density and the thermal conductivity of the substance, but Hensel's data plotted with corrections for both of these effects do not collapse the data towards a single trend line. In a recent survey, Carras and Young[372] examined additional studies on this issue, but Hensel's work can probably be considered the most exhaustive.

Hardy[370] also tested coal contaminated with hydrocarbon oils and greases. Adding these contaminants to coal dust had no effect, or else raised the critical temperature, but some of the greases had a tendency to increase the smolder rate, if ignition did occur. In addition, Hardy conducted a few tests where hot brass balls were dropped into beds of very fine (< 20 µm) coal dust. A 10 mm diameter ball needed to be heated to 400 – 420ºC to ignite the coal, but for a 25 mm ball 315 – 325ºC sufficed. Feng et al.[369] have surveyed various coal characteristics and mining practices with regard to their effect on self-heating. Handa et al.[373] developed a computer program for the numerical calculation of the self-heating of a pile of coal in the shape of a truncated cone. Unlike most other researchers, they included a 2-step reaction mechanism and also modeled the flow of oxygen through the pile. Full-scale results however were not available for validation of the computer code.

Mine *ventilation* can exacerbate self-heating tendencies. This happens when increased air flow rates supply oxygen to locations where previously sufficient oxygen was not available for thermal runaway. In general, the mining environment is considered to be more important in governing whether spontaneous combustion will occur than are details of the coal itself[369].

In view of the inapplicability of the standard F-K theory, as mentioned above, it is not surprising that anomalous results may be found when conducting oven-basket tests. Jones[374] discovered that some coal samples show two peaks, with a trough in between. According to F-K theory, there should never be a drop in temperature except after the (sole) peak is passed. The ultimate drop is due to fuel depletion. Prior to that, the theory recognizes only a rising curve, possibly with horizontal plateaus, the latter due to any antioxidants that may be playing a role. The reason for a trough with some coal samples was not fully elucidated, but tentatively it was suggested that it was due to a liquefaction in the center of the specimen. When a portion of the material is liquefied, access to oxygen would drop precipitously and so would the reaction rate for that portion. In general, researchers in the coal safety field have rarely used standard test methods for self-heating and have generally developed purpose-built test equipment. As an example, the Bureau of Mines considered that relative self-heating tendencies of coal may simply be ranked by determining the propensity of finely-ground specimens to remove oxygen from the atmosphere[375]. For this purpose, they used a sealed Erlenmeyer flask from which air samples are periodically extracted for analysis.

Schmal produced a theoretical model which is probably the simplest that can predict the self-heating of coal over a broad range of conditions[376]. The model is 1-dimensional, but five simultaneous differential equations are solved:

- conservation of oxygen mass
- conservation of heat
- conservation of moisture
- reaction of coal with oxygen
- evaporation and condensation of water.

Of special note is that, unlike most earlier efforts, the model was validated against large-scale data. The modeling was also supported by a large amount of laboratory-scale research at TNO. One of the interesting variables that was documented was a progressive dropping of the heat of combustion with time and temperature of exposure. By contrast, a simple material obeying one-step Arrhenius kinetics would show a mass loss with time, but the heat of combustion of the remaining substance would be unaltered. One of the conclusions from running the model with test cases was that there is a very large exothermic effect from wetting, if dry coal adsorbs moisture from water vapor in the air. One unexpected finding is that within a certain range, if the coal has a higher reactivity, then, in the long run, a lower temperature rise occurs. This was understood to be because higher reactivity coal adsorbs oxygen preferentially closer to the surface, where good heat transfer exists, and this keeps the interior temperature from running away. In line with other studies on moist material, Schmal found that for moist material, until all moisture is used up, the temperature tends to stay 'clamped' at a value way below 100ºC, normally 77 – 87ºC.

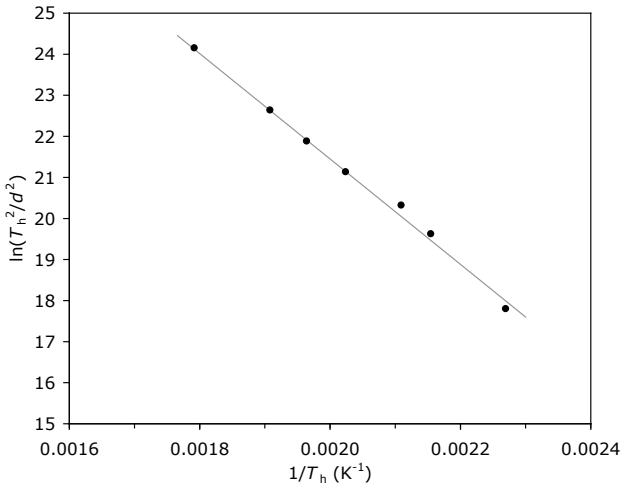

Figure 22 Layer ignition temperatures for Silkstone coal dust as a function of layer thickness

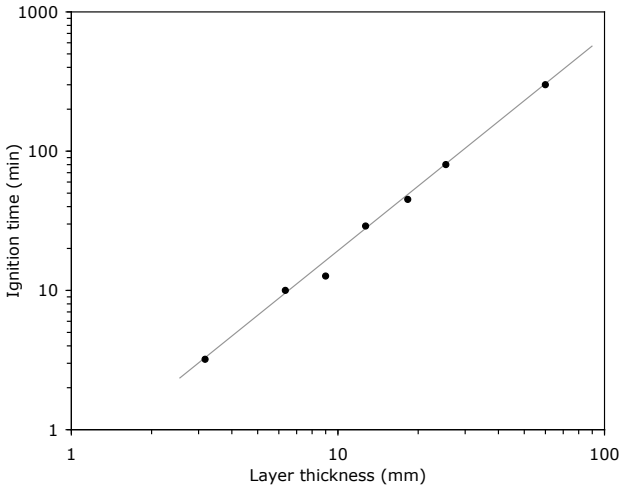

Figure 23 Ignition times for hotplate tests of Silkstone coal dust

The validation exercise confirmed that coal pile porosity has a huge effect on the outcome. Three outcomes were found in modeling and confirmed in validation:

(1) if porosity is very low, diffusion and conduction are mainly responsible for transport of heat and mass. Critical conditions will probably take longer to develop than the pile will be kept in storage.
(2) at intermediate porosities, mass transfer is mainly by convection, while heat transfer is by conduction. Critical temperatures can develop in a relatively short time.
(3) for very high porosities, convection dominates the transport of both heat and mass. Critical conditions will not occur, since the heat generated is being efficiently removed.

It was also found that the initial temperature has a profound impact on the results. Thus, the recommendation follows that any coal arriving at higher than prevailing temperatures be cooled in small piles before being aggregated into large ones. Schmal made the recommendation that a temperature of 77ºC, as measured in the center of the pile, be considered the upper limit for safe storage. Paradoxically, higher peak temperatures were found to be attained in winter than in summer. This is due to the way that convection depends on the ambient temperature. He found it impossible to give simple guidelines with respect to size, since the experimental work showed that coal piles do not behave in an isotropic way. The horizontal dimension is generally less important than the vertical one; but the role of the height of a pile is strongly dependent on the porosity. Finally, he concluded that any relations based on steady-state results would be of little relevance, since the time constants of the system are so long (typ. years) that a coal pile will generally be used up before a steady state would be achieved. Other recent numerical modeling studies have been by Salinger et al.[377] (2-d) and Monazam et al.[378] (1-d).

COAL DUST

Theories and data on the ignition of coal dust are presented in Chapter 8. Extensive data on coal dust in the form of clouds (as contrasted to single particles) are provided in Chapter 5. The percent of volatiles in coal plays a dominant role in determining whether coal dust clouds are ignitable. If the volatile fraction is less than 7 – 8%, than clouds are unlikely to be ignitable. However, if the coal particles are highly porous (specific surface area greater than ca. 100 m^2 g^{-1} as measured by nitrogen adsorption), then dusts of even lower volatility have been shown to be ignitable[512].

In some cases, smoldering ignition of coal is a concern when coal dust accumulates on hot surfaces. For such problems, it is simplest to run hotplate tests. The data from the test can be used with little need for extrapolation, since layer thicknesses to be expected in practice are not very large. Figure 22 illustrates data on Silkstone coal dust[379]; T_h is the hotplate temperature (K) and d is the layer thickness (mm). The times needed to reach ignition are shown in Figure 23.

Bureau of Mine testing[581] showed that, when tested in their test standard depth of 12.7 mm, Pittsburgh coal shows a critical temperature of 233ºC. When tested in a 50 mm depth, a critical temperature of 205ºC was found. Thermal runaway required over 9 h. Smoldering ignitions generally exhibited red glowing and occasional pale blue flames. With one type of British coal, hot glowing sparks were also emitted during smoldering.

COAL PULVERIZERS

Explosions in coal pulverizers have been found to be mainly due to self-heating of layers of coal dust, accumulated upon various machine surfaces which may sustain elevated temperatures[380]. Explosions tend to occur in startup or shutdown, whenever conditions promote an increase in surface temperatures over the normal condition. Within the operating portion of a coal pulverizer, it is possible to arrange things so that explosion potential is minimized by operating

above the UFL of the dust cloud[381]. This is one of the few process types where operation above the UFL of a dust cloud is a viable strategy.

Coffeemakers and teapots*

Modern, electrically-operated coffeemakers are made largely of plastics, generally polypropylene, and prior to the mid-1990s there were large numbers of fire cases involving models that had faulty designs or faulty components, leading to ignition of the plastic case and, subsequently, a possible room fire. The problem is that most consumer models have a sizable electric heater and have casings made of an ignitable plastic. If the heater operates indefinitely, without being turned off, a fire will be likely. Thus, for its basic fire safety, the appliance depends on the proper operation of devices which will shut off the heater at an appropriate temperature level. Up until 1994, coffeemakers typically had one thermostat and one thermal cutout (TCO) device. But a thermostat can fail through fusing of the contacts, due to long use, corrosion, or exposure to moisture[382] and several failure modes are possible for TCOs. In those cases where both the thermostat and the TCO failed, thermal runaway ensued, commonly followed by ignition. In coffeemakers, the TCO is normally a non-resettable component, and service is required after it opens up.

There are several different types of coffeemaker designs in regards to the way in which the water is heated and then the coffee is kept warm. The most common in the past was a high-powered hot-water generator that heated cold (room temperature) water to boiling which allowed the water to percolate up into a filter basket containing the ground coffee. This requires a large heater, up to 1625 W in order to make a pot of coffee in a reasonable length of time. If this same heater is used to keep a pot of coffee warm, then it must be cycled on and off to keep the proper liquid temperature. A cycle time might be 15 seconds on and 2 minutes off. It can be readily calculated that a large number of cycles on the control thermostat will occur. Since thermostats are rated only for a finite number of cycles, eventually a failure in the 'on' position may occur.

Tests on 6 units indicated that when the control devices were bypassed, simulating a failure, autoignition of 4 units occurred within 12 min; the other two units did not go into flaming ignition[382]. Since some of the fires caused by coffeemakers were due to failures of thermal cutout devices, UL tightened up its standard UL 1082[383] in 1994 to require two thermal cutout devices. In that same revision, they also mandated that the thermostat have a ceramic, not a phenolic, body and that it be rated for 300,000 (instead of 100,000) cycles. Under the new UL requirements, coffeemaker fires have become rare and some manufacturers claim that they have never seen a thermal runaway from a dual-TCO design. Apart from fires, coffeemakers are normally very reliable devices, thus, some have been kept in service for many more years than was the manufacturer's life projection. Under these conditions, failures are not unexpected.

Other aspects of coffeemaker design and failures have been discussed by Finneran[384]. During the 1990s, coffeemaker fires became well enough known that arsonists have been found to tamper with coffeemakers in a way as to simulate a well-publicized mode of fire ignition[385]. Owners have also been known to bypass safety devices instead of repairing a faulty device.

Historically, in a now long-discontinued model of coffeemaker, fires were occurring because electrical circuit components were located in places where steam was condensing upon them. This led to arc tracking and sometimes an eventual ignition.

Some electrically-operated teapots are designed for 'attended' use and may not have the same level of thermal protection as a coffeemaker. Some may have thermostats only rated for 100,000 cycles and no thermal protection. If the thermostat fails, there may be melting and a fire. In addition, very inexpensive devices are available for heating tea water which have not thermal protection whatsoever. These comprise a heating coil which is inserted into water and should not overheat, so long as it remains submerged. If the water boils away, or the device is energized while not submerged, a hazardous situation can exist, however.

Composite materials

FIBER-REINFORCED PLASTIC

The term 'composite' can include almost any product which contains two or more distinct components. Perhaps the most widely encountered in fire safety studies, however, are composites which are a fiber-reinforced plastic (FRP). The fiber is often glass, in which case the abbreviation is GRP. GRP panels are in wide use for homeowner construction purposes. Ignitability data for such composites are given under: *Siding, plastic*. Extensive studies have been published on GRP, FRP, and other composite panels used in the shipbuilding and aircraft industries, especially radiant ignitability studies using the Cone Calorimeter[386- 397]. Some example data from a recent test series[398] are given in Table

Table 23 Ignition properties of some glass-reinforced composites for marine applications

Material	Thick. (mm)	Density (kg m^{-3})	Glass content (%)	T_{ig} (°C)	$\lambda\rho C$ (kJ^2 s^{-1} m^{-4} K^{-2})
epoxy, FR	3.9	1910	71	393	1.12

23.
A variant of the Cone Calorimeter test method has been promulgated by the US Navy[402] specifically for testing FRP composites. A large number of studies have been conducted by Sorathia and coworkers[403-416] and other investigators[417] using this method. Stevanovic et al.[418] investigated glass-reinforced polypropylene composites using a non-standard test apparatus. They found that the critical flux for ignition varied directly with the volume fraction of the glass reinforcement—for no reinforcement, a critical flux of 8 kW m^{-2} was recorded, rising to 12 kW m^{-2} for 40%.

HIGH-PRESSURE LAMINATES, LOW-PRESSURE LAMINATES, AND RELATED PRODUCTS

High-pressure laminates consist of multiple layers of substrate material interspersed with a thermosetting polymer and heat-cured at high (over 7 atm) pressures. The polymers are typically phenol formaldehyde (phenolic), melamine formaldehyde, epoxy, or silicone. The substrate is paper or cloth. The resulting product can be made in large thicknesses and machined, or it can form as a thin facing to yet-another substrate. As a thin facing, it finds wide usage in kitchen-countertops. Laminates can also be prepared in a low-pressure process. In addition, there are surfacings used for furniture and cabinetry where PVC comprises the face layer. Setchkin furnace ignition data for several laminate types are given in Table 24. Data on radiant, piloted ignition of horizontally oriented specimens tested in the Cone Calorimeter are given in Table 25. Some laminates cannot be successfully studied in bench-scale tests, since they delaminate explosively.

Compost, manure, garbage, sewage, and landfills

Compost self-heats during the decomposition process. This can result in fires if packaged and shipped without being fully 'mature.' To test whether compost is finished and ready for shipment, a Dewar test for self-heating has been proposed[419]. The authors also reviewed the general field of study of compost self-heating. Apart from self-heating, fires in compost facilities are reported to often occur due to welding spatter[420]. Manure also self-heats as it ages. A fire incident and some field measurements on spontaneously combusting manure have been reported[421]. A typical history of spontaneous combustion in a landfill used for demolition wastes has been described[41] where discarded timber constituted the fuel. Compost can also be externally ignited. One fire occurred when a compost turning machine wrapped barbed wire fencing around a wheel during operation which then ignited the compost material when the machine was stopped[422].

Decomposition of vegetable or animal matter, as found in garbage or sewage, or in nature, produces a variety of gases, including methane and hydrogen. In some cases, sufficient amounts of these two gases have accumulated to either reach the LFL within a basement, or to actually result in an explosion. Zabetakis reviewed a number of case incidents[423]. The generation rate of flammable gases is great enough that co-generation plants or flares that capture the gas from sewage treatment plants and capped landfills are common in many locales.

Computer and information technology equipment

For computer equipment, telecommunications equipment,

and electrical business machines (commonly referred to as *information technology*, IT, equipment), most countries have adopted either verbatim or with modification IEC 60950[427]. In the US, the nationally-modified version of IEC 60950 is UL 1950[428]. From a fire safety viewpoint, this is a weak standard. Low-power devices are permitted to be entirely based on HB plastics, including the outer enclosure. Devices using more than 15 VA are expected to mainly use materials rated V-2 or better in the UL 94 test (see Chapter 7), but there are numerous exceptions. 'Fire enclosures' are required in devices using more than 100 VA. For equipment of less than 18 kg, fire enclosures must meet V-1 while for heavier equipment, the 5V requirement is imposed. However, the permissible size of openings in the sides and top of fire enclosures is effectively unlimited, unless the opening is either directly over a bare-metal part carrying line voltage, or the opening is so situated that objects falling through the opening at 5º from vertical would hit the line-voltage part. The exterior cabinets are declared to be 'decorative parts' and may be made of HB-rated plastics. Some small decorative parts are allowed to be unrated. A tougher standard for exterior cabinetry plastics is only imposed for products intended to be used in computer rooms and having an area over 0.9 m^2 or a single dimension over 1.8 m. For such cases, a flame spread rating of 50 in the Steiner Tunnel is required. The net implication of UL 1950 is that HB-rated plastics are used even for large, vertically oriented surfaces unless the manufacturer voluntarily adopts a higher specification. When HB-rated large, vertically oriented plastics are subjected to a small flame ignition, the expected result is rapid, total consumption of the material.

In actual fact, many IT-equipment manufacturers produce CRT monitors out of V-0 plastics. But computer front panels are commonly made of HB plastics and these can contribute substantial HRR to a fire. A possible ignition scenario is one where a power switch fails (power switches are usually mounted through a hole in the plastic front panel) and the burning switch then ignites the front panel, which serves to propagate the fire outside the device. This type of fire has, in fact, been observed. IBM is on record[429] opposing the use of HB-rated plastics, except for non-power-carrying small parts such as mice and keyboards. Their in-house guidelines require the use of fire enclosures for equipment using more than 15 W, and the fire enclosures (for under-18 kg equipment) must meet V-0, not V-1 requirements.

Computer printers are generally made of HB-rated plastics worldwide. Computer printers from two different, multinational manufacturers were tested by SP[430], who found that both easily ignited from a methenamine pill, burned vigorously, and burned up essentially completely. The plastics for both successfully passed the UL 94 HB requirements.

Conveyor belts

Wilcox et al.[431] provided some early UK statistics on ignitions of conveyor belts used in mines (Table 26). Laboratory tests on friction-caused ignitions showed that ignition may generally occur at the time that the belt breaks due to excess temperature and failing mechanical strength. Temperatures up to 500ºC were recorded in such cases.

Elastomeric conveyor belts can pick up an electrostatic charge and this can lead to a spark discharge under some circumstances. If the conveyor is operating in a dust-laden atmosphere, a potential can exist for a dust explosion. It had been proposed that 'conductive' belts would eliminate this potential. But a research study[432] examining belts having surface resistances from 5.3 kΩ/sq to 6.7 GΩ/sq did not bear this out, and showed that the conductive belts did not lead to spark discharges of lower energy than did standard PVC conveyor belts. This was interpreted to occur because the more conductive belts were able to drain charge from a larger area of the belt than did the low-conductivity specimens.

Table 26 UK statistics on ignitions of conveyor belts used in mines

Cause	Percent
faulty bearings in rollers	30.0
overheating of drive head due to load or worn out belt	18.6
improper belt alignment	14.3
obstruction in belt or torn belt	7.1
electrical faults	5.7
faults in compressed air turbines	5.7

undetermined	10.0

Cooking appliances

The majority of cooking appliance fires involves rangetops (Table 27), according to NFPA statistics[433]. A 1963 British study[434] gave the breakdown of causes in 1444 fires originating in electric cooking appliances; Table 28 shows that the vast preponderance involved misuse, not technical faults. A comparison was also made between electric and gas appliance fires (Table 29).

Table 27 US statistics for 1998 on home cooking fires

Appliance	Percent
rangetop	72.1
oven or rotisserie	17.3
portable cooking or warming unit	3.7
open-fired grill	1.8
grease hood or duct	1.1
fixed food warmer	1.0
deep fat fryer	0.5
unclassified	2.5

Table 28 Causes of UK electric cooking appliance fires

Fault	Percent
misuse	97.0
faulty thermostat	1.11
faulty switch	0.35
ground fault	0.55
defective insulation	0.42
faulty installation	0.28
short circuit	0.14
collapse of insulating material	0.14

A much more recent CPSC survey[435] examined the losses during 1994 – 1996. The basic findings are shown in Table 30; breakdowns were not prepared according to fuel type. The action or event leading to ignition are given in Table 31. The detail provided in these two tables is limited, since they were compiled only from national US statistics. A field study with a much smaller sample size (289) gave the results shown in Table 32.

The CPSC study also identified that the risk of ignition (fires per installed appliance, per year) from gas and from electric appliances was nearly equal, but the risk for a fire fatality was about 4× greater with gas appliances. Perhaps surprisingly, this difference appears not to be due to the potential of explosions with gas appliances—in the CPSC field survey, there were no explosions among the 289 cases studied. The CPSC study also identified that the single most common scenario for cooking appliance fires involved frying in fat, with the cook absent from the kitchen. The NFPA study indicated that the risk for a fire fatality was only about 2× greater with gas appliances; furthermore, it indicated greater likelihood of ignition and higher expected dollar losses associated with electric cooking appliances, but did not offer any explanation.

A test where a skillet with corn oil was placed on a gas range and left at the 'high' position showed ignition of the oil at 22 min and flames at the ceiling at 24 min[436]. When repeated with an electric range[437], the ignition took place at 28 min. Self-cleaning ovens can show very high temperatures at certain outside-surface locations when in a self-cleaning cycle. Peak temperatures of 380ºC were recorded and cardboard was ignited on a metal surface near the top of the unit in one test[438]. Switch failures have occurred on electric ranges such that the elements are thought to be off and yet are still heated.

Some gas appliances have had problems with control valves, burners and mountings such that temperatures at the exterior of the housing exceeded acceptable values and adjacent combustible surfaces ignited.

Table 29 A comparison of causes of UK fires with electric and gas cooking appliances

Cause	Percent	
	Electric	Gas
ignition of material being heated or cooked	84.9	69.9
appliance accidentally turned on	2.95	0.85
furniture or fittings too close	2.86	3.37
fabric goods falling onto appliance or being aired too close	2.46	6.74
fat spilt	1.56	1.12
appliance in need of cleaning	1.15	0.56
electric wiring placed too close	1.15	--
curtain blown into appliance	0.98	5.06
flammable liquids, waxes or polishes placed too close	0.66	0.28
portable hot plate used for space heating purposes ignites furniture	0.49	--
paper blown onto appliance of placed too close	0.33	0.84
clothing in contact	0.16	2.53
clothing in contact with hot plate used for space heating	0.16	--
appliance turned off, but still sufficiently hot to ignite fat placed too close	0.16	--
leakage of gas	--	8.7

GRILLS

The US Fire Administration has compiled some statistics on cooking grill fires[439]. These occur primarily in residential occupancies (71%), with less than 1% being in campsites or recreational areas. The breakdown of causes is shown in Table 33.

Table 33 Causes of fires due to grilles

Ignition cause	Percent
mechanical failure, malfunction	43
operational deficiency	16
misuse of material handled	16
misuse of heat of ignition	15
natural or other factors	4
incendiary or suspicious	3
design, construction, installation deficiency	3

Cork

Cork is obtained as the bark of the cork oak tree, which grows in Mediterranean countries. The chemical composition of cork is approximately 35 – 70% fatty acids and wax alcohols; 15 – 25% lignin; 15 – 25% tannins and catechins; and 3 – 9% cellulose and carbohydrates. In the first half of the 20th century, cork was commonly used as thermal insulation for refrigeration and freezing facilities. Because of its porous nature, it can be ignited in a smoldering mode, although systematic testing has not been reported on this aspect. At least one food-processing facility fire occurred when hot particles from an arc-cutting operation ignited cork insulation. NIST conducted unpublished tests on 9 mm cork board in the Cone Calorimeter and obtained radiant, piloted ignition data shown in Table 34. Hallman[440] examined the piloted, radiant ignition of cork samples of 253 kg m^{-3} density and 12.7 mm thickness. His data show $\dot{q}''_{cr}$ = 22.4 kW m^{-2}, B_{ig} = 124. Cain[441] tested 3 mm tiles in the ISO 5657 apparatus and obtained a minimum flux for ignition of 10 kW m^{-2} for piloted conditions and 32.5 kW m^{-2} for autoignition.

Table 34 Piloted ignition times for 9 mm thick cork board

Heat flux (kW m^{-2})	35	50	75
Ignition time (s)	8.8	3.5	1.1

Self-heating data based on a small-specimen study in an adiabatic furnace were obtained by Gross and Robertson[109]. Their values are: E = 80 kJ mol^{-1}; $QA = 8.0\times10^9$ W kg^{-1}; ρ = 130 kg m^{-3}; λ = 0.42 W m^{-1} K^{-1}; C = 2000 J kg^{-1} K^{-1}. Cork dust samples were also studied by Hensel[442] using the oven basket method. His data indicate E = 114 kJ mol^{-1} and P = 51.0. The above two values of activation energy are exceedingly different, but reasons for this are unclear.

Cotton

Cotton is primarily composed of cellulose, and it is often the commercial source of cellulose for producing filter paper. Tests for the AIT of various forms of cotton were conducted by NIST in 1947, with results reported only in summary form. The data[443] were: absorbent cotton 266ºC, cotton batting 230ºC, and cotton sheeting 240ºC. The test method has only been described very sketchily, see *Wood* for details. The specimens ignited by glowing ignition, with the absorbent cotton test requiring 2.5 h for the ignition of a 1.3 g specimen[191].

Cotton shipped as bales is commonly packed to a density of 360 to 450 kg m^{-3} and a mass of 85 to 227 kg, although in recent years[444] they have been typically at around 218 kg. Bales of cotton are susceptible to self-heating if moist and unclean; dry, clean conditions make self-heating much less likely[445]. A study by the Fire Research Station[446] claimed that most incidents of fire attributed to spontaneous combustion have not been correct. It was considered more likely that either long-term smoldering occurred due to accidental introduction of some hot material, or that contamination with 'drying' oils occurred. It was also concluded that friction of steel bands could cause ignition, but details of this proposed mechanism are not clear. A study by the Southwest Research Institute also deprecated self-heating and concluded that the most common cause of cotton bale fires when shipped in railroad cars is friction of steel bands along with sparking when impact occurs. This study was only published as a news item[447] and experimental results were not cited; the Institute did recommend that strapping be sprayed with a coating that reduces the sparking tendency. Instead, industry found it simpler to over-wrap the strapped bales with a fabric or film covering and this practice is now widespread. Other reports, however, suggest clean material may also, on rare occasions, self-heat, and that wetting appears to promote self-heating[448]. Actual case histories were mentioned by Back where bales of cotton coming from a dry climate ignited when transported to a humid harbor area[2115]. For external ignition, the ease of igniting a bale of cotton depends on its packing density[449], being relatively easily ignitable if 200 – 300 kg m^{-3}, and hard to ignite if around 600 kg m^{-3}. Internal ignition normally takes place due to some smoldering material having been introduced accidentally. This may occur due to sparks or heat of friction association with the ginning process and bales which are in that condition are referred to as 'fire-packed' bales. Once a bale of cotton starts smoldering, the process may be exceptionally long-lived. Several cases are noted of bales that have floated in a river or a canal for 2 – 4 weeks, yet were still smoldering inside at the end of that period[450].

Wakelyn and Hughs[444] conducted a laboratory experiment where they used an electric heater to ignite the center of a high-density (ca. 450 kg m^{-3}) bale. Smoldering ignition could not be sustained from this source, which the authors attributed to the poor access of oxygen into a tightly-packed bale. The authors also stated that bales of less than 225 kg m^{-3} density were able to sustain smoldering, but details were not provided. They also were unable to get cigarettes

and matches to ignite the bales; for this testing, only bales covered with polypropylene film or with burlap fabric were used. The authors also noted that, in recent years, fire incidents generally involved bales of 225 kg m^{-3} or lower density, but not high-density bales. Additionally, tests on clean cotton fibers loosely packed into an cubical oven basket passed the requirements of UN Test N4.

The layer ignition temperature for cotton fibers was studied by Chan and Napier[451] using a hotplate test. Unlike most results for hotplate testing (and unlike predictions from self-heating theory), little effect of layer depth was found. For 23 mm long fibers and a density of 12 kg m^{-3}, a critical hotplate temperature of 265ºC was recorded for a 10 mm layer, decreasing to 255ºC for a 60 mm layer. This may be due to the low packing density of the samples. But the authors found that the density when cotton fiber 'fly' is deposited on surfaces tends to be about 3 kg m^{-3}. At higher densities, the critical temperature does go down, as shown in Table 35. The authors also determined the AIT of the fibers by testing them for ignition in air, using an unspecified method. An ignition temperature of 260ºC was found.

Table 35 Results from hotplate tests on cotton fibers

Layer depth (mm)	Density (kg m^{-3})	Fiber length (mm)	Critical temp. (ºC)	Time to runaway (min)
10	12.2	23	265	2
20	12.2	23	260	17
40	12.2	23	258	13
60	12.2	23	255	14
40	36.7	23	220	11
40	24.4	23	250	12

Gray et al.[452] conducted oven-basket self-heating tests on cotton fibers, packed to a density of 50 kg m^{-3}. For equicylinders of 75, 115 and 175 mm diameter, they obtained critical temperatures of 230, 212, and 198ºC, respectively, giving E = 93.8 kJ mol^{-1} and P = 42.42. Oven self-heating results were also reported by Mitchell[156]. Self-heating data based on a small-specimen study in an adiabatic furnace were obtained by Gross and Robertson[109]. Their values are: E = 144 kJ mol^{-1}; $QA = 6.93 \times 10^{15}$ W kg^{-1}; ρ = 320 kg m^{-3}; λ = 0.042 W m^{-1} K^{-1}; C = 1300 J kg^{-1} K^{-1}. The activation energy in their results appears to be too high; a more plausible set of results was reported by Jones[453]. He gives: E = 102 kJ mol^{-1}, $Q = 17.3 \times 10^3$ kJ kg^{-1}, $A = 1 \times 10^5$ s^{-1}, λ = 0.04 W m^{-1} K^{-1}. On the basis of these data, Jones also calculated the minimum size/temperature relationship needed for a hot steel particle to ignite a cotton bale. He concluded that a 2 mm diameter particle heated to 700ºC, or an 0.5 mm particle heated to 977ºC would suffice to cause thermal runaway and ignition.

Cotton batting has traditionally been used in providing resilient padding for mattresses and upholstered furniture, although nowadays polyurethane foam in much more common in these applications. Mattresses are required to be resistant to cigarette ignitions (but not open flames) according to Federal regulations (16 CFR 1632). Untreated cotton batting cannot meet this requirement, so typically boric acid is added at about a 10 – 12% level to impart smolder resistance. The boric acid powder is adhered onto the cotton batting by use of a small amount of oil. Mattresses so treated may also resist ignition from matches (although not from burning bedclothes). When using an entire book of 20 paper matches to ignite small mattress mockups, it was found that treated mattresses only charred locally, but did not continue burning[454]. The same results were found by piling up 34 wooden matches in a small bonfire on top. In the same study, all mattresses using ordinary polyurethane foam that were tested ignited fully from both the paper matches and the wooden matches and continued burning the full extent of the specimen. Holleyhead reports tests where in 60 trials lighted cigarettes were placed on untreated cotton waste—charring was observed, but no flaming ignitions could be achieved[304]. For unclear reasons, his results are different from results typically obtained for mattress and upholstered furniture, where both smoldering and flaming are readily found when using non-FR cotton batting.

Crankcase explosions

Since crankcases of internal combustion engines contain both air and a combustible liquid, it is not surprising that there can be a possibility of explosion. Typical causes for explosions in ship engine crankcases include seizure of bearings and restarting the engine while parts are still hot[455]. Four-stroke engines with cylinder bores over 300 mm are most prone to these explosions; the relative risk for two-stroke or smaller four-stroke engines is at least a factor of 3 lower[461]. In addition, V-type engines are much more prone to explosions than are in-line types. Some explosions take place after the engine is stopped and a crankcase door opened for inspection[456]; this suggests that availability of sufficient oxygen may sometimes be the critical factor. In that vein, two-stage explosions have proven to be especially hazardous—the first explosion blows off the crankcase doors, while the second spreads burning oil throughout the engine room[457]. The second explosion takes place when new oxygen is introduced into the crankcase upon blowing off the doors. Serious explosions also have occurred in locomotive engines and in stationary engines, and in external combustion (i.e., steam) engines; similar types of explosions also take place in gear cases and other enclosed, lubricated mechanisms.

Concerted scientific study of the problem dates back to a 1947 crankcase explosion on the REINA DEL PACIFICO which resulted in 28 fatalities. At normal operating temperatures, oil vapor concentrations within a crankcase are negligible, and the oil that is present in the air space is in the form of a mist[458]. The mist in a crankcase is normally not due to mechanical agitation but, rather, due to condensation[457]. Oil is vaporized at hot surfaces, then condenses into a fine mist as it leaves the heated area and cools. The mist particles are very small[459], typically only 1 – 2 μm. Burgoyne and Newitt[460] found that the LFL of engine oil mist was 41 g m^{-3}, which is essentially identical to the LEL of common hydrocarbons in vapor form. They also pointed out that mists at a high enough concentration to reach the LFL have a notably high optical density, that is, even over short distances they will appear to be opaque. In normal marine engine operation, fuel concentrations of the crankcase mist were found not to exceed 1/100 of the LFL. The authors also showed that flame burning velocity and explosion pressures of crankcase oil mist explosions were very similar to those of pentane, allowing pentane to be used as a surrogate test fuel.

If the engine is overheating, then concentrations of oil mist can become significant. Except in the case of hot-spot faults, normal crankcase temperatures[461] are about 65 – 90ºC, which is significantly below the AIT of a lubricating oil mist (about 265ºC). In small-scale tests, Hoare et al.[458] set the crankcase temperature at 85ºC and sprayed mineral oil (flash point 227ºC) to produce a mist. Any practical concentration of mist could be ignited by a small flame when an agitator or an air injector was used. But explosions were hard to create in the absence of agitation and air injection. For atmospheres ignitable with a flame to be ignitable by a hot surface required using a 25 mm tube heated to 600ºC. But explosions did not take place if oil was actually sprayed on the hot tube, rather, the tube quickly dropped in temperature to ca. 200ºC. In some tests, upon attaining an ignitable atmosphere, a door was opened to the chamber. The opening sometimes caused a burst of flame, but never an explosion. In large-scale tests, Hoare used a standard 12-cylinder, 2-stroke marine engine and created a hot spot of unspecified size (possibly around 25 mm) on a metal pipe cap introduced into the crankcase. "Substantial" explosions required a hot spot temperature above 820ºC. None of Hoare's test explosions were detonations and, in fact, the most violent explosions only registered an over-pressure ca. 1 atm. Even this low explosion pressure does not make for an easy design problem, since crankcases of large-size marine engines can typically withstand only about 0.3 atm overpressure. Hoare also observed that none of the explosions were 'instantaneous,' and that they were sometimes preceded by a flaming oil fire. Inerting the crankcase by putting exhaust gas through it was shown to be a satisfactory means of preventing explosions. The oxygen concentration was 9% under these conditions.

Safety features[461] to reduce the potential of a crankcase explosion which are sometimes implemented include: (a) pressure-relief vents; (b) oil mist detectors; (c) emergency inert gas system for the crankcase; (d) ducting of the crankcase breathers to a safe area; (e) exhaust fans on the breathers, to reduce flammable gas concentrations; and (f) gas detectors at the outlets of the crankcase breathers. The latter two features are specific to dual-fuel, i.e., methane and diesel, engines. Flame arresters fitted to pressure relief vents are also beneficial[456]. Lamb provides a number of safety suggestions to minimize the possibility of overheated bearings, pistons, and other engine parts[456].

Crude oil

The properties of crude oil vary enormously, depending on the exact source of the oil. An early study[462] using the Abel apparatus showed flash point values ranging from –18ºC all the way to +170ºC. The distribution was somewhat bimodal, with most results being in the range 10 – 30ºC or 90 to 120ºC. Iwata et al.[463] tested various Iranian crude oils for ignitability by presenting a small flame to open pools of oil held in a 90 mm dish. All samples ignited immediately upon application of flame, suggesting the open-cup flash point was below room temperature for all. Elam et al.[464] conducted ignition tests on various crude oil types using the Cone Calorimeter and piloted ignition conditions. They found that at the lowest heat flux used, 5 kW m^{-2}, not all 2-mm thick layers ignited. But for 4-mm and greater thicknesses, all samples ignited at 5 kW m^{-2}. For thick layers (13 mm), ignition times at 5 kW m^{-2} were 54 – 248 s. Shorter times were recorded when a pilot flame was used, instead of the standard spark device.

Curling irons and hair dryers

Tests have reported on five different makes of domestic electric curling irons to determine if they can set fire to combustibles[465]. As is typical, the irons did not have any thermal cutout devices. When completely wrapped with towels, the irons caused charring of the towels and some melting of plastic parts, but did not start any flaming or smoldering fires. Curling irons have, however, on occasion been found to be manufactured defectively (commonly, a faulty line-cord connection) and caused ignition of fires, although published material does not appear to exist. In use, a curling iron often is repetitively rotated, often in a single direction. Thus, failures have been noted at the connection between the cord and the iron caused by the repeated flexing and twisting of the cord during the normal use of the device. Most modern curling irons, however, have a rotating connection designed to prevent this type of failure. The same failure at the cord connection sometimes occurs with hair dryers and these are normally not equipped with rotating connections.

Curtains

The potential of cotton curtains to ignite room furniture when their burning fragments were blown into a room by a bomb explosion has been studied[466]. The results generally

indicated that probability of ignition increased with increasing basis weight (g m^{-2}) of the fabric. The Fire Research Station[467] tested polyester/cotton curtains using the ISO 5657 test method and found that disintegration occurred at heat fluxes of 20 – 30 kW m^{-2}. Ignition required a heat flux of 40 kW m^{-2}. See also: *Fabrics*.

Diapers, disposable

Holleyhead reports that efforts to ignite the cellulosic-fiber padding of disposable diapers with a dropped cigarette yielded only local scorching, but not sustained smoldering or flaming[304].

Diesel fuel

Diesel fuel is a petroleum distillate which is in the 'gas oil' family of petroleum products; it falls between kerosene and light lubricating oil in the distillation process. The fraction of carbon is 85 – 88%, and hydrogen 11 – 14%; other elements are present only in minor amounts[468]. The flash point is typically controlled to be above 65.6ºC (150ºF), although this is for safety and performance reasons. The specifications of diesel fuel in the US are governed by ASTM D 975[469]. A Chinese study determined the minimum heat flux for piloted ignition to be 3.7 kW m^{-2} for light diesel and 5.2 kW m^{-2} for heavy diesel fuel[470].

Dinitrosopentamethylenetetramine

Yoshida[300] has reported that self-heating of stored dinitrosopentamethylenetetramine (3,7-dinitroso-1,3,5,7-tetraazabicyclo[3.3.1]nonane; DPT; $C_5H_{10}N_6O_2$) caused a harbor explosion. The chemical is used for foaming rubber or for gas generation in propellants.

Dishwashers

A UK study[471] found that the plastic parts of dishwashers were generally ignitable by a tiny 'needle flame' and in some cases even by an electric arc. Cheaper models do not contain a steel shell and a sizable fire was possible with those units. Throughout Europe[472], it was found that the main causes of dishwasher fires were:

- ingress of water, detergent, or rinse-aid onto wiring
- damaged door wiring
- overheating of elements
- faulty internal electrical connections.

Less than 5% of ignitions were attributed to consumer misuse. In the UK[473], two additional causes were identified:

- faults within the programmer/timer
- overheating of the main motor.

While no statistics are noted for the US, similar failure modes have been seen in the US and these types of problems have resulted in several recalls.

Because detergents create a very conductive mixture with water, any leakage onto an electrical component can result in arc tracking. This can be easily seen by making a mixture of detergent and water and inserting a conductor and applying a voltage. For explosions in dishwashers, see: *Hydrogen*.

Dryers and washers (for clothes)

Clothes dryer fires in the US represent about 3 – 4% of the reported residential fires. CPSC[474,475] performed in-depth investigations on 70 clothes dryer fires. The failure modes for fires of known cause are given in Table 36; in 33% of the incidents the cause could not be determined. In 14% of the cases, the timer switch was in the 'off' position when the fire occurred (the timer switch does not fully de-power the unit, however; see below). The proportion of fires with gas dryers (27%) is nearly identical to the fraction of gas dryers sold (24%), the remainder being electric. A breakdown of the point of origin of the fires is shown in Table 37; for 19% of the incidents, the exact origin could not be identified.

In addition to obtaining the statistical data, CPSC also conducted laboratory studies. In one test—a simulation of a bearing failure in the motor—the thermal protective device is supposed to cut out. But the exemplar tested, which was designed for cycling (auto-reset) operation, failed after 50 cycles and lint on the motor ignited. The study also pointed out that, surprisingly, venting to the exterior of the building is only required for gas dryers and not for electric ones. The CPSC study concluded that certain improvements were desirable in standards for both gas[476] and electric[477] dryers.

The Ontario Fire Marshal[478] found that the major causes of fires originating in clothes dryers are:

- lack of maintenance
- improper venting
- drying of 'flammable materials'
- accumulation of lint
- use of plastic ducts

Table 36 Failure modes for dryer fires of known cause

Failure mode	Percent
Electrical ▪ drive motor ▪ thermostat ▪ control malfunction ▪ power cord ▪ timer motor ▪ relay ▪ arcing	36
Restricted airflow ▪ improper venting or installation of vent	19
Heat source ▪ gas control valve ▪ lint ingestion ▪ gas supply line ▪ heat exchanger, gas	13
Mechanical ▪ drum seal bearing ▪ broken drum belt	11
Misuse, abuse	7.5

Plastic exhaust ducts can play two roles in initiation of fires: (1) they can collapse, bent or be pinched and cause a lint buildup or blockage, that may result in high temperatures within the dryers; (2) they are often the direct mechanism whereby a fire internal to the dryer ignites external combustibles. UL have warned that plastic or aluminum-foil types of vent ducts should not be used[479]. They have had requirements since 1987 for using only metal ducts; however, dryers are commonly self-installed by the user, who may not be aware of safety precautions. Not listed by the OFM, but also known to occur, are fires due to inept repairs or maintenance. Fitz[480] considers the following to be the primary causes of dryer fires (not ranked):

- self-heating materials being dried;
- drying of materials soaked in gasoline or other sources of flammable vapors;
- overfilling the drum with clothing, leading to disruption of design air flow patterns;
- improperly designed dryers where lint tends to accumulate near the heating elements;
- improperly designed dryers that have high discharge temperatures (e.g., one dryer model was found, under normal conditions, to produce a temperature close to 400ºC at the heater discharge into the drum);
- faulty venting of dryer (this may also cause buildup of lint in unexpected locations);
- failure of motor;
- arcing from a wiring failure;
- failure of a gas burner or gas control valve;
- failure of the operating thermostat;
- a cord or receptacle failure.

In rare cases, instances have been reported where friction of clothing alone has been responsible, with the clothes getting trapped between the drum and the housing. Even more rarely, incidents have been found with washers, where excessive friction of clothing against the lid develops.

Statistics on the point are not available, but a certain fraction of dryer fires occur when the drying cycle is unexpectedly stopped, for example, due to a power outage. Case reports exist where self-heating-prone items (e.g., padded brassieres) thereupon ignited; it is not clear if ignitions have been found when drying loads did not contain any items with a known self-heating propensity. Ignitions sometimes happen when metallic objects such as paper clips or coins fall out of clothing and short out some electrical component in the dryer[481].

Dryers usually do not control the heating device (gas or electric) by means of the user-operated timer switch. Instead, the heating device is turned on by a centrifugal switch attached to the motor. If the centrifugal switch fails and remains in the 'on' position, the heating device will operate without the operation of the motor and without there being an airflow through the dryer. A high-limit switch (TCO) is supposed prevent actual overheating, but high-limit switches can be subject to two shortcomings: (1) Same as with high-limit switches on other appliances, these devices are not designed for indefinite life; if the normal control means fails and the appliance operates on the high-limit switch, a fail-unsafe failure might be expected. The use of a manual reset high-limit switch would draw attention to the user that a problem has occurred. (2) In some designs, the location of the high-limit switch is such that excessive temperatures may occur in some location where combustibles could get caught, yet overheating will not be sensed by the high-limit switch.

Some dryer fires occur when the electric heating element sags due to aging and contacts the grounded metal portion of the drum. Current flow becomes possible since dryer manufacturers normally use only single-pole switching to disconnect current flow from the heater element, with one pole remaining live at the 240 VAC connection. Opening the door stops current flow to the motor and to one side of the power line, but not to the other (Color Plate 55, Color Plate 56). Additional information on fires originating from the heating elements is given under *Heaters, electric*.

Sanderson[482,483] has discussed the safety features of clothes dryers and common failures modes of them. The most common cause of fires in commercial-laundry gas-fired dryers is considered to be failure to properly clean the lint trap[484]. Another is improper maintenance or repair by staff.

A number of fire incidents have been reported where terry-cloth towels were laundered and ignited a while after removal from the clothes dryer due to self-heating[485,486]; similar incidents have been reported with mopheads that had been washed, dried, and put in a hamper[487]. Jones[488] convincingly demonstrated that uncontaminated fabrics have such a low HRR due to self-heating, even at dryer temperatures, that thermal runaway is precluded, but that if an oil-contaminated sphere of 100 mm diameter were present[489], then the sphere itself would only need to have self-heated to 170 – 180ºC to successfully drive the entire dryer load to thermal runaway. This is within the range of plausibility. For example, in one case[485] it was found that up to 30% of vegetable oil remained on oily towels after laundering. A

cotton terry-cloth towel can absorb up to 3 times its weight in cooking oil. Since the oils are only partly soluble in water, oil remains after washing. If significant amount of oil having a self-heating potential remains on towels after washing, then a fire can occur during drying. Fires typically occur in commercial laundries, not in residences, since large loads of oil-soaked materials are uncommon in the home environment. Dixon[490] reports of a fire in a prison laundry, which originated in a hamper used to store washed and dried clothing which had been heavily soiled with rapeseed cooking oil. Another fire was reported in a commercial laundry where towels soaked in unidentified oils and greases spontaneously combusted in plastic and canvas containers, where they were placed after drying[491]. In laboratory testing, as a control, Dixon[490] determined that a clean 2 kg cotton-fabric dryer load would not spontaneously combust at a 100ºC drying temperature. The procedure involved placing the clothing into an open-top 25 L plastic tub immediately after drying was completed and monitoring the interior temperatures. For clothes where detergent was entirely omitted from the wash, a minimum of ca. 187 mL of rapeseed oil was found needed to cause spontaneous combustion in a 1 kg load of cotton fabrics dried at 100ºC. A small amount (e.g., half a scoop) of detergent used in the wash did not have a significant effect in counteracting self-heating. Despite claims of the detergent industry that only cotton, and not synthetic-fiber towels have the potential to self-heat[492], polyester and polyester/cotton fabrics were found to also be liable to self-heating. Open flaming did not occur typically until 3 h had elapsed, but in some cases it took more than 4 h. It must be emphasized that these tests all involved spontaneous combustion *after* the clothing was finished drying and removed from the dryer.

Mackey tests on cotton and cotton/polyester towels soaked with 20% oil by weight showed temperature increases of 34 – 60ºC for corn oil and 31 – 76ºC for sunflower oil[485]. This was accompanied by dryer testing, where it was found that dryer fires readily occurred with heavily-oiled towels, especially if a cool-down cycle was not used. Additional tests, conducted by the detergent industry[492], showed that after a single washing, roughly 4 – 15% of soybean oil remained, depending on details of the wash load and the washing procedures. In independent testing, Sanderson[493] examined the fraction of corn oil that gets removed from towels with each washing. Hot water and detergent was used in these tests, but the effects of varying either washing temperature or detergent amount were not examined. The results indicated that each wash/dry operation tended to remove only roughly 1/3 to 2/3 of the oil that was present. The effect of fiber type was also examined, but the results were inconclusive on that point.

After a dryer fire which may have been caused by self-heating of oiled cloths, it is sometimes possible to analyze fatty-acid residues and determine if vegetable or animal fats were involved; a chemical analysis procedure based on ether extraction, saponification, and derivatization was given by Coulombe[494]. Another alternative is to collect samples of wash water from the clothes *washer* and subject these to analysis. The water pump is a place where often some residual water can be found[495].

It has been claimed[496] that use of bleach contributes to the self-heating. This has some credibility in that bleaches are oxidizers; however, apart from anecdotal reports, no studies appear to have been conducted. Furthermore, it would be likely that most highly oil-contaminated cloth would be bleached as part of the washing procedure and it is not clear that self-heating would be less if the circumstances were identical but the bleach was omitted.

It has also been alleged[497] that lint in a clothes dryer's lint trap can self-heat and lead to a dryer fire. This issue was experimentally addressed by Sanderson and Schudel[498]. They conducted tests with dryer lint placed in a temperature-controlled oven at various temperatures in the range of 66 to 121ºC. Even though the upper range was significantly above temperatures found in actual dryers, no self-heating was found. Packing density of the lint, its origin, and its moisture content were varied, but these did not affect the outcome. The authors concluded that cases attributed to such cause were more likely attributable to other malfunctions which resulted in the ignition of plastic dryer parts, a number of which are often associated with the lint trap.

Domestic gas-fired clothes dryers can be a source of ignition if they are located in a garage or other area where an accidental spill of flammable-liquid vapors may occur. In testing[499], it has been found that whether or not a dryer will ignite vapors along the floor depends crucially on the exact setting of the appliance-leveling legs. The gap available at the bottom governs the distribution of entrained air flow through the dryer. The situation is complicated, since safe conditions were found with no gap and with a gap of 37 mm (1.5"), but unsafe conditions at a gap of 13 mm (0.5").

A European study determined that the main causes of clothes *washer* fires were[472]:

- faulty internal wiring or connections
- ingress of water or detergent onto wiring
- overheating of resistors or timers
- vibration and rubbing of cables or other parts
- overheating of motors.

Less than 5% of ignitions were attributed to consumer misuse.

Dryers (process dryers)

Causes of fires in grain dryers have been investigated by Lasseran[500]. Incandescent particles ejected from gas or oil-fire burners were found to be the largest cause of ignitions. Some of these originate as combustible matter inducted through the combustion air supply openings. Cases have been found of this sequence of events even in dryers that

are of the heat-exchanger type, i.e., with sheet metal separating the combustion chamber from the drying chamber. Other ignition causes included blockages and excessive temperature settings. In the case of drying sunflower seeds, these have a fuzz attached to them that can be liberated in the drying process and drawn into the combustion chamber and ignited[46]. Corn kernel debris and rapeseeds are also susceptible to the same behavior.

The potential of dust explosions in spray dryers has been studied by Gibson and Schofield[501]. They pointed out that dusts considered as 'non-ignitable' at room temperature may, in fact, ignite at the 140 – 500ºC found in the dryers. Thus, they recommend that the AIT of the dust be considered as the governing variable, instead. The authors also concluded that ignitable dusts will not be ignited by incandescent particles at 600 – 800ºC, if particle diameter is smaller than 3 – 5 mm. This is best accomplished by having fine-mesh screening at the air intake.

Self-heating of material can occur if deposits of granular or powdery material are allowed to build up in an industrial dryer, leading to dryer fires. Beever[502] points out that this is sometimes due to faulty design where 'dead' corners allow material to accumulate. The remedy is to provide fairings which eliminate dead corners. A book has been published giving extensive loss prevention advice on industrial dryers[503].

Dung, fecal matter

Dried cow dung ('cow chips') has been found to be particularly susceptible to ignition by firebrands. Once ignited, the dung can then cause a propagating fire by igniting adjacent grass. If the dung has been pulverized by cow hooves, Ford[1153] reports that cigarette butts will 'invariably' ignite it. Bunting and Wright[504] conducted field experiments where bulldozed piles of vegetation were set alight and used as a source of generating brands. The target vegetation was generally grass, but the cow chips were found to be the first-ignited target items. Analysis indicated that air temperature was the dominant factor in determining the distance to which spotting would occur, and Figure 24 shows these results. Wind velocities were in the range 5 to 11 m s^{-1}, and relative humidity 11 to 45%. The latter two factors were found to be less important than air temperature. In accompanying laboratory studies, the authors used glowing, non-flaming, cylindrical-shaped juniper brands. For the largest size brand used, 5 × 20 mm, they found that ignition required a minimum air temperature of 4ºC and (with a few exceptions) RH < 50%. Until temperatures exceeded 16ºC, however, for ignition to occur a wind speed > 4.5 m^{-1} was also needed. Also, fuel moisture content of < 13% was found to be a prerequisite for ignition. When brand size was varied, brands of 3 × 15 mm were found able to cause some ignitions, but no ignitions were possible with 2 × 10 mm brands.

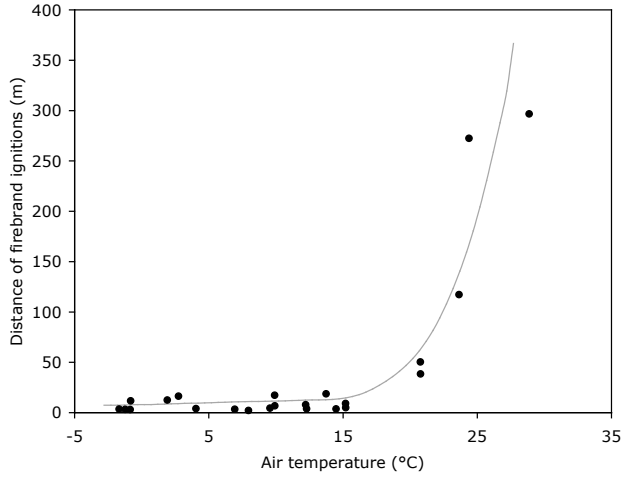

Figure 24 Effect of air temperature on the ignitability of dried cow dung from controlled-burn firebrands

A report exists in the literature[505] where it is claimed that a fire was ignited by the self-heating of a single soiled diaper enclosed in a plastic bag and left in direct sunlight for three days at a location where temperatures were over 38ºC. The mass of potentially reacting material represented by the contents of a diaper is very small and it would be hard to give credence to this report in the absence of confirmatory studies.

Dusts

IGNITION OF LAYERS

Dust layers are generally ignitable in a smoldering mode from glowing cigarettes. van Laar[506] demonstrated this for dusts of tapioca and soybean meal. Radiant ignition of dust layers has occasionally been studied (e.g., Glinka et al.[507]), but not enough studies have been made to draw general conclusions. Leisch et al.[508] studied the smoldering of corn-soy mixed grain dust. Using relatively coarse (2/3 by mass between 106 to 425 μm, 1/3 between 38 to 74 μm) dust at a packing density of 410 kg m^{-3}, they found that smolder velocities were slow, 15 – 60 mm h^{-1}. Using an 0.33 mm platinum wire, a minimum heat flux of ca. 48 kW m^{-2} was needed to cause a smoldering ignition. The ignition source had to be sustained for a very long time in order to effect an ignition: 40 min at 48 kW m^{-2}, 23 min at 200 kW m^{-2}. Using slag from an arc welder, only a transient ignition was obtained for the corn-soy dust, but sustained smoldering was achieved for grain screenings. Identical results were obtained for slag from an oxy-acetylene torch. The slag particle size in both cases was only described as less than 24 g. The authors believe the screenings ignited because of a lower packing density, but a value for the density was not given. In limited testing with cigarettes, it was found that screenings ignited when a minimum wind velocity of 1.5 m s^{-1} was imposed, with no ignition for smaller velocities.

Xu et al.[509] conducted spark ignition tests on several types of dust layers and found the following MIE values: flax 0.365 mJ; cotton 0.456 mJ; and wool 0.41 mJ. The ignitions resulted in smoldering, not flaming.

Palmer[510] examined the hotplate ignitability of tea fluff (i.e., tea dust) and found a temperature of 260ºC for a 25 mm layer and 230ºC for 50 mm. He also noted that the fluff was readily smolder-ignitable by sparks from a cigarette lighter flint.

EXPLOSIONS

Dust explosions have been most prolific and serious in the agricultural products industries, especially in grain elevators. Kauffman[511] presented a detailed survey of grain dust incidents. A German study[512] of the causes of industrial dust explosions gave the results shown in Table 38. The materials involved are listed in Table 39. In view of the major role of pharmaceutical manufacturing companies in dust explosion research, it is perhaps surprising that explosions in their industry are not more frequent. The type of devices associated with dust explosions[513] are listed in Table 40. Despite the relatively high frequency of dust explosions caused by electrostatic discharge, this scenario is very difficult to re-create experimentally. Thorpe et al.[514] noted that sugar dust is one of the substances more frequently involved in actual silo explosions, but could not produce a single explosion in an experimental silo.

A survey[515] of US grain dust explosions for the years 1958 –1975 gave the results shown in Table 41. Extensive tables of BM experimental results on dust explosibility are given in Chapter 15. Since a dust explosion is typically an oxidation (occasionally, a reaction with nitrogen or carbon dioxide), substances which are already stable oxides cannot be involved. Thus carbonates, nitrates, phosphates, silicates, sulfates, etc., will not be involved in dust explosions. The primary members of these families are minerals; in fact, rock dust is used to prevent coal dust explosions. However, some ceramic dusts are explosible. Matsuda reported LFL values for a series of ceramic dusts (metal carbides, metal nitrides, metal borides, and metal silicides)[516,517]. The values ranged from 130 g m^{-3} to 2310 g m^{-3}, apart from a few substances which were non-ignitable.

Table 38 Causes of industrial dust explosions in Germany, 1965-1985

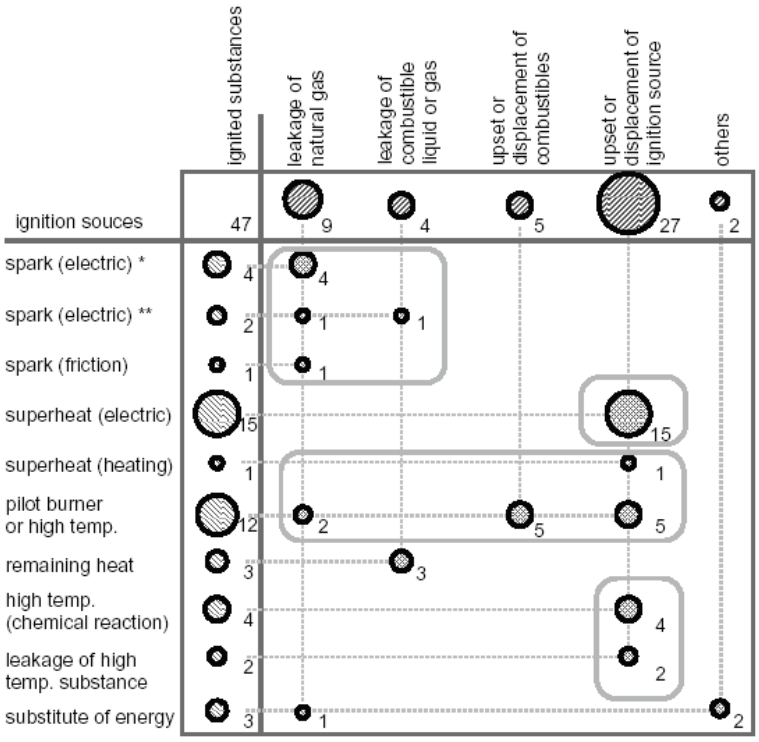

Figure 25 Statistical distribution of fire causes due to the Great Hanshin earthquake of 1995

Earthquakes

Fires after earthquakes have often been of great concern, both because of their prevalence and because firefighting resources may be much reduced, e.g., water mains broken, streets made inaccessible. In one recent fire, the 1995 Great Hanshin fire in Japan, a study was conducted to determine the causes of earthquake-caused fires[518]. The results are shown in Figure 25, with the following being the definitions of the ignition sources:

- spark (electric)*: spark from damaged electric appliances
- spark (electric)**: spark from electric appliances that can occur under normal conditions, e.g., from light switch
- spark (friction): spark from mechanical friction
- superheat (electric): overheating of damaged electric appliances except electric heat source appliances
- superheat (heating): overheating of heat source appliances
- pilot burner or high temp.: pilot burner or high temperature of heat source appliances
- remaining heat: residual heat of heat source appliances
- high temp. (chemical reaction): high temperature caused by chemical reaction of chemicals in vessels which were broken by the quake
- leakage of high temp. substance: leakage of high temperature substance, e.g., leakage of molten metal in a dental laboratory
- substitute of energy: unaccustomed use of energy, e.g., candle for lighting under power failure.

Electric (general statistics)

The US Fire Administration[519] estimates that about 7.7% of all fires are due to 'electrical distribution.' This is the fifth-ranking cause of fires, the fourth-ranking cause of fire fatalities, and the second-ranking cause in terms of dollar losses. Their definition of 'electrical distribution' is: Wiring, transformers, meter boxes, power switching gear, outlets, cords, plugs, and lighting fixtures. Separate categories exist for

Table 42 Average annual losses during 1994-1998 in the US for structure fires involving electrical distribution equipment, arranged by type of equipment involved in ignition

Equipment	Fires	Civilian deaths	Civilian injuries	Direct property damage (in millions)
Fixed wiring	19,100 (32.7%)	131 (37.5%)	415 (24.8%)	$384.4 (37.6%)
Light fixture, lampholder or sign	9,600 (16.4%)	31 (9.0%)	168 (10.0%)	$108.1 (10.6%)
Cord or plug	8,600 (14.7%)	93 (26.7%)	455 (27.2%)	$154.8 (15.2%)
Switch, receptacle, or outlet	5,700 (9.8%)	34 (9.8%)	163 (9.7%)	$82.8 (8.1%)
Lamp or light bulb	4,600 (7.8%)	23 (6.5%)	209 (12.5%)	$64.7 (6.3%)
Fuse, circuit breaker, or other overcurrent protection device	3,400 (5.8%)	8 (2.3%)	93 (5.6%)	$59.3 (5.8%)
Meter or meter box	1,200 (2.1%)	1 (0.2%)	10 (0.6%)	$11.8 (1.2%)

'cooking,' 'appliances,' and 'other equipment.' The above statistic is based on all fires, which includes vegetation fires, vehicle fires, and others, not just building fires. For residential structure fires, electrical distribution accounts for 9.9% of the total. Fires originating in cords or plugs of appliances are likely to be reported as appliance fires, thus the losses due to cord/plug ignitions will be spread over several categories. More detailed data from NFPA[520] are shown in Table 42. As with all of the statistics available through NFPA, only fires reported to municipal fire departments are tabulated. The data given in Table 42 include all reported structure fires and are not restricted to residential fires.

These general statistics do not give indications as to the actual reasons for ignition. The only highly-detailed study where an attempt was made to identify reason for ignition of electrical distribution components has been that of Hall et al.[521], who studied 105 residential-occupancy fires (Table 46). CPSC staff[522] continued this work and provided a

breakdown of factors leading to these (Table 43). Many of the faults found were attributable to abusive usage or faulty installation, often by amateurs. These studies reflect similar percentages as found in overall fire department reports[523].

Additional areas where fire department reports showed problems, but which did not occur among the fires studied in detail included overcurrent protection (6%) and meter boxes (1%). Fires initiating from electrical distribution system faults were disproportionately concentrated among older housing and increased substantially with dwelling age, once the age was beyond 20 years.

CPSC also conducted specific studies on problems with several of the electrical distribution system device types, and these are discussed in detail below. For example, the 9.4% attributable to 'faulty product' do not make clear the nature of the problem, but a CPSC study on electrical outlets (see below) found that fires or electrical failures may well arise due to flimsy designs of many devices.

Statistics for fires/explosions in UK factories from low-voltage equipment are shown in Table 44 and are based on 247 incidents. Peck[524] analyzed 262 UK industrial fires or explosions involving high-voltage equipment and provided a summary given in Table 45. Of these incidents, 36.6% involved only an explosion, while the remainder were fires or an explosion with fire. The most common fire/explosion cause was from circuit breakers, of which 93% were oil-filled and 7% dry.

The electrical fire statistics for Japan during 2000[525] are shown in Table 47. Electrical fires comprised 11.8% of the total fires reported. Statistics have been reported from Rus-

Table 48 Causes of 1996 electrical fires in Russia

sia, giving the breakdown of causes for electrical fires[526]. During 1996, electrical fires accounted for 20.5% of the total. For these, the breakdown is shown in Table 48. A Norwegian study identified that, in that country, 1/3 to ½ of the electrical fires in buildings are due to poor contacts or heating/glowing at contacts[527].

Cooper[622] has pointed out that a fire originating in electrical equipment is not necessarily a fire of electrical origin, even though some statistics inappropriately classify them as such. An example is a fire in an electric deep-fat fryer that occurs when the person using it allows the oil to overheat.

Electric appliances and electronic equipment

The statistics in Chapter 1 include information on fires originating in certain primary types of appliances—heating equipment, cooking equipment, and cooling equipment. The major causes of ignition of electrical appliances or equipment, as determined by NFPA[528] are given in Table 49. CPSC estimates[529] for fires originating in miscellaneous appliances are given in Table 50.

For devices which use electricity, such as consumer appliances, computer equipment, telecommunications equipment, etc., there are basically two ignitability issues:

(1) Will an electric fault within the appliance be contained by the housing, so that a fire does not erupt at the outside of the appliance?
(2) Will the exterior surfaces of the appliance resist ignition from a small external ignition source, or, if they do ignite, will they readily self-extinguish or otherwise be limited to only producing a low heat release rate?

Detailed statistics on this point are not available, since in Table 49 ignitions from external sources are lumped into "other known."

There is a widespread opinion that devices which can only consume a very small amount of power cannot cause ignitions. Some authors[530] consider this limit to be 20 W. The UL standard for information technology equipment[428] considers the limit to be 15 W. A more conservative view[527] is "several watts." The realism of such claims is unclear, and there does not appear to be much research on the topic. As shown below under *Electric lamps and lighting fixtures*, even a 1 W incandescent light, upon being broken, can ignite a methane/air mixture, while a 1.25 W source can ignite notebook paper.

In the US, the fire performance of enclosures of electric appliances is effectively governed by the standard UL 746C (see Chapter 7). Safety of electric appliances is covered by a very large number of UL product-specific standards. But, with some exceptions, these standards either refer to the requirements of UL 746C or paraphrase them. In the UL 746C standard, the required performance of enclosures is governed by three variables:

- whether the appliance is portable or not
- whether a portable appliance is intended for 'attended' household use
- whether current-carrying parts inside have a minimum insulation thickness of 0.71 mm.

Stationary appliances must have a 5V rating, while portable appliances need only an HB rating (and no hot-wire ignition requirement), unless they contain electrical parts with less than 0.71 mm insulation thickness. For housings which do have to fulfill an electrical safety function, if intended for 'attended' use, then an HB rating still suffices, but hot-wire

other or unknown	1500

ignitability must be no more than PLC 4. Unattended appliances need a V-2 rating and PLC 4. Decorative parts must be rated at least HB, unless they have a volume smaller than 2 cm^3 and all dimensions smaller than 3 cm. The consequence is that small appliances are normally only HB-rated. Television receivers are a special case and are discussed separately in this Chapter.

In 1998, CPSC reported on the results of a study to determine if the UL 746C provides an adequate level of safety for plastic enclosures[531]. The UL 746C standard provides that either flames be applied to end-use items, or, alternatively, the results obtained from UL 94 tests on plaques of the plastic can be used. Obtaining a V-2 rating is considered equivalent to passing the 12 mm and the 20 mm flame tests of UL 746C. But when subjecting actual enclosures to test flames, only a vague instruction is provided as to where flames should be placed. To examine the adequacy of these provisions, CPSC obtained a number of small consumer appliances and subjected them to tests, using both the UL 94 and the UL 746C procedures. The laboratory findings were:

- Some appliance enclosures failed the HB test, the least stringent test in the UL 94 series.
- Some materials that were Listed by UL as V-2 failed the V-2 test, when CPSC tested samples actually cut out from appliances.
- When tested with the 12 mm or 20 mm flames of UL 746C, a number of appliances made from HB and V-2 materials failed. All appliances made from V-0 materials passed. No V-1 materials were included in the study.

As a result, CPSC made the recommendations that:

- The concept of 'attended' use is vague and is not defined by UL. Consequently, appliances such as toasters and clothes irons can become classified as 'attended.' In the opinion of CPSC, appliances should be classified as 'attended' only if they cannot remain energized when unattended.
- The UL 746C provisions for placing flames on end-use articles are vague and unconservative. An enclosure rating of V-0 should be mandated, unless a more realistic end-use article testing regimen can be evolved within UL 746C that demonstrates adequate resistance to small flames.
- The UL 746C provisions that allow least-stringent performance (HB rating, no hot-wire ignition testing) for housings where current-carrying parts have ¤ 0.71 mm insulation thickness should be abrogated.

UL revised UL 746C during 2000 (effective 2004) to tighten up certain provisions, but for portable attended equipment, HB-rated enclosures continue to be acceptable. UL also clarified that blenders, vacuum cleaners, and hand-held drills are 'attended,' while clothes irons, toasters, electric fry pans, and coffeemakers are 'unattended.' While the new edition of UL 746C is generally intended to require use of V-2 rated materials for unattended equipment, these will still be able to use an HB-rated enclosure as an exception, if certain requirements for the current-carrying components thereof are met. Non-portable equipment continues to require a 5V rating. However, UL are gradually switching over to UL 60335-1[532], which is their version of the international standard IEC standard IEC 60335-1[533] and it will eventually replace UL 746C. Especially noteworthy is that the IEC standard has more strenuous provisions for glow-wire testing, applicable to plastics used within 3 mm of current-carrying conductors. Actual test requirements that must be met are laid down in IEC 60695-13 (glow-wire ignition temperature), and either IEC 60695-2-11[534] (glow-wire flammability index for end products) or IEC 60695-2-12[535] (glow-wire flammability index for plaques). In either case, minimum ratings of 850ºC for glow-wire flammability index and 775ºC for glow-wire ignition temperature must be obtained. The toughened requirements mostly affect parts made from polyester and nylon, which previously tended to be of lesser FR grades[536].

The general philosophy of UL requirements for the flammability performance of appliance housings is that ignition sources are likely to be found only *inside* the equipment, therefore, if certain design features are implemented to keep ignition sources away from the housings, the housings need only a minimal performance level (typically, HB). This means that the housings are unlikely to resist *external* ignition sources. The National Association of State Fire Marshals concertedly, but so far unsuccessfully, endeavored to have this philosophy changed. Some test information on this topic is discussed under *Television sets and computer monitors*. The standards of IEC generally adopt an even more lax philosophy, in that a 13 mm air gap between a possible ignition source and a potential ignition target is deemed to be a fireproof barrier.

CPSC has also expressed concerns that 'push-on' terminals used inside appliances have a disproportionate propensity to cause ignitions. Push-on terminals are mechanical, non-soldered connections where a male spade lug mates with a C-profile female terminal. Faulty connections can result when the fit becomes loosened.

Information on specific appliance categories is located alphabetically in this Chapter.

HIGH-LIMIT SWITCHES

Heat producing appliances are generally required to have a *high-limit switch* (also known as a *thermal cutout* or *thermal cutoff*) apart from the normal thermostat. In some cases, two high-limit switches are used. High-limit switches come in three basic configurations:

(1) Automatically-resetting. This type is functionally identical to a normal-use thermostat—it opens a circuit when a setpoint temperature is exceeded, then re-closes the circuit when cooled down to a lower temperature. Most commonly this is based on the principle of a bi-

metallic element—when two elements of dissimilar thermal expansion characteristics are joined together, a large movement can be generated by a small temperature change. The movement is then used to open a pair of electric contacts. If an overtemperature condition persists, the device will cycle indefinitely.

(2) Manually-resetting. This is most commonly an electromechanical device that opens a circuit and then latches in the open position. Pushing a reset button is required to reset the device.

(3) Sacrificial, one-shot operation. This is most commonly based on a scheme whereby electric contacts are held closed by the mechanical force of a fusible pellet. The pellet has a specific melting point and when it melts out, the contacts open. The device is destroyed by the melting and must be replaced to repair the equipment (Color Plate 57). The fusible pellet principle was first patented[537] in 1960.

In many cases, the pertinent standards allow an automatic-resetting type of high-limit switch to be used. A pervasive ignitability issue exists since in most such appliances there is no audible warning if either the thermostat fails or some other failure mode occurs so that the device 'runs on the high limit,' with the high-limit switch effectively now acting as the thermostat. This situation is hazardous because: (1) high-limit switches are usually rated for only 100,000 cycles and may fail closed, instead of failing open, at the end of their lifetime; (2) since the high-limit temperature is necessarily higher than the range of normal operating temperatures settable by the thermostat, this means that the appliance may equilibrate to a higher temperature and stay at that higher temperature for a long time. Color Plate 58 through Color Plate 60 illustrate the effect of cycling on contacts. An audible buzzer connected to the high limit switch (or use of manual-reset, not automatic reset devices) would solve most of these problems. Some UL standards require a signal, but the signal is permitted to be visual, i.e., a pilot light. It is not at all evident that users understand that a glowing pilot light means "fault," instead of simply "heating."

Electric batteries

Ignition hazards associated with electric batteries can be of three types:

(1) liberation of flammable gases;
(2) providing electrical energy for initiating a fire;
(3) ignition and burning of the battery itself.

The most significant hazard is the generation of flammable gases and their ignition, leading to a battery explosion. Lead-acid batteries, most commonly used in automobiles, are designed to be recharged. The charging process liberates hydrogen and oxygen and this can create a potential fire hazard. Extensive statistics on motor vehicle battery accidents and explosions have been compiled by NHTSA[538]. During a 1-year period, 2280 injuries were reported in the US due to motor vehicle battery explosions. The activities leading up to the explosions are given in Table 51. A common scenario for explosion is if connections are reversed in jump-starting, so that one battery effectively is shorting out the other. However, an error of this type is not required for an explosion to happen. Some accidents are reported when the vehicle is not in use, and there has been a suggestion that in some cases long-term storage of a battery may make a battery explosion more likely[539]. A general study[542] on reported injuries attributed to electrical battery accidents produced the results shown in Table 52. A large fraction of the accidents is due to either inadvertent (e.g., hooking up batteries with inverted polarity) or deliberate abuse (e.g., incineration).

Table 51 Activities leading to reported injuries from motor vehicle battery explosions

Activity	Percent

checking fluid level or adding water	19
unknown	5

Table 52 US statistics (1983-1992) on injuries from battery accidents

Type of accident	Percent
explosion or violent rupture	38
overheating	27
leak or mild rupture	23
flame or fire	12

An explosion of a lead-acid battery may be caused by attempting to recharge a battery with a dead cell or using too rapid a charging rate on a flat battery. In both cases, the water may be excessively electrolyzed into H_2 and O_2. This may raise internal temperatures sufficiently so that the lead plates buckle, contact each other, and produce an internal spark[540]. A spark may also be produced if the electrolyte level is allowed to drop below the base of the plates. A fire has been documented[622] where a wood shelf holding lead-acid batteries became sufficiently contaminated with battery acid as to become conductive. Contact of two electrodes with the shelf caused the wood to ignite.

Two explosions of automotive type, 12 volt batteries occurred at a battery manufacturing facility when a worker was peeling off a label attached to the side of the case[541]. The batteries were new and were sitting on a wood pallet, without any electrical hookup. Experiments conducted during the course of investigation showed that the battery case could be electrostatically charged up to 8 kV during the process of label removal. Battery cases are made of several pieces of plastic that are welded together. Further tests indicated that discharge into the interior of the battery is possible along minute defects present in a weld seam. Measurements indicated that the capacitance of the battery sitting on

a pallet is about 25 pF. When it was placed directly on earth, a value of 140 pF was found. If a fixed amount of charge is transferred during peeling the label, the battery can get charged to a higher voltage if its capacitance is low. In turn, the probability for an incendive discharge to occur is increased if the voltage is raised. Thus, the likelihood for this type of accident to occur is greater if the battery is situated so that its capacitance is low.

Attempts to recharge non-rechargeable batteries will lead to chemical reactions (evolution of H_2 and O_2) that take place in a way not anticipated by the manufacturer, consequently, an explosion may result[542]; the attempt may also result in metallic deposits being collected in such a way as to short out the cell. When subjected to fire, even a single 'D-size' dry cell can cause an explosion. In one case[543], an expended cell was put into a 55 gallon (208 L) steel drum used for burning trash. An explosion ripped apart the drum from top to bottom. Essentially any type of battery can be expected to rupture or explode if an attempt is made to incinerate it.

Hay et al.[544] determined that typical sparks resulting from loose battery connections on a motor vehicle battery are on the order of 0.5 J and 500 μs duration. Based on this, they designed a test apparatus for flame-arrester battery plugs. The latter are intended to eliminate the possibility of a spark outside the battery propagating fire into the battery, and causing an explosion inside. Since hydrogen/oxygen mixtures have an exceptionally low quenching diameter, these plugs are commonly constructed from sintered metal, which can more easily be manufactured with very small openings[545].

Batteries much smaller than those in motor vehicles can be involved in explosions. Accumulated hydrogen has caused hand-held flashlights to explode. NIOSH has documented that even a specialized flashlight used by divers which contains a chemical catalyst to recombine hydrogen has been subject to explosions[546]. Small 9-Volt alkaline batteries have exploded in airline luggage; this usually occurs due to shorting out of the terminals. Lithium batteries can explode internally, due to excessive rates of gas generation within. One explosion[547] of a small lithium battery (Color Plate 61) was severe enough that it "blew the Assistant Chief out the office door."

The Tokyo Fire Department investigated several fires caused by small batteries[548]. In one case, 2000 used coin-type lithium batteries (3.2 V) were thrown together into a cardboard box; the box ignited. In another case, a person's pocket ignited when a Ni-Cd battery (1.2 V, 600 mAH) used for powering handheld tape players shorted out. Testing showed that, when short-circuited by an external metallic object, the battery was able to pass about 18 – 20 A through test clips and staples and heat them red-hot. In a third case, a portable telephone left in a parked car started a fire. The cause was identified as being due to an internal failure of its lithium battery; the battery was improperly manufactured and had been the subject of a recall.

All electric batteries represent a form of stored chemical energy which can readily be converted to electric energy. The latter, in turn, may serve as an ignition source. Most batteries, however, will not contribute much fuel to the fire themselves. A different situation arises with lithium batteries, since the metal lithium is easily ignitable, will burn readily, will contribute appreciable heat to fire, and is not extinguishable by water, gaseous agents, or most dry chemicals. NTSB[549] documented a fire caused by rough handling of lithium batteries being shipped as air cargo. Ignition was found to readily occur upon mechanical abuse of the packages of batteries. Lithium batteries are classified as Division 9 (Miscellaneous Hazardous Material) under the UN and DOT classification system for hazardous materials. The UN Manual[550] provides a whole gamut of tests to be run on lithium batteries, however, these address only the issues of prudent manufacture and not of accidents due to abusive handling, e.g., dropping, crushing, or puncturing. Test standards dealing with end-user abuse have been issued by UL (UL 1642[551]) and by the US Navy[552] and results from a number of studies conducted by manufacturers or US military agencies that simulate abusive handling have been published[542].

Electric blankets and mattress pads

In old-style electric blankets, heating was provided by a resistive wire, and safety against overheating by thermostats. Multiple thermostats (often 12) were embedded in an effort to avoid overheating, nonetheless, these were not always successful. Apart from defective units, fires sometimes originated when the blanket was doubled over or tucked in, so that excessive heat was locally accumulated[271]. A CPSC study[553] on old-technology (pre-1982) blankets provided failure mode statistics shown in Table 52; comparable data on current-generation blankets are not available. UL has a test standard (UL 964) for electric blankets[554].

Since 1990, there has been only one manufacturer of electric blankets in the US. In 1981 they introduced the PTC (Positive Temperature Coefficient) technology. This is a self-regulating, conductive polymer—primarily polyethylene with carbon black—that operates much like self-

Table 53 Failure modes identified in a CPSC survey of fires originating in pre-1982 electric blankets

regulating heat tapes (see *Heat tapes and heat cables*). Discrete thermostats are not needed, since the entire heater itself functions as a thermostat. Unlike the old-style resistive arrangement, here the electrical topology is of parallel resistance between two good conductors. The latter are small-gauge wires, each of which is helically configured[555,556]. The technology has a certain resistance to aging-induced failures, since aging causes the equilibrium temperature to fall, not rise. Despite the improved safety of this technology, McLaughlin[557] reports that 500 fires per year are estimated to originate in blankets of the new technology. The failure mode has been described by Carlson[558] as: a break occurs in a conductor, arcing then occurs at the break, and the polymeric PTC material ignites from the arcing. McLaughlin points out that fuses or safety devices are provided, but that these only provide partial coverage, with faults beyond a certain distance along the conductor not being able to activate the device. Similar to certain heat tapes, "the PTC material acts as a fuel, burning and sparking much like the fuse of a fire cracker"[557]. But fires due to damage to the cord or to the control box may be more common than failures at the heating elements[559].

Blankets in other countries do not necessarily use the same technology. A 1999 British study[559] listed the causes of electric blanket fires as shown in Table 54. The appliance faults were found to be due mainly to deterioration or due to lack of adequate overheating protection (until the 1980s, there were a number of blanket models sold in the UK market without any overheat protection). Deterioration was commonly manifested as heating elements becoming detached due to excessive use, elements bending, and the consequent formation of hot spots. It was estimated that a flaming fire can occur about 2 h after a hot spot develops. Very old blankets were found to have yellowed or disintegrated polymeric material. Abusive uses included excessive folding, doubling, and use of blankets as mattress pads. British designs and customs were quite different from the US, since blankets were designed and intended only for pre-warming a bed, and were intended to be turned off during actual sleeping. Regulations in the UK governing electric blankets were tightened in 1990, and ignitions have been much decreased with newer-technology blankets. The earlier technology in the UK was badly antiquated, but post-1990 designs involve a sensor wire which is helically wrapped around the heating wire and separated from it by a polyethylene insulator which melts at a moderately overheated temperature. When contact between the sensor wire and the heating wire occurs, the control circuit deactivates the blanket. Earlier designs where PVC was the meltable polymer were found not to be reliable. The UK study concluded that the US-type PTC technology is probably significantly safer than the current UK technology.

Published information on fires associated with electric mattress pads (heating devices intended to be placed between the mattress and the bed sheet) is not available, but is sometimes believed that these are more prone to ignitions, since they have less extensive over-temperature protection and are more likely to be doubled over or tucked under by the user. In the US, the same electric heating technology as used for blankets is also used to produce heated 'throws,' 'cuddle-ups,' and heated comforters[560].

Electric circuit interruption devices

Circuit interruption devices are fuses and circuit breakers. Fuses are considered more reliable, since their failure modes are generally 'fail-safe,' while circuit breakers can 'fail-unsafe.' For fuses, unexpected circuit interruption can occur at currents below the rated capacity, if the fuse had been subjected to many overloads that did not quite blow the fuse. This is understood to be due to weakening of the metal fuse element by the excessive heating cycles. The forensic examination of fuses has been described by Twibell and Christie[561]. However, there is one important safety function which is customarily provided by circuit breakers that cannot be provided by fuses: simultaneous opening of all phases. If a fault occurs requiring the opening of a circuit interruption device and more than one phase conductor exists in the circuit, then current made available through the phase conductor which did not blow its fuse may still continue to cause damage. With circuit breakers, the problem is easily solved by mechanical or electrical means for gang-operation.

Expulsion fuses are the simplest form of high-voltage fuse and when they operate hot particles are discharged. Stokes[562] found that the greatest discharge of incandescent particles was when short-circuits currents of 50 – 200 A were used. The particles showed a range of diameters from 0.4 to 1.3 mm under those conditions. Color Plate 62 shows a shower of particles from a test conducted by Stokes. In that test, he placed an 0.7 × 1.0 m tray filled with hardwood twigs and leaves 2 m below the fuse. In 30 trials, there was only 1 ignition of the fuel bed by an ejected copper particle.

In a survey of low-income housing, CPSC found that 31% of circuits protected by circuits were overfused, compared to 12% for circuits protected by circuit breakers[563].

The role of a circuit breaker is a multiple one. If a modest overload is sustained over long periods of time, the circuit breaker must trip. But if a moderately high overload is presented for a short time, it must not trip. This is because electric motors present a very large load when first starting up, and circuit breakers would be constantly tripping if they did not permit such brief overloads. For highly excessive

overloads, however, a circuit breaker should trip nearly instantaneously. Modern circuit breakers are of the combined thermal/magnetic type. The thermal element is slow-acting and is designed to protect against sustained overload. Its action corresponds to the rated capacity of a circuit breaker, which specifies the current level at which tripping should occur for an overload of 'very long' duration. The magnetic portion responds very quickly to high-current faults. But the short-term tripping level is subject to the discretion of the manufacturer and is not marked on the device.

It is considered a good practice to periodically open and close circuit breakers, since it reduces the chance of a breaker being stuck in the closed position. Exercising breakers periodically cleans the contacts and verifies that the mechanism works.

Failure of a circuit breaker to open under electric fault conditions can be due to[564]:

- a defect in either design or manufacturing
- lack of maintenance
- inappropriate settings (on adjustable circuit breakers)
- fault current in excess of interruption rating
- insufficient fault current.

Early molded-case circuit breakers were of 'thermal' action alone. Some of these were subject to a failure mode if encountering a very large overload, under which condition the contacts would sometimes get welded shut, instead of opening. The commercialization of dual-mode (thermal/magnetic) circuit breakers has eliminated this failure mode (there are also some circuit breakers that only have magnetic action, but these are rare). Over the years, there have been a number of product recalls due to defects. Product defects leading to failure have included rusted parts, excessive mechanical friction, and contacts plated with a poorly-chosen metal, leading to excessive fouling in the presence of moisture and SO_2 in polluted air. Residential type circuit breakers connect to the supply bus by plugging on, rather than by being bolted down; there have been a number of failures at the supply-side connection, due to its limited robustness. Aronstein[565] presented laboratory studies showing failures due to other causes, such as improper oiling during manufacture and harsh climatic conditions. Some fires have been attributed to incendiarism, where an individual deliberately misadjusted an adjustable breaker to an excessive setting.

Some test data comparing various devices have been published by Franklin[566]. Franklin claimed that most arcs caused by short-circuiting in 120 VAC circuits range between 200 and 250 A, and that often a fire can get ignited from a short-circuit arc before a US-made circuit breaker will trip. To characterize the performance of a number of different types of circuit protection devices, he conducted tests specifically at 200 and 250 A. Table 55 indicates that the majority of breakers did not provide fast enough response in their supposedly-fast (magnetic trip) mode and that in most cases their instantaneous trip current exceeded the 200 A level characteristic of 120 VAC arcs. Franklin concluded that adequate protection can be obtained if the design of the European '5X' breakers was followed, which limits the instantaneous trip level to 5× the rated current.
Shefchick[567] investigated the realism of using the European

breakers in North American power systems. He concluded that the design of the breakers was such that they can only be used successfully in the 240 VAC systems for which they were designed, and not in 120 VAC applications. This was because the contacts—which need to be more robust in lower-voltage systems—would not have withstood 120 VAC service. Also, the higher European voltage reduces starting currents, and permits use of breakers with lower instantaneous trip currents. If used in North America, nuisance tripping would result. If used to protect a 20 A circuit, a '5X' breaker would instantaneously trip at 100 A. This would cause unacceptable nuisance tripping, according to a study by UL[568]. They tested a vacuum cleaner, a circular saw, and an air compressor. These appliances drew steady-state currents of 7.4 – 11.4 A and, consequently, should properly be usable on 20 A branch circuits. But their inrush currents were measured to be 94 – 124 A, indicating that nuisance tripping would occur if a breaker instantaneously tripped at 100 A. In fact, the appliances would be unusable, since resetting the breaker and re-starting the appliance would repeat the cycle. Furthermore, the trend towards more efficient motors has adversely affected the situation, since efficiency is increased by decreasing the iron content of the motor and this leads to higher inrush currents during startup. UL also studied the consequences of re-powering entire branch circuits, for example, after a power outage. In these cases, inrush currents of 102 – 176 A were found for typical loads of electronics + lamps. The conclusion was that '10X' breakers would be practicable, but '5X' would not.

In testing, circuit breakers are only tested in ambient environment temperature. But the thermal-action portion of the circuit breaker is sensitive to ambient temperature, and the actual opening current will be raised if the breaker is in a cold environment (e.g., outdoors), or lowered if the breaker is in a hot environment (e.g., a panelboard full of other breakers drawing high currents. Thus, in order to avoid nuisance tripping under conditions where the panelboard is running hot, the NEC requires that "The rating of any one cord- and plug-connected utilization equipment shall not exceed 80% of the branch-circuit ampere rating." Branch-circuit circuit breakers are normally rated for an operating temperature range of –5 to +40ºC. Goodson et al.[569] conducted some tests to determine the effect of installation in some low temperature environments. Tests on 15 and 20 A rated breakers conducted at –14ºC and carrying a load 2× the breaker rating showed that trip times were increased, but remained below 120 s. By contrast, a 20 A breaker at –27ºC did not trip while carrying a current 3.1× its rated value.

Table 56 Available short circuit current in residential branch circuits

Available short circuit current (A)	15 A branch circuits	20 A branch circuits
average	300	467
minimum	77	81
maximum	1650	2260

The maximum current that can be delivered into a fault on a branch circuit will depend on the characteristics of the breaker and on the resistance of the wiring in between the breaker and the fault. A UL survey[568] of residential branch circuits gave the results shown in Table 56. These are not necessarily the current values pertinent to operation of a protective device, since if the short in an arcing short rather than a bolted short, the current in the circuit will be less than the available short-circuit current. For further details see: *Electric transmission and distribution systems*.

Circuit breakers have a finite capacity for sustaining over-current without damage—greatly excessive currents may lead to the destruction of the breaker. Reiter[570] conducted tests where the over-current failure of a 4000 A circuit breaker was simulated by presenting it with an internal phase-to-phase bolted short, located on a feed line capable of supplying 13,000 A short-circuit current. The fault current was sustained for approximately 10 cycles and the results are shown in Color Plate 65.

A circuit breaker may trip and clear the original fault, but the process can induce a new fault. Masumura et al.[571] studied this situation. The possibility arises because molded-case circuit breakers have a vent hole through which hot ionized gases are ejected. If these gases impinge across a narrow gap between two external electrodes, breakdown may be induced at that location. In limited experiments on a 110 VAC system using a circuit breaker with a short-circuit rating of 5000 A (rms) they placed the circuit breaker in a circuit having 24.5 kA short-circuit capacity and were able to induce an external fault; the measured arc current for the original circuit was 8.3 kA. Further modeling and testing produced a relation between the conductivity of the gases needed for breakdown, versus the voltage across the external electrodes. Over the range 150 – 350 V, the necessary conductance was 10^{-3} – 10^{-2} S.

Electric fences

Electric fences have been known to start grass fires in dry weather when vegetation contacts the conductor. The incendive ability presumably depends on circuit design details, which will not be identical for all units. Types using controllers described as 'weed clipping' or 'weed burning' are particularly liable to cause ignitions[572].

Electric lamps and lighting fixtures

Lamps* come in two basic types: (a) incandescent, and (b) arc discharge. An incandescent lamp is based on resistance

* The commercial terminology and the lay-person's terminology are confusingly different. The fixture itself is called a luminaire in commercial and engineering usage, but a lamp in lay usage. Meanwhile the lighting device that is inserted into the fixture is called a lamp in commercial/engineering usage, but a light bulb in lay usage. In addition, what is

heating of a tungsten filament. A sub-category which has recently become very popular is the *tungsten-halogen* type, also identified as *quartz-halogen*, or just *halogen*. Sealed lamps based on electric arc discharge are grouped into low-intensity and high-intensity types. Arc discharge lamps are not to be confused with traditional *arc lamps*, such as used in movie projectors. These involve an arc created in open air between two carbon electrodes and are not devices that are enclosed in a glass envelope.

ORDINARY INCANDESCENT LAMPS

Electric lamps, under certain circumstances, are known to be competent ignition sources. The effects of a lamp are two-fold: heating by direct conduction and radiative heating. If a lamp is not directly touching the potential target then, of course, conduction heat transfer will not exist. Convective heat transfer is present in all cases and is essential for cooling the glass envelope, but this only plays a limited role in ignition of combustibles. A number of sources list temperatures measured at various locations on lamps of various sizes. This type of information should only be used for very rough guidance, because the temperatures invariably are measured in free air. But except for very powerful lamps, ignition normally occurs only if a solid comes into direct contact with the lamp. As soon as a solid does come into contact with the glass envelope, however, the heat balance within the lamp changes significantly, since convective and radiative cooling is cut off at the location of the solid body. By simply comparing the tabulated values of lamp-surface temperatures with ignition temperatures of various solids, one would conclude that hardly anything can be ignited by an incandescent lamp—an incorrect conclusion!

Nonetheless, for the sake of completeness, some tabulated lamp-surface temperatures are given. Table 57 shows a large set of temperatures measured by one investigator for a variety of lamps[573]. These temperatures appear to be rather low, since one investigator[574] measured a peak temperature of 247ºC and another investigator[575] measured 263ºC for 100 W lamps. The temperatures at the lampholder are normally lower, for instance ca. 100ºC can be found for a 100 W lamp[576]. A peak temperature of only 89ºC has been reported[575] for 25 W lamps, yet decorative material was ignited in one fire from such a lamp. Even 89ºC is still above the rated temperature of general-purpose wires, so incandescent lighting fixtures often need to use high-temperature fixture wire.

Incandescent lamps are well-known as a cause of fires when placed in contact with towels, bedding, and similar low-density combustibles[522]. Incandescent lamps of a 50 W size or larger have also been known to cause fires when dropped into cellulosic attic insulation. A 75 W lamp has been documented to fully char through a plywood floor assembly[577] (Figure 26). If kindling or wind had been present, a flaming ignition, instead of full-depth charring might have been possible (although this was not demonstrated). Even 6 W night-light lamps have ignited highly insulative Dacron comforters[578], and manufacturers now offer 4 W lamps to reduce this risk.

commonly known as a lamp post is termed a light standard in commercial/engineering usage.

Table 57 Maximum temperatures measured for incandescent lamps in free air

Lamp type	Max. temp. (ºC)	Location of max. temp.
200 W clear	237	top, when lamp on its side
150 W clear	208	top, when lamp upright
100 W frosted	193	top, when lamp upright
75 W frosted	168	top, when lamp on its side
60 W frosted	145	top, when lamp on its side
40 W frosted	121	top, when lamp upright
250 W reflector flood	304	top, when lamp on its side
75 W reflector	213	top, when lamp upright
50 W reflector	196	top, when lamp upright
125 W infrared heat lamp	126	top, when lamp upright

An entirely different situation occurs when the glass envelope of a lamp is missing. Filaments are not designed to withstand the high-temperature oxidation which occurs in air, and a naked filament exposed to air will conduct electricity only for a short time before burning out. Its temperature, however, will be vastly greater than the surface temperature of the glass that is found in normal operation. Thus, arsonists are known[223] to have tried ignition devices where the glass envelope is carefully broken under de-energized conditions, then the lamp is positioned to ignite some flammable item immediately as the power is applied.

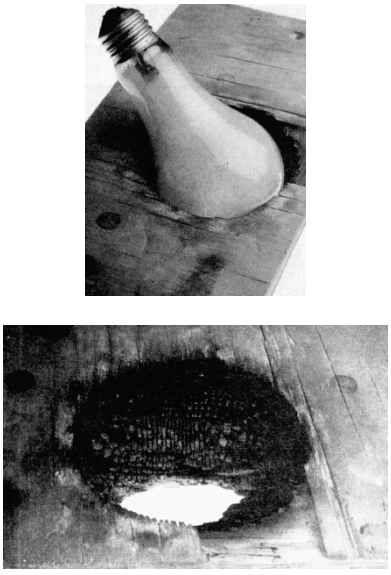

Figure 26 Charring of plywood floor from 75 W incandescent lamp
(Courtesy IAAI Fire & Arson Investigator)

During steady-state operation, the tungsten filament at 1800 – 2300ºC in a miniature incandescent lamp, around 2500ºC in larger lamps, and up to 3000ºC for special-purpose lamps. If the glass envelope is broken, the tungsten filament rapidly oxidizes, rises in temperature, and can actually flame for a short while before burning out[579]. When a filament burns out, an arc is sometimes formed across the gap. In the process of arcing, it will not necessarily be true that most of the original resistance of the filament will be available as a current-limiting series resistor. Thus, the arc can draw a substantial current. For this reason, manufacturers often incorporate a fuse in the wire leads going to the filament. This fuse can open up and arcing is then stopped. Occasionally, failure of lamps takes place in a manner not as anticipated by the manufacturer and the glass envelope shatters explosively. Incandescent debris can be ejected under such circumstances, and this may have a potential to ignite materials it lands upon.

Most incandescent lamps have short, straight filaments between the lead-in wires; however, some lamps, e.g., lamps for night lights and decor, have long, folded filaments which zig-zag between the lead-in wires. The filament folds are kept from touching and shorting out by supports. However, toward the end of life the filament may become weak, sag and stretch allowing the folds to touch. If they weld together, the normal wattage of the lamp may be increased by 50%. Series-connected street-light lamps often fail by arcing since the resistance of the other lamps in the series stabilizes the arc. The molten metal produced by the arcing can break the bulb and fall, igniting any combustible materials below[578].

An early investigation at the Bureau of Mines[580] examined the possibility for incandescent lamps to ignite methane/air mixtures upon the breaking of the glass envelope. They found that the probability of igniting the mixture depended on several factors:

- the way that the glass envelope was breached
- the diameter of the filament wire
- the over-voltage supplied
- lamp type, standard or miniature
- the type of filament used, carbon or tungsten.

Carbon filaments are no longer in common use, so their results are not reviewed here. Smashing the envelope usually broke the filament of standard lamps, but not of miniature lamps. In some cases, ignition was exacerbated because pieces of filament shorted together due to mechanical impact. Filaments were less likely to break in cases where a hole was made in the glass envelope, without shattering it. A higher probability of ignition was associated with filaments that did not quickly break. When an over-voltage was applied, not surprisingly the probability of ignition increased. At any given voltage rating, the probability of ignition increased with the wattage rating of the lamp. The diameter of the filament was seen to be a major factor, much as found in ignition testing with hot wires (Chapter 4). Ignition probability was high for wires of 0.17 mm or higher, and very low for 0.15 mm. The probability of ignition from very small (ca. 1 W) miniature lamps was much lower than from standard lamps. In another BM study[581], tests were conducted solely on miniature lamps used in mining applications. The glass envelopes were broken off the lamp before testing. Lamps rated for 3 – 6 W at 120 V were found to consistently ignite methane/air and coal dust/air mixtures when 120 V was applied. Likewise, a series of lamps rated 0.95 – 1.8 W at 2.38 – 28 V commonly caused ignitions when the design voltage was applied. A few types, however, did not cause ignition when supplied with the rated voltage, although these too led to ignitions if an over-voltage was applied. Lamps rated at 0.74 W or less never caused ignitions when supplied with the rated voltage, although, again, ignitions could be provoked by overload.

Similar systematic studies of lamps in larger wattage sizes intended for general illumination uses are not available. Normal, 75 and 100 W incandescent lamps, when dropped onto a floor and shattered, have been shown to readily ignite a gasoline spill[582]. Spraying water onto a hot bulb generally shatters the glass, but spraying gasoline may not, unless the spray is prolonged. The chances of igniting gasoline vapors are increased with 'rough service' lamps[499], since these have filaments which take longer to burn out when the glass envelope is shattered. Teflon-coated lamps were found not to break from liquid sprays and were quite resistant to impact breakage[582]. It has been found[583] that automotive taillight lamp filaments glow for about 7 s after the glass envelope is shattered, while those of sealed-beam headlights glow for about 5 s. Both of those 'immediately' ignite gasoline vapors.

In dust-laden environments, the insulating effect of a dust layer will cause temperatures of a lamp to rise. Likewise, deposits of dust on a protective globe can cause an increase in temperature; in one set of tests, the increase was measured to range between 22–34ºC for a globe over a 150W lamp averaging 130ºC in clean air[584]. The possibility of a breaking incandescent lamp igniting a dust cloud was tested by Morse[585], who used grain dust of an unspecified type but of small particle diameter (< 74 μm). She found that even a 6 W pilot light was able to cause an explosion, as were all higher wattage sizes tried.

Lamps made with a sub-standard sized insulator between the hot terminal and the ground threads have been known to cause fires[586]. This can occur when the defective (2-way) lamp is inserted into a 3-way socket. An intermittent short can then occur between the secondary hot terminal of the socket and the grounded screw base of the lamp, since the space that should be occupied by an insulator in a 2-way lamp or the secondary contact in a 3-way lamp is encroached upon by the metallic screw base.

Excessive temperatures and possible ignition may result if an infrared heat lamp is used in a lamp socket not designed

for the high base temperatures associated with this type of lamp[587].

Sanderson[588] tested the ability of 250 W infrared heat lamps to ignite various combustibles. When placed at distances of 50 – 130 mm above a wood stud, the lamps were able to create progressive charring within the wood, but a flaming ignition did not occur. A similar situation was also found for straw. But a cotton towel placed 50 mm below the lamp ignited in 3 min, while placed at 130 mm below the lamp it ignited in 4 min with a red lamp and 12 min with a clear lamp.

An incandescent lamp represents a resistive load, but with a non-constant resistance. The resistance is much lower when the filament is cold; as soon as it heats up, the resistance increases and the current drawn decreases. UL has measured the currents drawn by incandescent lamps[589] and determined that the peak inrush current is 10 – 15 times greater than the peak current that is found in steady state, when the lamp has equilibrated thermally. The large spike is present only in the first half-cycle, and by the second half cycle the value is only about twice the steady-state value. The exact value of the inrush current depends on when in the AC cycle the lamp is turned on. A much larger spike is found when a lamp's filament burns out. This was found to be 164 A for a 300 W lamp, and "in excess of 50 A" for a 75 W lamp.

In explosions involving flammable vapors or gases, broken incandescent lamps are sometimes found and it becomes of interest to determine whether the explosion was caused by a breaking lamp, or if the lamp simply broke due to being in an explosion. Allsop et al.[590] conducted experiments and examined the remains under a microscope. Their conclusions were:

- Filament broken when cold: the fracture is sharp-edged and there is no plastic flow of the tungsten. The surface resembles a bright steel wire.
- Filament broken due to natural burnout or due to overvoltage: the tungsten surfaces are bright and unoxidized; bright beads of molten metal are formed.
- Filament burned out due to shattering of glass envelope: a yellow or greenish-yellow deposit of tungsten oxide can be found on the supports of the filament; the metal ends at the filament gap are usually pointed, unless the lamp has been running at under-voltage prior to burnout, in that case there can be a thick deposit of tungsten oxide at the gap; the color of the filament ranges from steel gray (near the gap) to blue or blue-black near the supports, and it is rough-textured; beads of molten glass may adhere to the filament unless the glass was broken first and current only applied subsequently.
- Filament ignited vapors but did not burn out (possibly due to removal of power): the filament is covered by a film of blue-black oxide; if the filament broke subsequently (due to mechanical forces), the fractured ends are sharp-edged.

The condition of lamp filaments is also an important part of aircraft accident investigation, if examination of the filament can help to determine whether the lamp was illuminated or not at the time of impact, a Canadian guide[591] can be useful. The background document[592] to this guide contains much valuable forensic metallography information.

HALOGEN LAMPS

Halogen lamps were invented[593] in 1882, but were not commercialized for a long time, first coming onto the consumer market in the US in 1983. They operate with a tungsten filament, the same as common incandescent lamps. The differences are: (1) a halogen gas fills the envelope; (2) the envelope is made of fused quartz, not soda-lime glass; and (3) much higher surface temperatures can be reached by the lamp. Either iodine or bromine is used, filled to a very small pressure of 0.05 – 1.5 kPa. The filament in a standard incandescent lamp vaporizes a certain amount of tungsten, and the tungsten gets deposited on the glass walls, preventing small lamp sizes from being used. In a tungsten-halogen lamp, the halogen gas interacts with the tungsten vapor and an equilibrium is established which keeps the glass envelope largely free of metal deposit. In place of the argon which, along with nitrogen, is used to fill a standard incandescent lamp, a tungsten-halogen lamp commonly contains krypton or xenon, which reduce the rate of filament evaporation and extend its life. The envelope is usually made of vitreous fused quartz (which can operate at higher temperatures than glass), but sometimes from borosilicate glass or Vycor. Halogen lamps come in two types: (1) Lamps which comprise only a single quartz envelope. These must be used in fixtures with an external shield to prevent excessive UV radiation and minimize the danger of exploding fragments, should the lamp rupture. For many consumer applications, it is also desirable to have an outer wire-mesh shield which minimizes the possibilities of external combustibles contacting a hot surface. (2) Lamps with an inner quartz envelope which is enclosed within a thick glass outer envelope. These have PAR, MR, MB, TB, or BT industry designations and do not need any other shielding.

In a statistical study, CPSC noted 277 accidents during 1992-1997 with halogen lamps[594]. The breakdown was (numbers rounded to nearest percent): 29% fire due to ignition of nearby objects; 19% fire due to exploding lamp; 15% fire due to electrical short; 12% fire due to lamp tip-over; 11% fire, other; 3% exploding lamp, no fire; 4% shock or burn; 8% other.

In lab studies[595], CPSC measured typical equilibrium temperatures of 611ºC for a fixture using a 500 W halogen lamp, 585ºC for one with a 300 W lamp, and 602ºC for one with 250 W lamp. In comparative testing, a 150W incandescent lamp was found to indicate 284ºC, while a 100 W

incandescent lamp gave 224ºC. Industry sources report that some halogen lamps, however, can run at up to 900ºC. CPSC also conducted tests using cheese cloth and terry cloth material placed on top or near the lamp. From this testing, they concluded that if a 300 W lamp is used with a supplemental guard, ignition of most combustible materials which could come in contact with the lamp can be avoided. Lowe et al.[596] measured a temperature of 630ºC on the surface of a 300 W halogen lamp and 421ºC on the tempered-glass shield above the lamp.

A paper gives the results[597] of operating a 300 W halogen-lamp fixture within 229 mm (9 in) of walls and ceiling which were covered with cardboard. The highest temperature reached on the wall was 88ºC, with the ceiling being only 70ºC. No scorching occurred. At least one case has been documented where a halogen lamp placed under a low plywood-paneled ceiling caused a house fire[598]. Subsequent testing suggested that the fixture probably used a 500 W lamp and might have been as close as 0.1 m to the ceiling[599]. A house fire has been claimed to be started from a halogen lamp (300 or 500 W) igniting a fabric valence located 127 mm (5 in) away[600], but this has been legally disputed. Béland[601] reported some experiments where he placed strips of paper on a 300 W halogen torchère lamp. For paper strips placed on a hot lamp, ignition was "in seconds." For a condition where a paper strip was placed on a lamp, then the lamp was turned on, charring started in 2 min. Ignition did not always occur and sometimes the paper just charred. Béland did not specify the exact relation of paper to lamp, i.e., whether a guard was in place.

Halogen lamps may explode and act as ignition source. Ignition of bedding occurred when a halogen lamp exploded and deposited hot glass upon a bed[602]. The same author notes a case where an eyewitness observed a lamp explode as soon as its power was turned on; a fire was avoided in the second case. In another case[596], hot glass fragments from a halogen lamp that exploded ignited a carpet, which was extinguished by the owner.

CPSC's investigation of accidents associated with halogen floor lamps led to a number of changes in the standard (UL 153[603]) under which these devices are generally tested. The main changes were that 500 W lamps were no longer permitted, with 300 W being the largest allowed wattage. Also, a mechanical shield was required which is intended to keep combustible matter from coming too close to the hot lamp.

Holmes[604] reports that some tests have been made on the possibility of 300 W halogen lamps igniting gasoline/air atmospheres without shattering. This was normally not possible, but in one case when a fixture containing a halogen lamp was violently thrown against a concrete floor, an explosion did result. Examination of the lamp indicated that the filament did not have as many filament support wires as other makes of lamps and, consequently, the hot filament could deflect enough to cause a hot spot on the quartz envelope, with the flammable vapor mixture being ignited from that hot spot.

It is reported[605] that some halogen lamps have to be positioned within 5º of horizontal lest they shatter unexpectedly due to a phenomenon of halide migration.

ARC DISCHARGE LAMPS*

Arc discharge lamps are divided into two basic types: low-intensity and high-intensity. Low-intensity discharge lamps include low-pressure sodium and fluorescent types (the latter are discussed separately, below). High-intensity discharge (HID) lamps include mercury vapor, high-pressure sodium, and metal halide types. All discharge lamps require a ballast to start and stabilize the arc discharge. Mercury vapor and metal-halide HID lamps (Figure 27) have a tube made of fused quartz (silicon dioxide glass) that contains the arc discharge. The arc tube for high-pressure sodium HID lamps is made of polycrystalline alumina (aluminum oxide). In all three types of lamps, an outer glass envelope then surrounds the inner arc tube to prevent contamination and, for mercury vapor and metal-halide types, to absorb the intense ultra-violet radiation. The space between the arc tube and the outer glass envelope is filled with a small amount of dry nitrogen to prevent oxidation of the metal supports.

The arc tube operates at around 600 – 800ºC in mercury vapor lamps, 900 – 1100ºC in metal-halide lamps[606], and up to 1200ºC in high-pressure sodium lamps[607]. At operating temperature, the internal pressure in the arc tube can be as high as 7.5 atm and the outer glass envelope temperature[608] can be as high as 400ºC. The arc tube of HID lamps can unexpectedly rupture and shatter the outer glass envelope, resulting in the discharge of hot glass fragments and extremely hot particles of the arc tube. Arc tubes rupture from internal causes (such as manufacturing defects), from external causes (such as ballast failure, lamp misapplication, or injury to the outer glass envelope), and from old age.

(Courtesy Ross F. Firestone)

In addition to their incandescent temperature, the amount of heat in the arc tube fragments is high, equivalent to 10 or 20 matches; thus, even after falling 7 – 9 m through the air they can ignite combustible materials, such as furniture and cardboard. If the lamp is enclosed in a fixture with a thermoplastic lens/diffuser, the arc tube fragments will melt and ignite the plastic causing flaming drops to cascade to the floor. These can ignite hardwood floors such as are used in basketball courts even when they are 9 m below the lamp.

Devitrification is a cause of rupture unique to lamps using fused quartz arc tubes. Fused quartz is a glass and, like all glass, is unstable. Over time it reverts to crystalline quartz from which it is made. This process is called devitrification. Normally this does not occur before the lamp has burned out from other causes, but it can occur in an operating lamp if the arc tube is contaminated with water vapor, sodium or other materials during manufacturing, or by the environment if the outer glass envelope is broken.

Devitrification starts at the surface of the arc tube from the formation of quartz crystals at a region of contamination. The crystals have a lower volume than fused quartz glass so devitrification causes the surface to contract and produces a network of cracks which appear frosty white (Figure 28; a normal arc tube is shown for comparison in Figure 29). The cracks grow along the tube surface and into the wall until the tube is so weakened that it ruptures from internal pressure.

The crystallized region undergoes several sudden volume shrinkages at different temperatures as it cools. If a lamp with a partially devitrified but intact arc tube is turned off, the arc tube will sometimes shatter as it cools, or the devitrified layer may exfoliate, exposing a network of cracks in the fused quartz glass. Devitrification is slow below 810ºC, hence it is more common in metal-halide arc tubes which operate as high as 1100ºC than in mercury vapor arc tubes which operate below 800ºC under normal conditions. The aluminum oxide arc tube used in high-pressure sodium lamps is crystalline and therefore immune to devitrification. In addition, it is 4 to 5 times stronger than a fused quartz arc tube[609].

Arc tubes may bulge and rupture if run under improper conditions due to:

- Incorrect or defective ballasts which operate the lamp at over or under the rated wattage or do not fully start the lamp (Figure 30).
- Fixtures with improperly designed reflectors which redirect energy directly onto the arc tube.
- Improper positioning of the lamp so that a "Base Up" lamp is burned in base-down position, or a vertical lamp is burned horizontally or visa versa.

Arc tube bloating is more common in mercury and metal-halide lamps because fused quartz[609] softens at approximately 1350°C while alumina[610], which is used in high pressure sodium lamps, does not weaken until approximately 1600°C. If the outer glass envelope of an HID lamp is broken, the lamp may continue to operate for weeks or even years. During this time the exposed arc tube produces hazardous ultra-violet radiation and also can be an ignition source for explosive concentrations of dust or gas in air.

Since a failure of an HID lamp can eject material at up to 1200ºC, there is a potential for ignition if a non-

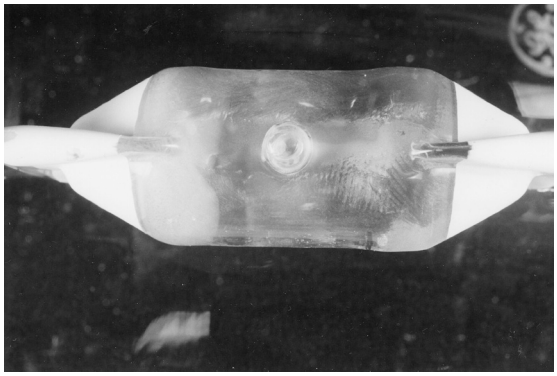

Figure 29 A normal arc tube from a 400 W HID lamp
(Courtesy Ross F. Firestone)

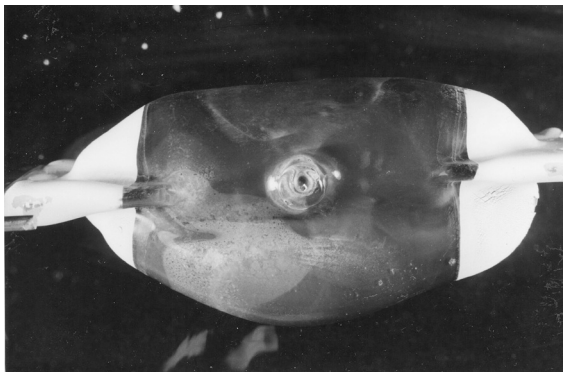

Figure 30 Bloated arc tube from 400 W HID lamp due to ballast failure
(Courtesy Ross F. Firestone)

combustible shield that can capture and retain any broken material is not installed below an HID lamp. There have been 29 losses at premises insured by FM Global during the 1990s due to ignitions from HID lamps[611]. Of these, 14 were metal halide, 12 mercury vapor, and 3 sodium vapor. In the US, the industry recognizes three types of lamps: E, S, and O types. E types must be used with a bottom shield, O types have an integral barrier within the lamp and consequently do not need a barrier, while S types are a low-cost choice which is approved for use in open-bottom fixtures. The electric industry trade association NEMA considers it to be acceptable risk[612] to use S-type lamps, although this is a decision that users must make for themselves. The risk is lower if lamps are systematically replaced after a certain number of hours, before end-of-life failure occurs. In addition, HID lamps may fracture due to overpressure if continuously operated. Manufacturers' recommendations are that the lamps be turned off once a week for at least 15 minutes; if overpressure has occurred, the lamp will not restart. Requirements for HID lamps used to be given in UL 1572; this was superceded in 2000 by UL 1598/CSA 250[613] which is a master standard governing a variety of lamp types.

Because sodium reacts pyrophorically with air and water, it has been shown that breaking a low-pressure sodium lamp not connected to an electric supply can result in the ignition of a methane/air mixture[581]. This is because these lamps contain up 1 g of sodium. However, high-pressure sodium lamps, which only contain about 8 mg sodium were found to be non-incendive.

FLUORESCENT LAMPS

Even though the temperatures developed by fluorescent lamps in normal operation are modest, this is not necessarily true if the lamp is used abusively, e.g., by covering it up with combustibles. A Japanese study documented that 300ºC can be reached from a 27 W compact fluorescent lamp that is covered up by bedding, and this corresponds to a fire that occurred under these circumstances[614]. Verweij[615] conducted tests on fluorescent lamps and classified ignitions of flammable atmospheres into the following categories:

- The glass envelope is broken, exposing the insides and extinguishing the electric discharge between the electrodes. The tungsten wire spiral preheating the electrodes is energized by the starter and begins to glow, rapidly oxidize, and break. When it breaks, an electric spark occurs and this can ignite a flammable atmosphere.
- In some exceedingly-flammable atmospheres (e.g., hydrogen in air), explosion may be caused merely by the residual heat of electrodes. This mechanism cannot ignite natural gas/air atmospheres, however.
- Likewise, only in exceedingly-flammable atmospheres explosion can be initiated by a shock-wave mechanism, due to rapid expansion of gases into the previously-evacuated space. In extreme cases, this can take place in a cold lamp.

LIGHTING FIXTURES: INCANDESCENT

Until the energy crisis of the 1970s, many attics were uninsulated; it was also uncommon to use recessed ceiling lights in residential-type construction. The energy crisis caused many owners to insulate their attics, and they often chose low-cost cellulose insulation. Also, recessed incandescent ceiling fixtures started becoming popular. The early fixtures were just a sheet metal can. Ignitions of combustible ceiling insulation started being reported from these fixtures. To avoid these ignitions, three solutions are possible: (1) box in an air space around the fixture; (2) make a double-walled fixture, possibly with non-combustible insulation in the gap; (3) provide a thermal cutout on the fixture. Solution #1 is labor-intensive, but can be effective. Solutions #2 and #3 have been present in the NEC since 1981 and have been incorporated in UL 1571, where detailed requirements for 'IC' fixtures are given. These are fixtures which have been tested and found to be safe in insulated-ceiling constructions. To also avoid direct ignition of wood members, the NEC requires either that the fixture have a 13 mm clearance from wood members, or that parts of the fixture in contact with the wood not rise above 90ºC. Non-IC-rated fixtures remain on the marketplace, since IC-rated ones are not necessary if combustible insulation is not placed in the ceiling.

Issen[218] reported on a special rig that was built at NIST in the 1970s to examine ignition of cellulose insulation by non-IC fixtures. The test was a simulated attic space where the attic temperature was maintained at 60ºC, representing high summer temperatures. For fixtures installed without protection, there was no cellulose insulation found that could be sufficiently FR-treated in order to not get ignited. Ignition times are not given, but the test time was always less than 7 h.

The hazard of ignition is directly increased if the fixture is 'over-lamped,' that is, operated with a lamp of greater wattage than the rating permits. Extensive testing at the Oak Ridge National Laboratory documented the increases in temperature for various over-lamping conditions[616]. Tests showed that ignition hazards from recessed ceiling fixtures are much lower when reflector lamps are used, rather than ordinary light lamps[617]. This is not surprising, since the reflector minimizes heat transfer upwards, where there is the highest potential for ignition.

While ignition of thermal insulation is the main hazard caused by improper installation of ceiling fixtures, it is also possible to ignite high-density combustibles such as solid wood. CPSC documented a fire[522] where solid wood was ignited from a 100 W lamp used in a fixture rated for 60 W, having the additional installation fault that the occupant had failed to install the heat shield that was a needed part of the light fixture. Cooksey[618] described tests where temperatures

were monitored in and around 150 W non-IC fixtures improperly covered with R-19 attic insulation. A peak temperature of 343ºC was reached at 105 minutes in one test, and wire insulation was found melted off the wires upon examination. In another test, a peak temperature of 482ºC was reached in 90 min, at which point the wood members ignited. Apart from these basic results, test details were not supplied.

A subtle form of hazard was also discovered in connection with non-recessed (i.e., *surface-mounted*) ceiling fixtures. NIST laboratory studies showed that addition of even a minimal thickness of thermal insulation directly above surface-mount fixtures holding two or more, properly sized lamps caused wire temperatures to exceed the 60ºC insulation rating[619]. Excessive wire temperatures can lead to thermal degradation and subsequent failure.

Failures of lamp sockets have been noted which were due to thermal effects destroying a good contact between an aluminum shell and a brass eyelet through which current was fed[710].

Cooper[622] has described an arc tracking failure of a phenolic lampholder. Arc tracking occurred between the pins due to a damp environment. The resistance was measured and indicated an acceptably high value, yet, upon reconnecting to the power source, a loud crack was heard. The lampholder was then studied by connecting it to a high impedance power source (which limits the available current). Under those conditions, it was possible to watch "a glowing thread gradually extend from one pin to the other."

CHRISTMAS TREE LIGHTS

Christmas tree lights are a low-power device, with current products commonly being arranged as two or three strings joined in parallel, with each string containing 50 lights in series. The current drawn by a set of 100 lights is 0.3 – 0.4 A and each light is typically rated at 2.5 V and consumes about 0.4 W. It can be difficult to make miniature lights that are reliable from a fire safety point of view, and the industry has progressively made improvements. Thus, over the years, fused plugs were introduced, the light filament shape changed so to decrease the potential of a drooping filament contacting the glass envelope and creating a hot spot on it, and the contact configuration between the lamp base and the lampholder was improved (greater depth, use of ribs). With the current contact types, errant wires are less likely to make an unintended electrical contact. Despite their low power dissipation, Christmas tree lights continue to start house fires, and, CPSC requested UL to upgrade their standard for this product. Consequently, in 1997 a major revision was made to UL 588 to make it a tougher standard. The tightening up was done 'on general principles' and there was no specific experimental study program. The major changes in the UL standard governing products using push-in type lamps, which are the most popular in the marketplace, are summarized in Table 58. A small fraction of Christmas tree lights can be found in retail stores that are not compliant to UL 588; a much higher probability of ignition may be expected with those. Testing has indicated that the most likely ignition mode is one of a bad series-connection. A fault of this type effectively decreases, rather than increases, the current consumption, so fusing is ineffective against it. Using UL 588-conforming products, tests showed that as little as 1.25 W dissipated in a resistance connection can ignite notebook paper and 2.2 W dissipated in a similar connection can ignite the lampholder itself[623].

Table 58 Flammability-related changes in UL 588 for Christmas tree lights (series-connected, push-in type lamps)

Item	UL 588, 16th ed.[620] (1990)	UL 588, 17th ed.[621] (1997)
plug flammability	V-2	V-0
wire size, min.	24 AWG	22 AWG[b]
cord type	FXT	CXTW
wire insulation thickness, min.	0.51 mm	0.76 mm
wire temperature rating	60ºC	105ºC
wire flammability test		VW-1
wire environmental rating		"W" rating required for outdoor use; must pass sunlight & water resistance testing
lampholder/husk	phenolic or urea	V-1, or phenolic or urea, or meets UL 1694[c]
max. surface temperature	125ºC rise	65ºC rise anywhere; max 90ºC on lamp (absolute, not rise)
fuse[a]	3 A[d]	3 A
mechanical tests		added/upgraded

[a] both sides must be fused in non-polarized plugs; higher ratings allowed for larger wire gages
[b] 20 AWG min. if polarized plug
[c] for lampholders smaller than 2500 mm^3
[d] no fuse required in plug if a special design is used where the first and last lamps act as current-limiting devices.

LIGHTING FIXTURES: FLUORESCENT

A British study[624] provided a breakdown of the causes of fires due to fluorescent lighting fixtures (Table 59). Wiring failures were identified largely to be caused by overheating of the tube socket and resulting breakdown of insulation.

The main component in fluorescent lighting fixtures that has been associated with ignitions, especially of combustible-tile ceilings, is the ballast. A ballast raises the line voltage to a value sufficient to cause a gas discharge in the lamp; ballasts are needed for fluorescent fixtures operating at less than 277 VAC. The main component of a traditional

ballast was an iron-core inductor or transformer, potted in pitch and contained within a sheet-metal housing. The failure mode is normally a shorted turn in the inductor windings, which causes the device to overheat. If no protective measures are in place, ballasts have even directly ignited wood members[625]. The inside of the metal case of a ballast is filled with a pitch-like potting compound. The compound prevents ingress of moisture, reduces noise from the inductive components and acts as a heat sink. Problems arise if a temperature increase causes the potting compound to melt out of the enclosure. If the potting compound melts out, wire insulation often breaks down and the coils overheat. The overheating can cause a break in the wire, and a spark can be emitted as the break occurs. If the melted potting compound created sufficient flammable vapors, a fire can result.

In the US, in 1968 the NEC initially introduced requirements for 'Class P' ballasts. These are thermally-protected, using the requirements of UL 935[626]. The thermal protection is allowed to be of the cycling, self-resetting type. These fixtures are marked with a 'P' to identify the presence of a protective device[634]. Other safety features of fluorescent lighting fixtures apart from the ballast are covered in UL standard 1570[627]. Yarbrough et al.[628] studied temperatures of fluorescent fixtures equipped with Class P ballasts but not specifically designed for use with insulated ceilings. The thermal protection devices kept temperatures below 80ºC in all cases, but in one case ballast potting material was found to liquefy and melt out.

Ignitions occur most readily when the ballast is mounted directly onto the metal fixture housing, which in turn is directly mounted onto a combustible ceiling. Designs which use a spacer to keep the inductor away from the metal fixture housing are less likely to cause ignition of ceilings. An ongoing fire may damage the thermal cutouts of ballasts in the vicinity; thus, care is needed in investigating to determine whether a particular ballast was actually the cause of the fire. The ballast should be opened up and the overheat patterns examined inside. These can make it clear whether the fault was internal or due to external heating. Occasionally, excessive ballast temperatures cause an accumulation of vapors of the molten pitch, with a subsequent explosion[271]. There are alternate means for providing the needed voltage apart from an iron-core inductor. 'Electronic ballasts' have become common in recent years, and these replace much of the bulk of the iron-core inductor with an electronic circuit. Due to the history of ignition of combustible ceilings from ballast malfunctions, the NFPA Handbook[290] carries the warning: "Fixtures containing ballasts should not be mounted in contact with low-density, cellulose fiberboard, unless they are specifically listed by a qualified electrical testing laboratory for mounting in that manner."

Table 59 Causes of fires from fluorescent lighting fixtures

Cause	Percent
ballast	53
wiring	15
tube (overheated or in contact with combustibles)	8
transformer	8
starter	7
fitting, component	7
capacitor	2

Apart from shorts in the windings of the inductor, another way that fires can originate from a fluorescent lighting fixture is a failure of the capacitor, which is used in all but the simplest ballasts. Thermal cutouts are only rarely effective against failing capacitors[223].

An Australian investigation of fires caused by fluorescent lighting fixture starters identified a common failure mode[629]. A starter is a small cylindrical device whose primary active component is a glass bulb containing bimetallic contacts. The glass bulb is filled with a mixture of helium, hydrogen, and argon at low pressure, along with a radioactive material to facilitate ionization. When inactive, the contacts are in the open position. When voltage is first applied to the bimetallic contacts, a glow discharge occurs and the contacts begin getting heated and eventually close. This allows current to flow through the heating elements at the ends of the fluorescent tube and start heating it. A current flow occurs in the tube then and the voltage across its two ends (and across the starter) then drops and the starter's contacts open up. Tiny wire leads are attached to the glass bulb of the starter and initiation of the fires was found to involve a faulty design where wires have an excessively sharp bend (Color Plate 63), leading to failure at the bend. The heating of the wire at the failing spot ignites thermoplastic components of the starter. In turn, molten, burning material from the starter then falls onto a thermoplastic light diffuser, allowing it to ignite. These types of fires are avoided by use of properly manufactured starters where the lead wires do not contain sharp bends.

Another mechanism which has been identified as a potential cause of fluorescent lighting fixture fires is the thermal relaxation of the spring contacts in the lampholders[630]. A laboratory investigation in the aftermath of a fire revealed that, with certain lampholder designs, after sufficient aging and thermal stress, a spring no longer makes contact to the pin of the light. The fixture appears to operate normally, because current is carried by means of an arc over the gap. A glowing connection between the lampholder and the lamp's pin was also observed in some laboratory tests. Under such conditions of a glowing/arcing connection, the urea formaldehyde insulating material comprising the body of the lampholder gradually turned from white to brown to black, and eventually ignited in a smoldering mode. By contrast, virgin urea formaldehyde would not ignite in a

smoldering mode. This failure mechanism is specifically limited to certain models of 'push in' types of lampholders and does not apply to the more common 'twist in' type.

Overheating of the lamp base and lampholder can occur if fluorescent fixtures are improperly wired in converting fixtures from conventional ballasts to instant-start ballasts. The wiring must be such that the current of one lamp does not pass through the second lamp, and NEMA provides detailed instructions[631].

An ignition hazard can exist with certain compact fluorescent lamps that are a direct screw-in replacement for Edison-base incandescent lamps[632]. These come with a built-in electronic ballast in the base. Excessive heating and melting of the base can occur when the lamp reaches its end of life and the electronic circuit repeatedly attempts to unsuccessfully light it.

Electric motors

Motors are one of the few types of electric devices that are likely to fail due to insufficient, as opposed to excessive, voltage being supplied. There are two possibilities: (1) Low voltage. Below a certain voltage, many (but not all) types of motors will stall. If a motor stalls, it can no longer generate the back e.m.f., which is essential to limiting the current flow through it. Consequently, unless a protective device activates, damage and possibly fire[633] may result. (2) Single-phasing. Higher capacity motors are commonly 3-phase devices, dependent on current through 3 phase conductors being available. If one of the phases drops out, the motor may still turn as a single-phase device but overheat.

Failures of motors driven by electronic variable-speed controllers are sometimes found to be due to the overvoltage created by the spiky waveform generated by the controller[867].

Apart from electrical or mechanical faults which lead the motor to ignite itself, a motor may end up as an ignition source to external combustibles, especially dusts. Motors which are not fully-enclosed present a spark ignition hazard in cases where an explosible gas or dust atmosphere may be present. In addition, if used in a dusty atmosphere, a motor whose external surface would otherwise be at a low enough temperature may sustain a sufficient temperature rise to ignite combustible dust. In the same vein, some totally-enclosed, fan-cooled motors contain an outer annulus through which air is moved. In a dusty environment, this annulus may get plugged with dust, causing its ignition. Motors that are not fully enclosed and are used in a dusty atmosphere can get clogged within their operating innards and ignite themselves.

When compressors are of moderate size, the motors used to drive them are almost invariably a sealed unit, integral with the compressor. The experience is that, because they contain thermal protection devices and have a sealed construction, it is extremely unlikely that a fault within the motor would cause an external ignition[634].

Table 60 Failure modes of electric outlets studied by CPSC

Electric outlets, plugs and connections

The ignition problems related to electric outlets (receptacles), electric plugs ('attachment plugs,' in UL's terminology), and various connections are often interrelated, thus they are considered jointly in this section. In the US, electric outlets are generally sold in four quality grades, which are, in descending order:

(1) hospital grade
(2) Federal Specification grade
(3) commercial/"specification" grade
(4) general/residential grade; often does not carry any designation of grade.

In an extensive study[635], CPSC collected 66 outlets with problems actually or potentially leading to fire. The causes of failures are given in Table 60.

In a 1995 Japanese study[636] some 28,112 wiring devices (outlets and plugs) that were located in moist places (kitchens or bathrooms) of residences were surveyed for deterioration and hazardous conditions. Out of the total, 27 devices were found to be damaged, most showing more than one type of damage. The gross damage rate was thus 1×10^{-3}. This rate, of course, is not for failures leading to fires, but only for damaged conditions that indicate a seriously diminished level of safety and could—given a combination of circumstances—eventually lead to fire. The results are

Table 61 Damages found in the 27 devices showing hazardous conditions in a Japanese survey

Damage found	Number of devices
charring around plug blades	17
plug blades discolored due to overheating	17
bent plug blades	11
arcing signs around plug blades	8
charring or melting around openings in receptacles	7
verdigris	6
charring between plug blades	5
discolored prongs of receptacles due to overheating	4
poor connections within screw-assembled plugs	3
poor connections of wires in receptacles	2
oily or dusty	2

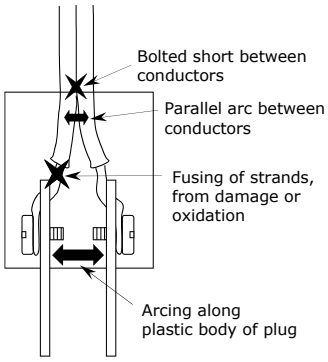

Figure 31 Four common failure locations at electric plugs
(Courtesy Yasuaki Hagimoto, NRIPS)

summarized in Table 61.

A Canadian survey of households[637] conducted in 1982 identified that 52% of the respondents had encountered problems in their households with poor mating contact at wall outlets, i.e., "contacts too loose." Even though the sample size was small (25) the finding was of serious concern, since it implied a lack of sufficiently rigorous standards for outlets and plugs to ensure that plug/outlet connections are sound and do not lead to overheating and possible fires. The study also noted that while higher grades of devices are available in the marketplace, they are difficult to sell, since the wiring device market is highly cost-competitive and consequently the least robust devices that can meet minimum standards predominate.

A NIST investigation[638,639] on the nature of failures of connections concluded that a reliable mechanical connection between two current-carrying metallic contacts is not trivial to make. The only thing preserving a mechanical (i.e., not welded or soldered) connection is spring force in one or more components of the connection. But spring force diminishes due to repeated heating, creep, and resultant stress relaxation. Due to thermal cycling occurring from variations in electric current, the wire connection undergoes a "squirming" micro-motion. The motion causes a buildup of metal oxide, which, in turn, increases the electric resistance of the connection. The probability of failure greatly increases with increasing ambient temperature. If all portions of the connection are not made of the same metal, then additional effects due to differential thermal expansion come into play and can further contribute to cold flow of components.

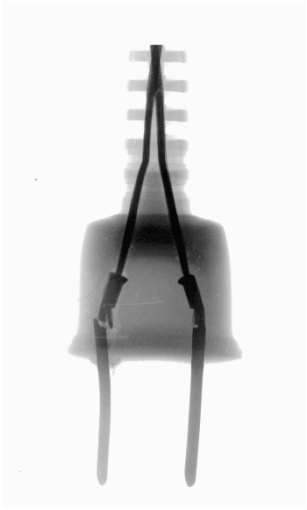

Figure 32 X-ray of molded plug at the end of a vacuum cleaner cord. The blade broke due to repeated stress of pulling on the cord sideways. Fire jetted out from the plug, but was noticed by the user.
(Courtesy T. Hijikata)

FAILURES AT PLUGS

An electric failure of a plug can originate in several ways:

- degradation due to excessive temperatures or excessive electrical loads, including 'hot-plugging' under high load
- mechanical damage
- defect in manufacturing, e.g., improper crimping
- insufficient tightening of screw connection
- poor contact with the mating female part
- contamination leading to arc tracking.

These failure modes have not all received equally extensive study, but sufficient studies (although mostly only in the Japanese literature) now exists so that general failure modes can be understood. Hagimoto et al.[640] consider that there are 4 locations at a male plug where failure is most likely (Figure 31).

Plugs associated with high-current devices are especially likely to sustain degradation which can later lead to a fire. Failure under 'hot-plugging' conditions was studied experimentally by Blades[641]. He repeatedly inserted and removed a plug to which was connected a 1500 W load. Initially, only brief, self-extinguishing arcing could be produced. But after about 10 min of continued insertions and removals, sustained arcing at the plug/outlet interface occurred. The arcing was sustained at that point and accompanied by voluminous emission of pyrolysis products from insulation materials. Inspection of the plug surface showed carbonization of insulation. Color Plate 64 shows a hair dryer plug which was found to be degraded due to normal use.

Mechanical damage is common in plugs, especially if they are removed by yanking or are subject to pounding from furniture, doors, etc. If a cord is yanked sufficiently frequently, wire strands inside may break, leading to overheating and possible failure. An example of the ultimate consequence of such repeated mistreatment is shown in Color Plate 66. Ignition due to failure of a blade from mechanical abuse is shown in Figure 32. Several researchers have conducted laboratory experiments to explore failures due to mechanical damage. Uchida et al.[642] found that the propen-

sity for separation of wires from the plug connection (only plugs with screw-attached wires were tested) depended greatly on the exact details of the cord and plug used. They conducted tests where the cord was repeatedly pulled until failure occurred. For some arrangements, 20,000 pullout cycles were successfully sustained. But when the wire was sloppily terminated in the plug, failures occurred in as few as 2000 cycles (no load) or 4000 cycles (7 A load). In their tests, the connection was not subjected to other stresses that can occur in real life, for example, shoving of objects against the plug, leading to a sharp bend in the wire. Thus, their numbers should be viewed as an upper limit. The failures in Uchida's tests all involved open-circuits rather than ignition.

Shimizu[643] also studied the failure at the cord/plug junction due to mechanical forces. In one series of tests, he bent the cord back and forth over a ±70º angle until strands broke. Using a 1 kg pulling force on the cord, it took 2000 cycles to break all 30 strands of a wire entering a molded plug. Two types of do-it-yourself plugs that attach by screwing together were also examined. For one it took 250 cycles, while for the other 2000 cycles. After the strands were broken, Shimizu conducted ignition tests by connecting an incandescent lamp load of 1000 W to each cord, bending the cord by hand back and forth at about 30 times per minute, and watching for ignition. For tests where PVC plugs and PVC-insulated cords were used, only arcing holes were made in the specimens, without flaming ignition. But for tests using (a) PVC plugs and rubber/cloth insulated cords (such as used for some heaters), and (b) PVC plugs and neoprene-insulated cords, flaming ignitions were recorded, with the duration of flaming being from 3 s to 2 minutes. Typical results are illustrated in Color Plate 68. Target fuels were not present, so ignition of other objects was not observed.

Shimizu then conducted a second series of tests where he abused the plugs by bending until a break was created at either **P** or **Q** (see Figure 33). He then maintained arcing at **P** or **Q** by moving the body of the plug back and forth by hand. Doing this, he documented ignitions accompanied by more extensive flaming in the second series. A typical experiment in this series proceeded as follows: Arcing was observed at the failure point after bending an average of 86 times. After 3 – 8 s, smoke jetted out from the root of the plug prongs and a 15 mm length of flame burst out through a 1 mm-diameter hole in the PVC body near the failure point. The flame height then decreased, but spread across the surface of the plug. After 1 – 7 minutes, the flame extinguished. A small current was still flowing through the carbonized PVC insulation. Some plugs restarted flaming by themselves. Others restarted both arcing and flaming when moved by hand a little. A test from this series (Color Plate 69) illustrates that a wood board was ignited from the burning cord.

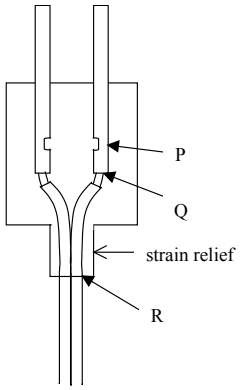

Figure 33 Failure points when electric plugs undergo mechanical stress
(Illustration courtesy Yasuaki Hagimoto)

The PVC-plug/PVC-cord, while evidently harder to ignite than other combinations, does get ignited, as demonstrated in the studies of Katayama et al.[644] They created wire failures at the cord/plug junction (point **R** in Figure 33) by repeatedly bending the plug over a ±60º angle, with a pulling force being created by an 0.5 kg weight attached to the cord (Figure 34). This method is a standard testing procedure described in a Japanese test standard[645]. After all of the wire strands in the wire had been broken in this manner, they conducted electric arcing/ignition tests by applying electrical loads at various power levels and bending the faulted wires by hand at a rate of about 30 cycles/minute. The results are shown in Figure 35. Not only were cord sets with PVC-insulated wires successfully ignited in this series of tests, but the amount of bending that it took to cause ignition was lower than for neoprene-insulated wires. Katayama additionally tested improved cord sets made from FR ethylene-propylene rubber and from FR PVC; none of these ignited in trials lasting 5000 cycles.

Plugs which have screw (as opposed to swaged) connections are susceptible to heating from a loose screw connection. Hagimoto[646] conducted experiments where a screw was loosened by one turn. A current of 10 A was then run for an extended period through the plugs. Temperatures around 200ºC were typically reached within about 1 h, with maximum temperatures ca. 400ºC being recorded. As discussed below, the degradation of PVC is severe once about 200ºC is exceeded. Uchida et al.[642] studied the same problem. Without load, even backing the screw off by a full 360º, they found that there was negligible increase in contact resistance (note that this pertains only to stranded conductors). They then conducted tests where a 12 A load was carried by the connections. Of 3 plug types tested, one led to failure when the screw was loosened by 90º, while a second type required 180º loosening; the third type tested did not fail for loosening up to 180ºC. Failure in all cases consisted of melting of conductors, sparking, and an open circuit being created. Fires were not initiated in the limited testing that was undertaken.

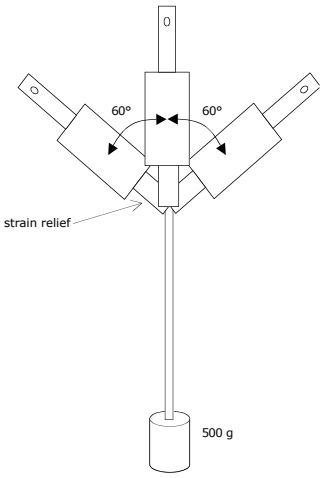

Figure 34 Arrangement used by Katayama et al. to break wires
(Illustration courtesy Yasuaki Hagimoto)

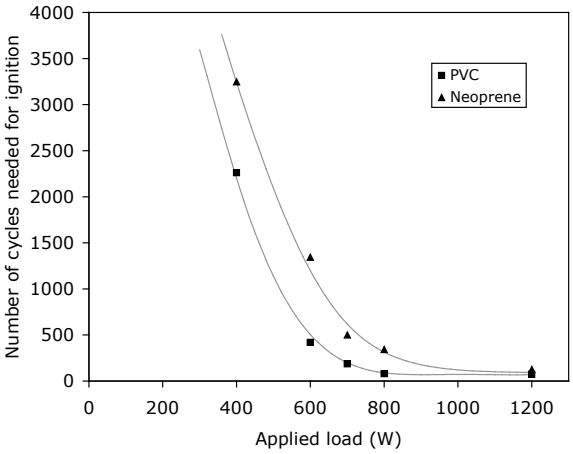

Figure 35 Number of cycles needed to cause ignition at cord/plug junction where all of the wire strands have already been broken by previous bending. Results for molded PVC plugs attached to cords insulated with two different polymers are shown.

Degradation can also be expected if the plug's prongs are not firmly gripped by the outlet; Color Plate 67 shows one such outcome. In running 20 A through molded PVC plugs, Hagimoto[646] found negligible heating if the removal force was 1 N or higher. But for a force of 0.1 – 0.2 N, serious heating was recorded, with temperature reaching 200ºC in the case of 0.1 N removal force. The same tests showed heating was negligible even at 0.1 N, if only 15 A was passed through the plug. As a basis for comparison, Japanese standards require that 10 N be available[647], thus a substantial safety factor should exist under normal conditions. Color Plate 70 shows a molded PVC plug which developed heating due to poor connection between the plug's prong and an outlet; a very similar outcome was found during laboratory testing (Color Plate 71).

Ultimate ignition at plugs is often preceded by arc tracking[648]. The insulation can become carbonized due to contaminants in the environment (electric plugs used near salt-water aquariums are notorious for this failure) or by thermal effects due to poor swaging, poor screw connection, etc. Ashizawa et al.[649] conducted studies to elucidate the details of the thermal degradation mechanism for the case when PVC is the insulation material. They determined that when PVC insulation breaks down due to heating at a poor contact, one of the reaction products is $CaCl_2$, with the calcium portion coming from the calcium carbonate normally used as a filler in PVC. The following sequence of steps was determined as leading to ignition:

(1) overcurrent and poor connection
(2) thermal degradation of PVC
(3) release of HCl gas from PVC (sometimes described as 'dehydrochlorination')
(4) formation of calcium chloride ($CaCl_2$) as a reaction product between PVC and calcium carbonate
(5) attraction of moisture to the highly hygroscopic $CaCl_2$
(6) initiation of surface and internal scintillations
(7) formation of carbonized paths in the PVC, both on the surface and internally
(8) arcing
(9) ignition.

As part of the study, laboratory aging and simulations were done. PVC plugs containing 20% calcium carbonate were oven-aged for several hundred hours. At 120ºC, no chemical activity was detected, but at 165ºC, over 20% mass gain occurred after 100 h of aging. This was moisture absorption due to the hygroscopic nature of calcium carbonate, which will absorb moisture during periods when there is no heating due to current flow. This absorbed moisture is later able to initiate the process of arc tracking. Typical test specimen conditions are shown in Color Plate 72 and Color Plate 73.

The authors next measured the drop in resistance between the blades at elevated temperatures. By 280ºC, the resistance had dropped to 100 kΩ; with further temperature rise, the resistance rose again, because the plastic could no longer sufficiently adhere to the metal contacts. The authors then conducted studies where the blades of the plug and the mating receptacle surfaces were initially degraded by inducing corrosion and oxidation. Using a load of 12 A, the plugs were then run for 1 week under these poor contact conditions, with additional heating applied externally. The results were variable, with the plugs developing temperatures of 250ºC or more in the worst case, and the plug's insulation resistance dropping to 100 kΩ. The plugs were then removed from the load carrying circuit and kept in the laboratory at ambient conditions for about 17 days. During this period, the moisture absorption increased significantly and the insulation resistance dropped to as low as 1 kΩ. For

the highly degraded specimens, the moisture pickup was not just a surface phenomenon, but involved in-depth absorption, including into the void spaces that had formed during thermal degradation. Finally, current (10 A, 100 VAC) was re-applied to the plugs to determine if ignition would occur. Plugs having an insulation resistance of 10 kΩ – 100 kΩ did not ignite, but the most degraded ones (1 kΩ) ignited under load (Color Plate 74), with scintillations preceding overt ignition. The degradation regimen used by the authors was clearly a very strenuous one, but necessary, in view of the probabilistic nature of failure and the impossibility of conducting a huge number of tests. Their reported temperature range for the initial degradation of PVC was very similar to that found by Van Luik[650], who reported that at 143ºC PVC degrades sufficiently to show a detectable mass loss rate.

Other insulation materials are also susceptible to arc tracking, although they have been less extensively studied. Plugs made from urea formaldehyde (UF), which are common as do-it-yourself items, are quite resistant to arc tracking, nonetheless exposure to prolonged heating can also lead to failure (Color Plate 76). Conversely, arc-tracking performance of old-style phenol-formaldehyde (Bakelite) plugs was found by Okamoto et al.[651] to be much worse than for plugs made of PVC or UF. They also conducted ASTM D 3638 Comparative Tracking Index tests on thermally-degraded material. Unaged materials, both PVC and UF, showed CTI > 600. The aging temperature used was 200ºC for PVC and 250ºC for urea. When aged for 1 h, the CTI for PVC dropped to 459 and for UF dropped to 116. When aged for 5 h, the respective values became 113 and 112.

FAILURES AT OUTLETS

The most common way that fire can originate at an electrical wall outlet is due to a poor connection at the screw terminals[652]; failures also occur due to improper grip of the prongs from the male plug. Other failure locations are more rare but can happen due to defects in manufacture. An actively glowing screw connection* is shown in Color Plate 75 in a test conducted by Reiter[570] where a receptacle was used to power a 120 VAC, 1500 W load for about 6 h. The type of damages that are seen from a glowing connection are illustrated in Color Plate 79. When investigating fires, it is important to distinguish between the damage caused to an outlet when one of its screws exhibits a glowing connection from the damage incurred when an outlet is heated externally by fire. Color Plate 77 and Color Plate 78 provide the comparison. It has been observed that most outlets recovered from fires and identified as the point of origin are found to have some missing metal, which implies that arcing may be common[652].

Meese and Beausoleil[653] conducted a series of experiments specifically focusing on glowing at the screw terminals of an AC duplex outlet. Glowing connections readily occurred when the screw was not tightly tightened. Visible glow occurred for currents carrying as little as 0.3 A in a 120 V circuit and also in low-voltage (3 – 4 V) circuits carrying less than 1 A. A poor connection which is glowing can re-establish the glow if the current is cut off and later turned back on. There does not appear to be any time limit for glows; in one experiment Meese and Beausoleil saw a connection glow for 129 h. In a circuit carrying 20 A, a glowing connection would dissipate 20 – 40 W, contrasted with 0.08 – 0.2 W for a good connection at the same current. Meese and Beausoleil also found that steel screws† are much more likely than brass screws to produce a glowing connection. This was attributed to the fact that the electrical conductivity of steel is about 1/10 that of brass, and the thermal conductivity of steel is about half that for brass. The higher conductivities of brass reduce ohmic heating and do not allow heat to be concentrated in one spot. The nature of the screw is crucially important since it was found that, with the devices tested, more than ¾ of the current from the wire flowed through the screw. The back plate carried much less current, since oxide was not being scraped off there in screwing down the connection. In their tests, which only used AC current, they could make copper-copper, copper-aluminum, and aluminum-aluminum contacts glow, but not copper-brass or aluminum-brass. In some additional explorations, they saw that glowing connections could readily scorch or char materials, but did not investigate circumstances leading to flaming fires.

Another NIST study[654] showed that for conventional outlets wired with 14 AWG copper wire, a minimum screw torque of about 0.7 N-m is necessary to achieve minimum heating at the connection; greater torques do not improve the reliability. Color Plate 80 shows an outlet where a fire originated due to a poor connection of an aluminum wire to a terminal screw.

In 1989 CPSC reported on investigations of outlets and the adequacy of the tenth edition of the UL 498 standard[635] then in force. In one series of tests, 25 insertions and removals were made while imparting bending and twisting forces to the mating plug (which may readily occur in usage, but is not simulated in the UL standard). Some outlet models sustained a 100% failure rate in this test. A number of other examples of inadequate design or poor manufacturing tolerances were found. The largest concerns of CPSC were with back-wired designs, and these are discussed below.

Similar findings concerning reliability of duplex outlets made according to the UL 498 standard were obtained by Aronstein in a 1993 study[655]. He documented that after less than 100 insertions of a male plug, some 3.5% of a test

* See Chapter 11 for basic information about glowing connections.

† Screws for electrical connections are often plated on the outside, but can be identified with a magnet.

sample of 200 positions (2 positions per duplex outlet, 100 outlets) effectively failed, by becoming palpably loose. Aronstein concluded that part of the problem was created when manufacturers reduced the thickness of metal in the duplex outlets as a cost-cutting measure. Outlets with this design were often unable to maintain adequate gripping force after a modest number of insertion/removal cycles. Using one model of a 'cost-cutting' 15 A outlet, he ran a 3-year test where a 10 A current flow was intermittently passed through the outlets, cycling no more frequently than 1 h on, ½ h off, with a total duty cycle of 5%. In that test, 4 out of 7 outlets developed failures. Most consisted of visible charring on the front face of the outlet, but in one case even the adjacent wall plate charred, albeit only in a non-flaming mode. In the worst case, the male/female contact became poor enough that the plastic of the male plug entirely melted away, the wire broke at the point of attachment to the male plug's prong, a break-arc was created, and the circuit opened up at that point. Another contributor to the problem has been inadequate tolerances on the thickness of the prongs of male plugs. Aronstein found male prong thicknesses ranging from 0.91 mm to 1.55 mm at the thinnest part, and concluded that the design of the mating female portion (outlet) cannot reliably cope with such variations. Plugs that had non-uniform prong thickness were considered to be the least reliable, because the thicker portion served to distend the mating female part, while presence of the thin portion made the grip poor, once the plug was fully inserted.

In North America, many duplex outlets available today either have a provision for *back-wiring* as an alternate to screw-termination, or are designed solely for back-wiring. A back-wiring design provides holes in the back of the outlet through which a straight, stripped wire can be inserted and held in solely by spring tension, without mechanical hold-down*. The relative safety of back-wiring versus use of screw terminals has been vigorously debated among fire investigators[656]. A limited CPSC-sponsored statistical survey[657] was only able to find a total of 11 overheating, copper-wired outlets in 130 homes surveyed. On this basis, a meaningful failure rate comparison could not be made between copper-wire back-wired and copper-wire screw-terminated outlets. However, two different series of laboratory tests have suggested that there is a distinct difference. Aronstein[655] conducted aging tests which showed that, after 9 years, the contact resistance was about 4× greater for the push-in type than for the screw-connected (copper wiring used for both). This was of concern, since the test program basically involved an idle circuit—current flow was for less than 2 h total, and never exceeded the rated device capacity. Peak temperatures of 98 – 111ºC were measured, in contrast to 27 – 28ºC for devices using screw-connections. The back-wired devices were approved under UL 498, since

* Some devices are available of a 'push-in, screw-tighten' variety, but these are uncommon, since spring-tension-retained arrangements are less costly.

Figure 36 Crack formation at a spring tab of a back-wired outlet
(Courtesy Jesse Aronstein)

they all passed a temperature rise limit of 30ºC during the first 30 days of use. The standard was consequently judged incapable of weeding out designs which deteriorate progressively over longer time periods. Aronstein concluded that back-wired connections are "unsuitable…for use as part of the permanent wiring system in buildings." An electron-microscope photograph of crack formation at a spring tab is shown in Figure 36; upon failure of the spring tab, there would no longer be an applied force to maintain a tight connection to the wire.

A CPSC study[635] subjected 275 back-wired, residential-grade outlets to a test program of approximately 1 year. During this time, cycling tests using 15 and 20 A currents were conducted using a duty cycle that was not particularly strenuous and would represent normal, not extreme, use conditions. Of the total, 10 specimens visibly failed due to arcing and overheating during the course of the tests. In addition, inspection after the test series was finished indicated that 31 other specimens had arced or overheated. Thus, a 15%/year failure rate was effectively observed. The high rate was presumably directly attributable to flimsiness of construction extensively documented for the lower grades of outlets. The CPSC study also noted that some outlet models were so poorly designed that even a single insertion and removal of a back-wired wire will lead to an inability of the outlet to retain any force on a wire inserted again. The CPSC study observed that 'screwless' outlet types (ones having 8 holes for backwiring, but no screw terminals at all), were the least reliable, to the point that some jurisdictions found them unacceptable. The study also documented how one outlet failed by arcing within 24 h, after a wire was inadvertently inserted into a release slot instead of a wire hole (the design of most outlets readily permits this mistake to be made, and presumably a certain fraction of outlet fires arises from this cause). As a consequence of the CPSC study, UL proposed a number of

changes for the 11th edition of UL 498, but there has not been a follow-up study to determine what improvements might have taken place.

An interesting failure of a back-wired outlet was reported by Graps[658]. The origin of a house fire was found to have been at a heating pad placed on a couch. Investigation revealed that the cause of the fire was not a malfunction of the pad. Instead, a daisy-chained outlet (which was of a back-wired-only type, having no provision for screw connections) exhibited a high-resistance connection. The resistance heating eventually caused a short to ground that vaporized the brass contact strip inside the outlet, partially burned the plug that was plugged into the outlet, shot out a jet of incandescent material from the ground pin opening and ignited a heating pad that was sitting on a nearby couch (Color Plate 81 – Color Plate 83). Figure 37 shows a X-ray of the failed outlet.

Despite their evidently inferior performance, back-wired outlets have not been prohibited by CPSC, and are still acceptable to UL. This is presumably because electric outlet failures are rare events and the risk of these failures—at this point—has not yet been deemed unacceptable. Similarly, despite Aronstein's warning, the unreasonable size variation found in male plug prong thicknesses has not been eliminated.

Not to be confused with back-wired outlets are outlets designed on the *insulation-displacement* principle[659-661]. A back-wired outlet requires that the wire be accurately stripped to a correct distance, then pushed into a provided hole. An insulation-displacement outlet does not require that the wire insulation be stripped. The wire is placed in a slot and a hinged cover is closed down upon it. In this process, sharp electrodes pierce the wire insulation and make contact with the conductor. Many commercial devices provide for a feed-through arrangement, so that if the outlet is in the middle of a daisy-chained run, the cable does not need to be chopped at the outlet. Conventional wiring practice for daisy-chained branch circuits can result in a heating connection (and potential ignition) occurring at an outlet to which no load is connected, with current merely being passed through the outlet and a faulty, high-resistance connection within it. But an insulation-displacement outlet cannot fail in this way, since current to the downstream device is passed through a solid copper wire, without any screw connections in series with the current flow. Devices of this type are commonly used in construction of manufactured homes. There are no known studies comparing the failure potential of this type of outlet to screw-terminated or back-wired outlets.

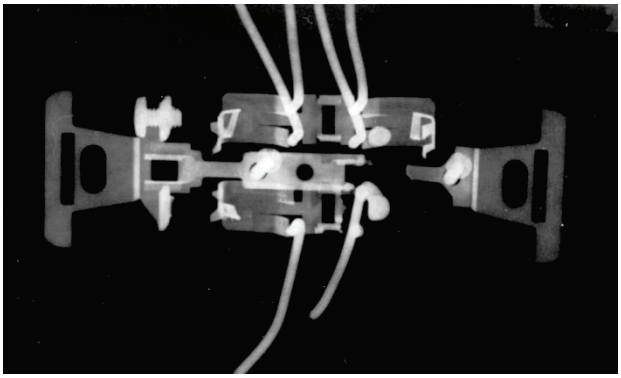

Figure 37 X-ray of failed outlet showing portion of hot-side contact strip that melted out
(Courtesy Al Graps, Electric Forensics, Inc.)

The potential for ignition from electric-outlet faults is discussed in some detail in connection with aluminum wiring, discussed below. Even though less studied, copper-wiring faults could presumably ignite the same combustibles. The propagation of fire from duplex outlets contained on the end of an extension cord was studied by Hagimoto[665]. He found that a long flame can be projected outside the device if an arc fault occurs inside the outlet box (Color Plate 84). Aronstein[662] states that he successfully ignited:

- Low thermal inertia furnishings (bedding, drapes, upholstery) placed directly against the face of an outlet, from a connection dissipating 28 W.
- Thermosetting-plastic receptacle cover plates, from a connection dissipating 30 W (thermoplastic cover plates, however, were prone to melt away rather than to ignite).
- Wood studs, from a connection dissipating 35 – 50 W.

Unfortunately, Aronstein gave few details of his experimental work. He did note that the burning of the thermosetting cover plates was a flameless, glowing combustion, and that a lightweight material (e.g., drapes) would have to be contacting the cover plate for further propagation to take place. In the case of ignitions of studs, again he found that initial ignition was of a glowing or smoldering type, but that this turned into flaming when it broke to the other side of the stud, or, in the case of wood paneling, when it broke through the front face of the paneling. Aronstein also reports that glowing connections were able to ignite:

- male plugs, cords, and small transformers plugged into the outlet,
- vapor barriers inside the wall cavity,

but he did not give details on the conditions needed for these ignitions to occur. He also found that a connection glowing at a 45 – 50 W level was able to melt aluminum wiring, and the globs of molten aluminum could ignite a cardboard box filled with papers.

Note that an electric outlet can be the cause of a fire *even if nothing is plugged into it*. In normal wiring practice, the wiring to outlets is daisy-chained, that is, many outlets are fed from an 'upstream' outlet, rather than directly from the panelboard. Apart from the special case of insulation-displacement outlets (discussed above), for a bad connection to develop at the outlet, it is not necessary that current be drawn by an item plugged into the outlet—current may

simply be drawn by a 'downstream' outlet. Of course, a faulty connection must exist at an outlet, for it to be a cause of fire.

MISCELLANEOUS CONNECTION FAILURES

The contacts of a switch, relay, thermostat, etc. can fail by becoming *welded* together (Color Plate 85) due to a combination of mechanical and electrical factors. But the fact the contacts of some circuit controlling a heat-producing device were found welded after a fire does not mean that this failure occurred prior to the fire, nor that the device started the fire. Béland pointed out that exposing contacts to an ongoing wood fire, without electric current flowing, is often sufficient to weld contacts together[663]. Especially notable was the finding that some bimetallic thermostats, which are designed to open their contacts upon reaching an elevated temperature, can respond in a fire environment by welding of their contacts (Color Plate 86 – Color Plate 88). Similarly, circuit breaker contacts can become welded due to an external fire exposure. Contacts welding due to external fire exposure can generally be identified by serious fire damage to the component, for example, a well-burned circuit breaker case.

Long-term failures of *twist-on connectors* (sometimes referred to by the trademarked term Wire Nuts) with copper wires was studied by Béland[663]. When a connector was poorly applied, without adequate tightening, he found that failures commonly occur due to metal loss, but this always occurred "several inches" away from the connector, not at the connector itself. This was discovered to be a corrosion problem. Overheating of the connector liberates HCl gas from the PVC wire; the gas is corrosive and attacks copper. Over long periods, metal loss occurs to the point that a connection can be completely severed.

Mechanical *vibration* can lead to failure of connections. CPSC has documented a case where the air bubbler of a spa caused a connection failure in a receptacle in an adjoining wall[522]. Some brass compositions, especially those containing over 15% zinc (by mass), are susceptible to *dezincification* when subjected to corrosive environments. If this occurs, the metal loses its strength and will not be able to function as an effective contact.

A significant fraction of fires originating in electrical appliances such as dishwashers and clothes washers was found to originate at internal wiring connections of the *quick-connect* (also called *push-on* or *push-in*) type[472]. These were either insecurely assembled originally or worked loose, resulting in a poor connection (Color Plate 89).

An investigation of a fire in Japan[664] documented the fire origin to be due to a glowing connection. Because of limited damage at the origin area, it was possible to use X-ray diffraction analysis on the components retrieved; this showed that the red-and-glassy material recovered was Cu_2O. Electrical analysis of the connection showed a negative temperature characteristic, which is typical of Cu_2O, but not of pure copper. Hagimoto[665] reports one unpublished experiment where a glowing connection was made in a knife switch. The switch was housed in a molded plastic case and attached to a wood board. After about 5 h of carrying 10 A, the wood had partly carbonized and a piece of plastic from the case melted, dropped onto the hot conductor, and ignited. This, in turn, caused the wood board to ignite.

THE ALUMINUM WIRING PROBLEM

Aluminum branch-circuit wiring, used by some contractors since 1964, increased in usage as a cost-saving measure due to the 1966-7 copper shortage. Many US houses and mobile homes were wired with aluminum wiring until about 1972, when sufficient problems were found with this wiring method for it to drop out of use. Connections where any kind of metallic conductor is connected to another conductor can be subject to failure. However, the problems associated with small-gauge aluminum wire have been sufficiently severe that numerous studies have been devoted to it. The problem was generally confined to AWG 10 and smaller connections, with large-size conductors—such as used for service-entrance wiring—not showing major problems. A 1977 CPSC survey[666] determined that—at that time—there was a very serious problem of overheating in aluminum wired receptacles (Table 62). The survey also found evidence of burning at outlets that had been replaced (due to some kind of fault) in 14% of the aluminum-wired houses, but in only 1% of the copper-wired houses. A laboratory study[653] showed that in 10,000 h, some 24% of screw connections with aluminum wire had failed, as contrasted to zero for copper and zero for copper-clad aluminum wire.

Color Plate 90 shows an incipient failure at an aluminum-wired duplex outlet. Color Plate 91 shows a gross failure, but note the cover plate of the same outlet (Color Plate 96)—almost no external signs are visible of the serious problem inside the electrical box. Color Plate 93 shows charring of wire insulation where one insulated conductor was touching another, but the insulation melted back from

Table 62 Measured temperatures found at outlets in survey houses when drawing a load equal to 75% of the rated circuit load

Connections	Percent of outlets	
	Over 75ºC	Over 100ºC
copper, screw-terminated	0	0
copper, back-wired	2.3	0.2
aluminum, screw-terminated	5.3	2.2
aluminum, back-wired	*	*

* - This combination was not permitted by NEC, but was found in 3.2% of surveyed houses; these outlets were not tested for overheating.

one insulator and has nearly charred through the insulation of the second.

In 1966 UL started to recognize wiring devices for use with aluminum wire and developed the "AL-CU" designation for connections deemed to be suitable[667]. Just as changing metal prices made aluminum wires attractive, rising prices for brass led to widespread shift in the mid-1960s to use of zinc-plated steel as connection screws. Unfortunately, the combination of aluminum wires and steel screws proved exceptionally prone to bad connections and ensuing fires. Because part of the problem was due to creep of aluminum wire, UL mandated that starting in May 1971 the exceedingly creep-prone EC-H19 aluminum alloy be no longer used for making wires; the UL procedures were further tightened in September 1972. The importance of this was confirmed in an NBS study on duplex outlets wired with aluminum wire[668] where a cyclic condition of moderate overload current was designed as a form of accelerated aging test. The duplex outlets were the older technology, prior to introduction of "CO/ALR" (copper/aluminum revised) devices. It was found that with wire made from the alloy EC-H19, failure occurred on the average in 18 cycles; the newer, more creep-resistant aluminum alloy required an average of 42 cycles for failure. Continuing problems with connecting aluminum branch-circuit wire to outlets and switches led UL to develop in 1972 the "CO/ALR" designation for wiring devices, which were designed for an improved connection to aluminum wire, and could also be used safely for copper wires. These devices were specified in UL 1567[669] and had a base plate with improved gripping capabilities, brass instead of steel screws, and indium plating. CPSC, however, concluded that there was little chance that a householder could correctly install these devices so that they would perform as intended[670]. Bunten et al.[667] published a history of aluminum wiring developments up to 1974 which provides many more details on problems and solutions.

While a reasonable conductor of electricity in the bulk, aluminum is a notoriously poor material for making reliable electrical contacts. This is due to a combination of several factors[671]:

(1) Upon exposure to oxygen, aluminum forms a tough layer of oxide which, unlike copper, does not readily pass an electric current by means of 'electron tunneling.' Conduction between an aluminum wire and a mating metallic surface occurs only at a sparse number of places where the oxide fractures. This weak connection is also susceptible to failure by electromigration[672].
(2) Aluminum is prone to creep and stress relaxation, which means that, with the passage of time and especially with an increase in temperature, connections which were initially tight become loose[673]. Not all alloys and grades of aluminum, however, are equally prone, and the grade EC-H19 used prior to 1972 was an exceptionally poor choice.
(3) Aluminum has a high coefficient of thermal expansion, which exacerbates the effect of creep, since screws were not used having a matching coefficient of thermal expansion.
(4) Because of the large heat of formation of aluminum oxide, when aluminum oxidizes, much more heat is liberated than when copper oxidizes. This heat becomes available towards accelerating the failure of a connection.

In addition, making connections at screw terminals with aluminum wire was more prone to failure than with copper wire since:

(a) The aluminum alloy used in making building wires prior to 1972 had an inappropriately high yield stress and resisted shaping itself to the mating surface so as to make a large contact area.
(b) A larger wire size needs to be used for the same current-carrying capacity with aluminum than with copper; combined with the previous factor, this meant that a much stiffer wire has to be looped and tightened than in the case of copper wire.
(c) Prior to the introduction of the serrated screw-connection baseplate design, there was no good means of breaking the surface oxide film in making a connection, since a 'wiping' action is hard to execute.
(d) The propensity for overheating of aluminum-wire connections can bring in a corrosion problem: If, as is most common, the building wire insulation is PVC, heating of the PVC will liberate HCl in the early stages of its decomposition. This is a corrosive gas which can then attack the connection and accelerate its worsening.
(e) Even without elevated temperatures, aluminum is prone to galvanic corrosion in high humidity locations, due to its highly-anodic ranking in the galvanic series. Aluminum wire connected to steel or brass screws or terminals, which was common before the recognition of the problem, is a particularly infelicitous combination.

The first experimental study of aluminum wire connectors was conducted by UL in 1954, but the report did not provide details of the connectors examined[780]. Later, Aronstein and Campbell studied the failures of twist-on connectors[674]. The connectors in their test series all had zinc- or tin-plated steel springs. Unlike several other studies, in this work the current rating of the conductor was *not* exceeded. A current of 13.5 A was run through wires rated at 15.0 A. The voltage drop across the connection was measured, and it was found that connections were stable if the drop was less than 0.04 V. If this drop was exceeded, the connection was found to start behaving erratically, and progressively developing ever higher drops with time. Overheating to the point of charred wire insulation occurred in numerous cases; actual ignition potential was not tested, since the splices were situated in open air, away from other combustibles. No failures during a 12 month testing period were found with cop-

per wires. For EC-H19 aluminum wires, failures predominated when the connectors were zinc-plated; failures were fewer, but not nil, for tin-plated connectors. Some shorter-term tests with the newer alloy wires showed improvements, but not full success. Improvements were also noted when using a larger-size wire connector. In a follow-on study[675], 'special-service' connectors were examined; these use a copper alloy, instead of steel, spring. The results indicated that this metallurgical improvement did not translate to connections which were reliable. The authors concluded that providing a copper cladding or plating may be the only means of achieving reliable field connections for building branch-circuit wiring with aluminum wires.

The effect of torque on the service life of an electrical connection was examined by Hicks[676]. The test program consisted of cycling the connections using a 3.5 h on/0.5 h off program using a modest over-current of 27.5 A. Twist-on connector pigtails using 14 AWG copper wire and 12 AWG aluminum wire were tested, as well as screw connections on a duplex outlet. The results are shown in Figure 38. The straight lines plotted have a slope of approximately 3, thus it was concluded that

$$\text{service life} \propto (\text{torque})^3$$

Apart from the service life issue, using both copper and aluminum wires, Hicks also examined the torque needed on a duplex outlet's screw connection in order to produce a low-resistance connection. With increasing torque, the resistance dropped greatly until about 0.4 N-m were reached. Further increase in torque caused little improvement in the connection, with thread stripping occurring at 1.7 – 2.1 N-m. The recommendation was to tighten screws to 1.0 – 1.6 N-m. For twist-on connectors, a good connection required > 0.2 N-m torque, with the recommended torque being 0.4 – 0.7 N-m. The completed connection must show twisting of wire in the portion not concealed by the connector for this torque to be achieved.

A similar study was conducted by Aronstein[677] using the worst-case combination of 12 AWG pre-1972 aluminum wire and outlets with steel screws. Running 12 A in a 1 h on/1 h off cycle he obtained overheating (as evidenced by charring of plastic parts) for connections that had been torqued to 0.45 N-m or less. At 0.45 N-m, 2 out of 40 connections overheated; at 0.23 N-m, 10 out of 40; and at 0.11 N-m, 22 out of 40. At a torque of 0.90 N-m, he observed no failures. By contrast, when using copper wire, there were no charred connections even at the lowest torque of 0.06 N-m.

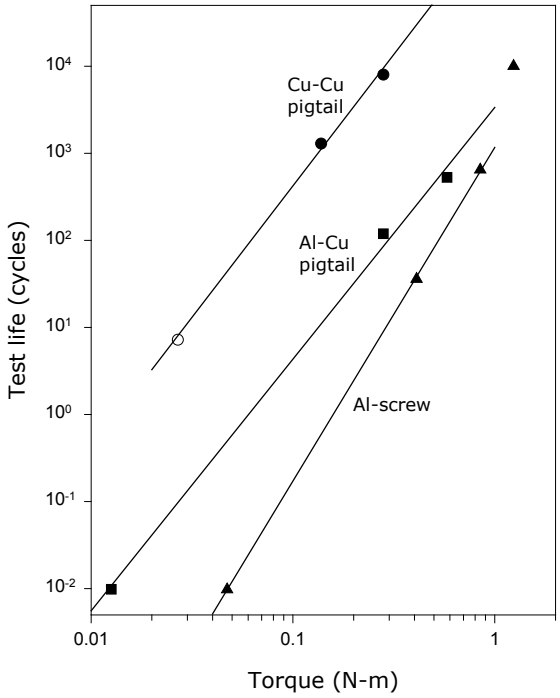

Figure 38 Effect of tightening torque on connector life (1 cycle: 3.5 h on/0.5 h off)

Prior to Hicks' study (see above), a common recommendation was to torque screws to 1.36 N-m (12 lb-in). This would seem to imply that a properly-torqued terminal will not fail. But Aronstein provided some further results which indicate that even if a screw is torqued down to 1.36 N-m, the subsequent manipulation of wires necessary to fit the outlet to the box generally results in an alarming loosening of pre-1972 aluminum wire and in occasional loosening of post-1972 wire. Aronstein also measured the temperatures at various locations. For an aluminum-wire connection dissipating 42 W, he found a peak temperature of 540ºC on the screw. Values in the vicinity of 200ºC were measured on the box and on the faceplate screw. When dissipating only 22 W, temperatures on the wire at 25 mm away from the terminal were also around 200ºC. He also found that a 12 AWG aluminum wire melted when poor-connection heating was increased to 50 W.

The effect of screw plating material was examined by Mastoris[678]. His results are summarized in Table 65. It is evident that zinc and nickel are unsuitable materials.

Table 63 Results from Ontario Hydro testing of duplex outlets with poor connections

Wall paneling	Insulation	Covering over outlet plate	Wiring method	Results
wood	cellulose	cotton blanket	screw	scorching only
wood	cellulose	cotton blanket	back-wired	wood paneling and cellulose insulation ignited after 4 cycles
wood	cellulose	cotton blanket	back-wired	fuse blew in 4th cycle; paneling and insulation ignited after current flow had ceased
gypsum wallboard	fiber glass	cotton drapery	back-wired	no ignitions after 42 cycles; plastic outlet parts charred

Table 64 Laboratory testing results on faulty duplex outlets

Power dissipated in connection (W)	Results
4 – 10	Arcing heard.
4	Newspaper over face; 425ºC measured at faceplate screw; slight charring only.
0.5 – 35	Charred bedspread
4 – 35	Face covered w. cotton bedspread; measured 450ºC at faceplate screw.
23	Measured 475ºC at faceplate screw.
34 – 57	Wire melted; wallpaper glowed and charred.
23 – 46	Insulation melted, wires shorted, melted, caused open circuit; towel against face charred.
4 – 9	Shorted wire due to melted insulation.
14 – 20	Flaming ignition of cotton towel against face.
12 – 46	Bedspread against face first smoldered then flamed; temperature at faceplate screw > 540ºC.
28 – 32	Bedspread ignited; 340ºC on faceplate screw.
29	Used 20 A current; ignition of wood members in 1 h.

Campbell and Ling[679] conducted glowing connection tests in aluminum-wired duplex outlets on behalf of CPSC and also developed a model for estimating the temperatures. Aluminum wires melted out when creating a connection that dissipated 40 W. Using lower dissipations of 20 – 27 W they successfully modeled the peak temperatures with a finite-element analysis computer code. Aronstein[680] conducted laboratory tests on duplex outlets provided by CPSC which had been removed from service as being 'failing' specimens. Connections were made by welding new wires onto the cut-off wire remnants. The current/time regimen was different for the various samples and typically comprised cycling up to the 12 – 15 A range. Some of his example data are summarized in Table 64.

Table 65 Effect of screw plating material on failures during a 2500 cycle test; values given are [failures/tests]

Screw plating material	Conductor	
	EC-grade aluminum	Copper
zinc	34/54	2/10
nickel	6/15	0/3
tin	0/30	0/4
silver	0/6	--

Ontario Hydro[681] conducted a series of tests using duplex outlets wired with aluminum wire and previously exposed to a modest overload of 27 A. The alloy composition of the wire and details of the outlet were not specified. In the test program, the outlets were cycled using a 15 A load applied for 3.5 h, then off for 0.5 h. A mockup up stud space was built, including thermal insulation inside the cavity and combustibles placed at the face. No male plug was used, the current being drawn by a daisy-chain connection. The results are summarized in Table 63. These results clearly indicate that back-wired connections are less robust than screw connections for aluminum wiring.

Currently, the National Electrical Code does not forbid the use of small-gauge aluminum wires for branch-circuit wiring, but many jurisdictions have local laws in force that preclude their usage and their use in new construction in the US is minimal. CPSC has issued a booklet[682] giving advice to homeowners whose residences have aluminum wiring. They recommend that the best solution is rewiring the building with copper wiring. Next best is crimping on copper splice wires using COPALUM connectors made by AMP/Tyco Electronics Corp.; these require a special tool and special training, so they can only be installed by electricians. CPSC does not consider pigtailing with copper splice wires using twist-on connectors (Color Plate 94), nor replacing switches and outlets with the CO/ALR variety acceptable, irrespective of whether they are approved by a testing laboratory. A solution that had been proposed and that met UL criteria, but was not accepted by CPSC, was a special wing nut filled with a corrosion-inhibitor compound. In laboratory testing[683], Aronstein concluded that the design was unlikely to be sufficiently robust. This was borne out in a follow-on field study[684], where he found that the connectors failed even during the first year after installation, with the failed units showing melting and charring that closely resembled the laboratory test failures.

Aluminum wire is very commonly used for high voltage wiring by electric utilities and for the service entrance cables that bring in the power to the distribution panel. Because of the large wire sizes involved, and since better connection mechanisms have always been available for service entrance cables, these connections have not been identified as a special fire problem. Nonetheless, a CPSC study on electric distribution system faults[522] did find some fires due to deteriorated connections to aluminum service entrance wiring at the distribution panel. A NIST investigation identified that twist-on connectors between AWG 8 stranded aluminum wires and AWG 12 or 14 solid wires were also prone to failure[685].

INCENDIARISM

Electric outlets, being a source of energy, are sometimes exploited by arsonists. Flocken and Bates[686] described a fire set by inserting two graphite pencil 'leads' into an electric outlet, then bridging across them with a third lead. The re-

sistance of the graphite was sufficient to cause heating, without drawing enough current to operate the circuit breaker.

Electric switches

Hagimoto et al.[687] investigated the ability of power switches used on domestic appliances to ignite flammable gas mixtures. They found that mixtures were readily ignited with the spark upon opening the switch. They were also able to find ignitions occurring during the closing of switches, but only when the switches were carrying approximately their maximum rated current. They also concluded that for the same spark energy, it was easier to ignite mixtures by opening the circuit to an inductive load than to a resistive one.

Electric transmission and distribution systems

In this section, large-current components are considered. Branch-circuit wiring and end-use device wiring are considered under *Electric wires and cables*.

TRANSFORMERS

Transformers in power systems can be cooled by a liquid (generally an oil), by air, or by another gas (e.g., sulfur hexafluoride); or, they may be potted in a resin, typically epoxy. Liquid cooling is required at higher voltages and capacities; air-cooled transformers are primarily found inside user facilities. Significant fire and explosion hazards are only associated with oil-filled transformers, since dry types have only a limited amount of combustible insulation material. Transformer fires or explosions can lead to major structure fires, apart from destroying the electrical equipment; as an example, a large warehouse was destroyed due to a transformer fire[688]. The nomenclature used for electric transformers by power utilities is confusing, since *distribution transformers* sensibly denotes transformers used in distributing energy to users, but *power transformers* is used as the term to refer to high-capacity network transformers that are employed in the power network prior to reaching the customer-distribution points. Distribution transformer ratings are commonly 50 to 2000 kVA, with 5 to 36 kV primary voltage. It must also be noted that power companies refer to the primary distribution voltage as *medium voltage* and the secondary (120 to 600 V) as *low voltage*.

Distribution transformers are generally highly reliable and failures are rare. Statistics vary widely among countries, but a probability of 0.1% for failure, per transformer, per year, is common[698]. Statistics are not available to indicate what fraction of failures result in fires or explosions. Cooper[622] examined a number of case histories and concluded that the following circumstances most commonly led to transformer fires or explosions:

- Failure of tap-changing mechanism; this is commonly caused by contacts that have become poorly conducting due to foreign deposits or carbonized oil deposits[689]
- Electric flashover above oil level (between leads, terminals, and ground), commonly due to overvoltage or internal arcing
- Inter-turn insulation failure
- Lead-in bushing failure (from lightning, overvoltage, or mechanical damage)
- Lightning damage
- Open-circuit arcing (loose connections, fractured conductors)
- Ignition of vapor above the oil level
- Puncturing of cooling tubes by ground leakage current
- Overloading.

In rural areas, damage due to snakes and birds is also a significant cause[693]. An insurance company survey[690] indicated that the top causes of transformer failures in 1998 were:

- Line surges, external short circuit
- Deterioration of insulation
- Lightning surges
- Inadequate maintenance
- Moisture
- Poor manufacturing workmanship
- Loose connections
- Overloading.

Sabotage or malicious mischief, which in the US were among the top causes in the 1970s and 1980s, became insignificant in the 1990s. These causes are still important in some other countries, however. In India it has been reported[691] that theft of transformer oil is one cause of transformer failures.

Figure 39 Experimental explosion in oil-filled pole-mount type transformer; 10 kA available fault current with a 25 mm arc
(© IEEE 1975)

Common faults that can lead to a transformer fire or explosion include[692,698]:

- Failure of inter-turn insulation in the main windings
  - relative movement between turns (due to faulty spacers, inadequate tightening of clamps, or overheating)
  - overheating due to overload or overvoltage (overvoltage on the primary side can lead to excessive primary current even in the absence of a secondary load)
  - overheating due to obstruction in oil circulation
  - overheating due to sludge accumulation
  - mechanical damage during manufacture (e.g., sharp edges on conductor)
  - local overheating due to proximity of steel and eddy currents due to stray magnetic flux
  - inadequate balancing and excessive heating of paralleled conductors
  - moisture penetration between turns
  - tracking across wood cleats
- Insulation failure between winding and transformer tank
  - aging or deterioration of insulation
  - moisture entry into oil
  - insufficient clearance between flexible lead and tank
  - tracking across wood cleats
- Failures of magnetic circuit, leading to excessive eddy currents in the core
  - shorting out of insulation one bolts holding together laminations
  - burrs on laminations, allowing their short-circuiting
  - metallic filings trapped between laminations
- External causes
  - steep-fronted surge voltages
  - external short circuit on the secondary side
  - heavy overload
  - rapidly fluctuating load
  - switching out of unloaded transformers (due to high induced voltages from inductive effect)
- Miscellaneous faults
  - failure at connections or bushings
  - loosening of laminations due to fault in clamping bolts (e.g., inadequate torquing)
  - inadequate spring tension on tap-changer contact springs
  - inadequate design, or a design unsuited to the service for which the transformer was installed.

Tracking across laminated wood cleats is often due a defect whereby a small air gap exists between laminations. Paper insulation is susceptible to mechanical damage and to thermal degradation. In addition, it releases moisture throughout its life, with chemical degradation being responsible for part of it, not just free moisture. Excessive arcing in oil-filled transformers causes bits of copper in the form of tiny balls to be formed from arced conductors. These balls then flow with the oil and can be deposited in places where further damage can result[693]. On rare occasions, catastrophic failure and explosion may be initiated by arcing of an internal fusible link, if the latter blows out of its housing, which can occur if the available fault current is greater than the interrupting capacity of the link[695].

More specialized causes of transformer failure include ferroresonance and geomagnetically-induced currents. Ferroresonance is a specialized form of fault which can be elicited by certain circuit configurations when the transformer is unloaded. Geomagnetically-induced currents are due to geomagnetic storms and cause a stray flux impingement which can develop a local hot spot, leading to breakdown[694].

Most transformer faults do not lead to an explosion, since the failure mechanism is progressive[695]. The initial fault commonly involves only a few turns of the winding and the fault energy is limited by the impedance of the undamaged portion of the winding. The fault may either cease to propagate or the current may increase until a protective device operates. A high energy fault is less common and it happens if there is a major insulation failure of a direct internal short to ground. Estimates of the arc energy that must be delivered to cause a catastrophic transformer failure vary from 30 kJ within one cycle, to 100 – 200 kJ of arc energy within a half-cycle. It is rare for a rupture to require more than 4.5 cycles. Oil-filled transformer failures, including explosions, are more likely in older units that do not have nitrogen blanketing (Figure 39[696]).

If an arcing fault occurs within the transformer, ejection of oil aerosol can occur, possibly accompanied by a physical explosion of the transformer housing. If the oil is ignitable, a serious fire or a vapor/mist explosion can happen. When an arc occurs in an ignitable oil, hydrogen and acetylene are the main gases produced; by contrast, breakdown of oil due to excessive conductor temperatures yields mostly ethane, ethylene, and methane, with smaller amounts of hydro-

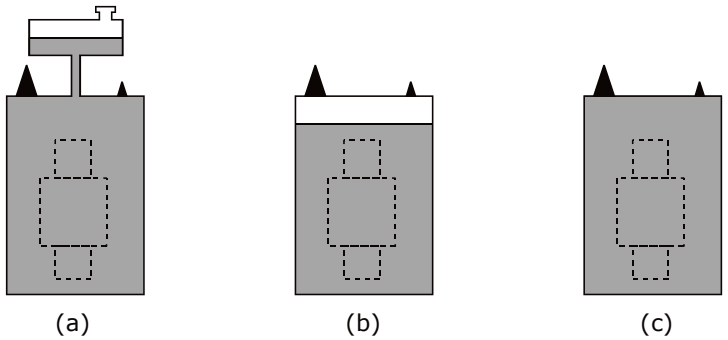

Figure 40 Three main types of liquid-filled distribution transformers: (**a**) open system with conservator; (**b**) hermetically sealed, with inert-gas blanketing; (**c**) hermetically-sealed system, with variable-volume tank and no gas cushion (after Rønningen)

gen[698]. A typical sequence of steps leading up to a transformer explosion is[697]:

- a heavy overload carbonizes the oil sufficiently to cause a fairly high leakage current
- the leakage current further degrades the insulation and eventually leads to a turn-to-turn or layer-to-layer fault
- the fault becomes large enough to cause the primary fused cutout to operate
- upon re-fusing and re-closing the cutout, the transformer insulation fully breaks down ('flashes over'), drawing a very large arc fault current
- the energy released from the arc gasifies the transformer oil, primarily into hydrogen and methane
- rapid pressure buildup from the gasification causes the transformer cover to be blown off
- the combustible escaping gases ignite either due to remaining arc energy or due to sparking associated with rapid metal breakage.

The flow chart developed by Rønningen[698] (Figure 41) is also useful. Pressure-relief devices are generally effective only for slow-rising overpressure events, thus they do not prevent serious explosions. A transformer explosion can almost be assured to happen if maintenance of oil is neglected. Oil degrades over time due to heat, moisture, arcing from on-line tap changing, and partial discharges. The Bureau of Reclamation makes available a short guide to transformer maintenance[699], while Myers[700] published an exceptionally extensive handbook on the subject.

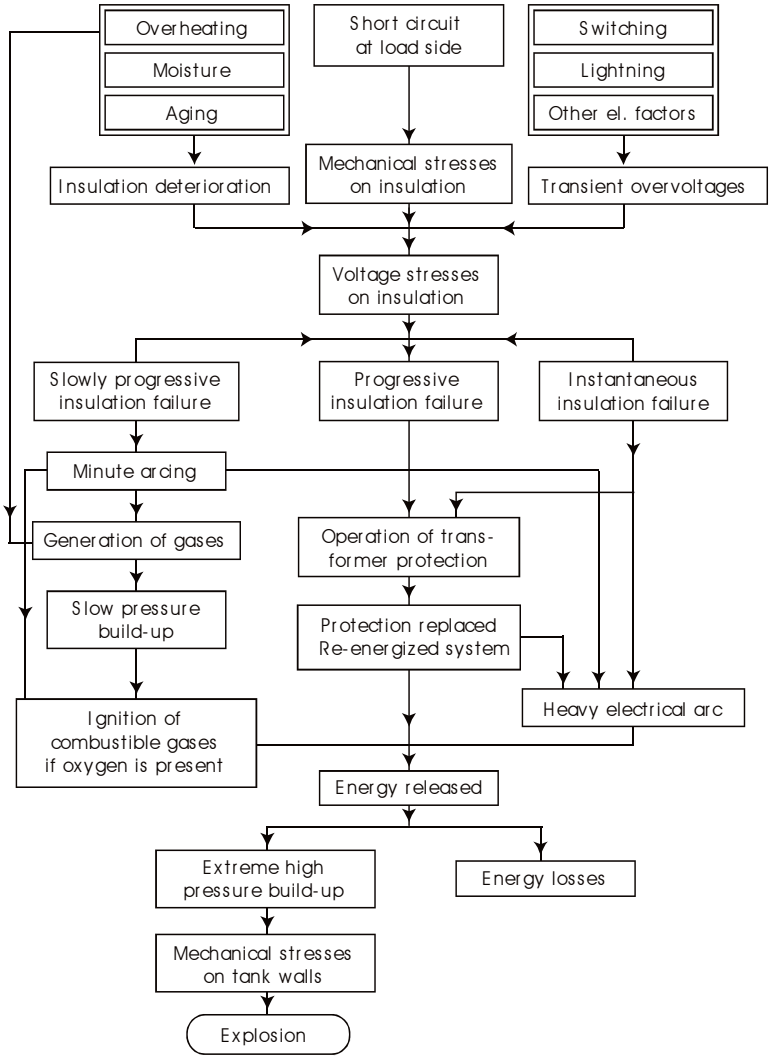

Figure 41 Sequence of events that can lead to a transformer explosion

Liquid-filled transformers come in several intrinsically different configurations (Figure 40), and these perform somewhat differently with regard to explosion potential. Type (b) is most common in the US, while types (a) and (c) are more prevalent in Europe; it is generally felt that type (c) is the most reliable. Oil-filled transformers are commonly equipped with a *Buchholz relay* for shutting down in case of a fault. This device comprises switches which are triggered by a dropping liquid level or by an excessive gas evolution from the oil. Thus, in principle, it is the transformer's first line of defense against an explosion.

All else being equal, the fire or explosion hazard is proportional to the flammability of the oil used. Silicone fluids have flashpoints of around 300ºC, much higher than the 150ºC or so for mineral oil. French explosion tests[701] on 100 kVA distribution transformers indicated that a serious explosion is most likely in the case of turn-to-turn fault in the secondary windings; lesser violence was normally found with turn-to-turn faults or phase-to-phase arcing on the primary side. With some transformer designs, the most vulnerable components are the wire links connecting the primary windings to the bushings—overcurrent sufficient to melt out this link usually leads to explosion.

When arcing takes place inside an oil-filled transformer, the outcome—modest damage versus serious explosion—is often determined by the clearing time of the circuit protection devices. For 'expulsion' type fuses, it is often assumed that the time is ½ cycle, but experiments indicate that actual arcing time may be longer[702]. Successful protection can be achieved by the use of 'current-limiting' fuses, which are able to open the circuit well before the first half-cycle of fault current has been passed[695]. If protection is by circuit breakers, then even the expected clearing time becomes much longer. Theories to predict the rupture (physical explosion) of oil-filled transformers (but not an ensuing chemical explosion or fire) were developed by Mahieu[696] and Barkan et al.[703] The two variables identified as controlling the process were I^2t and arc length. The quantity I^2t has units kJ/Ω and corresponds to the electrical energy dissipated per unit of resistance; with I = current and t = time.

A number of the failure mechanisms of oil-filled transformers are also common to other oil-filled high-voltage equipment such as capacitors, circuit-breakers, or reclosers. IEEE has published a guide to the investigation of transformer failures[704]. This manual contains a useful tutorial on transformer construction, but does not encompass fire/explosion as a failure mode.

Because they have large in-rush currents, and because transformers' short-term current carrying capacity is high in comparison to their continuous-duty rating, the primary side is typically fused with fuses much larger than the rated primary current, 250% being not untypical[705]. Consequently, arcing faults on the secondary side may not be protected against.

BUSBARS, SWITCHBOARDS, AND PANELBOARDS

The common ways by which an arc fault may occur on a *bare-metal electric bus* or other power distribution component are[706]:

- direct shorting by a metallic object, e.g., an electrician dropping a screwdriver.
- a loose connection causing progressive heating and minor arc formation. Over time, this may ionize the air in an enclosed space sufficiently that a general bus-to-bus or bus-to-ground arc occurs.
- surface conduction due to accumulation of dust or contamination[707], or due to a cracked porcelain insulator.
- conductive gases being discharged onto a bus conductor from a tripping circuit breaker or a blowing fuse. Arcing may occur if the conductors against which this flow occurs are not ones that have become de-energized.
- failure of a circuit interruption device upon short-circuit conditions.
- rodents or snakes entering into a space that should be an air insulator.

It has also been noted that some faults occur due to installations that leave inadequate clearances. Similarly, the main causes of ignitions originating at a residential 120/240 V panelboard are considered to be the following[708]:

- dirt and debris brought in by ingress of water or moisture
- rodents, insects
- mechanical abrasion of insulation
- resistance heating from loose connections
- improper wiring or overloaded circuit
- faulty circuit breaker.

In addition, the possibility of sabotage may have to be considered. Short-circuiting may be due to a faulty installation or may reflect a design problem. Color Plate 99 shows a panelboard fire which Lentini[709] identified as due to the use of a thermoplastic material to support the main power lugs. If these are insufficiently tightened, heating of the connection can then cause the hot lug to migrate through the plastic and to contact the metal rear wall of the enclosure.

The failure modes of residential panelboard circuit breakers that engage aluminum busbar contacts have been examined by Aronstein[710]. Even though the area of contact is large, he found that serious erosion is common. This was true not just for branch-circuit breakers, but was also documented for a 200 A main breaker. The primary factor was fretting, induced by microscopic interfacial motion. The latter can arise from thermal expansion, or from the forces involved in the circuit breakers, or from other forces. A fire within a panelboard can occur due to a poor connection of a primary conductor. Color Plate 100 shows melting and pulling back of insulation. If this continues, eventually the conductor is likely to short to the metal enclosure. Color Plate 101 shows a consequence of a fire in a panelboard.

An interesting case history documents a massive arcing fault and fire that occurred in an electric switchgear cabinet[711]. Due to an undersized transformer for a control circuit, a boiler-control relay lacked sufficient voltage for pull-in and was, instead, chattering. The arcing at the contacts due to the chattering caused sufficient ionization of the air that a breakdown ensued between conductors carrying high current.

Fires in panelboards can occur due to arc tracking. Aronstein[712] conducted experiments to simulate some events that took place during the Beverly Hills Supper Club fire. In that fire, some witnesses reported hearing bangs and flashes coming from various electrical panels. He was able to reconstruct the failure of an electric panel by arc tracking (Color Plate 102). It was sufficient to heat a section of conduit connected to the panel, but without heating the panel itself. Pyrolysis products from the overheated wire insulation traveled through the conduit and ended up in the electric panel, where they were deposited on the cold surfaces, including electrical insulation, thereby causing failure through arc tracking.

Arcing faults in secondary distribution systems can sometimes be hard to protect because the current levels under such fault conditions may be low enough not to trip circuit interruption devices. Voltage/current relationships for electrical arcs in general have been presented in Chapter 11. Here, some studies specific to distribution system arcing will be reviewed. Values of arc fault currents for typical circuit impedances were calculated by Kauffmann and Page[713] and widely publicized by Dunki-Jacobs[714], as shown in Table 66. The fault currents shown for the 208Y/120 V distribution system would be difficult to reliably detect and clear because they are so small. Sec. 230-95 of the National Electric Code requires ground-fault protection in 480Y/277 V systems that are rated at 1000 A or more. Thus, it might be expected that these devices would protect the circuit. However, both calculations and loss ex-

perience indicate that the arcing conditions may be such that the device is tripped late or not at all[706].

Table 66 Arc fault currents (rms) as a percent of symmetrical, 3-phase bolted-short current for two different secondary distribution systems, as calculated by Kauffmann and corrected by Dunki-Jacobs

Type of arcing fault	Secondary arrangement	
	480Y/277 V	208Y/120 V
three-phase	89%	12%
phase-phase	74%	2%
phase-ground	38%	--
multi-phase, w. one primary fuse open	80%	--

It is important to understand that values such as given in Table 66 are not absolute, mathematical constants. Instead, they came from calculations that were based on certain simplified assumptions:

- The circuit's impedance, apart from the arc, is wholly inductive and has no resistive component (0% power factor).
- After a voltage zero-crossing, current flow does not resume until the voltage rises to the value of the re-strike voltage, which is assumed to be 340 V except for the case of a phase-phase fault in the 208Y/120 system, where it is taken to be 275 V.
- Immediately upon restriking, the voltage across the arc drops to a fixed value and stays at that level until it extinguishes at the next current zero. This arc voltage is taken to be 140 V for a phase-ground fault and 275 V for a phase-phase fault. As shown in Chapter 11, the arc voltage depends mostly on the electrode gap, with a lesser dependence on current. If the busbars are spaced 100 mm apart, then an arc voltage gradient of 140/100 = 1.4 V mm^{-1} is, in fact, typical of experimental results. For the phase-ground fault, evidently Kauffmann assumed a larger gap of roughly 200 mm.

The computed current waveform is discontinuous and non-sinusoidal; the values tabulated represent the rms values of this computed waveform, compared to the rms bolted-short available current. Whether Kauffmann's assumptions were realistic must be determined from experiments. Wagner and Fountain[715] conducted experiments where arc faults were created across distribution system busbars for circuits with known values of symmetrical, 3-phase bolted-short currents. For 3-phase shorts across a 500 V busbar, arc currents during the first half-cycle were typically 0.7 – 1.0 of the symmetric, 3-phase bolted-short current. Single-phase shorts gave values in the range 0.5 – 1.0. For a 250 V busbar, both 3-phase and single-phase shorts gave widely scattered results, typically 0.3 – 1.0. During the initial half-cycle, a few values were slightly greater than 1.0; this is possible because the maximum asymmetric current flow that can be delivered is higher than the computed symmetric current value. The authors also pointed out that the distinction between a bolted fault and an arcing fault is not categorical—heavier shorts placed across the line start out with current characteristics of a bolted short, then progress to arcing characteristics. All of the Wagner and Fountain tests involved an ungrounded Δ-connected transformer secondary and busbars with a 100 mm conductor spacing.

Stanback[716] used a different arrangement, namely a single-phase fault between a busbar and a metal enclosure using 277 V with a power factor of 9 – 16%. His results showed a strong dependence on the electrode gap distance, as indicated in Table 67. Matters are somewhat complicated by the fact that there was also a current-level dependence in Stanback's results. Higher values of available bolted-short current led to arc-currents that were a smaller percent of the available current. However, this effect was not explored sufficiently to be able to produce a correlation. Stanback also measured arc voltages in his experiments; the values shown represent the average value of a nearly-flat-topped waveform; these can be compared to the peak-to-peak source voltage which is $\sqrt{2} \times 277 = 392$ V.

Another series of tests was conducted by Fisher[717], who examined arc fault currents for phase-ground faults in 277, 208, and 120 VAC circuits. In his tests, short-circuit currents ranged from 500 to 42,000 A, while the power factor varied from near-zero to 100%. Electrode spacings were 13 – 100 mm. His results (Table 68) show values that are similar to Stanback's at small electrode gaps, but do not drop as sharply with increasing gap distances. Fisher ran some additional tests using the 13 mm spacing but lower supply voltages (Table 69); at 120 V, the arcing was not sustained, but it was sustained at 146 V or higher. Additional testing indicated that the power factor, not surprisingly, has an effect on the outcome and that higher power factors lead to smaller arc currents. On the basis of this work, Fisher proposed that more realistic calculations should be done than are represented by Kauffmann's table. In his method, the resistance of the arc R_{arc} (Ω) is computed as

$R_{arc} = 4.96 \frac{\sqrt{L}}{I^{0.85}}$, where L = electrode gap (mm), and I = arc current (A). The equivalent circuit is expressed as a complex impedance $Z = R + jX$, where R = resistive component, $j = \sqrt{-1}$, and X = reactive impedance. The power supply voltage is a fixed, known value, while the total load

Table 67 Stanback's experimental results on phase-ground busbar faults at 277 VAC

Busbar-to-enclosure spacing (mm)	Arc fault curent, as % of bolted-short current	Arc voltage (V)	
		Average	Range
25	85%	109	91 – 153
50	70%	176	99 – 184
100	35%	268	207 – 342

is simply the vector sum of R_{arc} and Z. The desired value of arc current is obtained iteratively, by finding that value of I that gives $V = I \times (R_{arc} + Z)$ equal to the power supply voltage.

In real power systems calculating the available bolted-short current is not an easy task. Contributions to the short-circuit current come not only from the power utility connection but also from on-site motors. These contributions have different time response characteristics and this needs to be taken into account. A theoretical model for predicting arc currents in low-voltage (< 600 VAC) circuits has been described by Gammon and Matthews[718]. For design purposes, actual calculations are normally done with a computer program developed for these calculations. St. Pierre[719] has published a textbook devoted to the topic of short-circuit calculations.

In AC circuits, an arc extinguishes when the current waveform reaches a zero-crossing, but it can subsequently reignite when the voltage rises to a sufficient value. Kauffmann considered the *re-ignition voltage* (also called restrike voltage) to be 375 V. In principle, this would preclude sustaining an arc (arc re-ignition) for circuits with rms voltages less than $375/\sqrt{2} = 265$ V. In actual fact, the restrike voltage is highly dependent on the circuit parameters (i.e., resistance, capacitance, inductance), on gap size and arrangement, and on the timing when the voltage becomes available after the current zero-crossing. The dielectric strength of the ionized air starts to recover as soon as arcing stops, but the strength does not recover fully for a certain time period. In one study on low-current (< 25 A) arcs[720], restrike voltages of 320 – 400 V were found if the needed voltage could be supplied within the first 5 μs of the current zero-crossing. If voltage could not be supplied until 20 μs, then the range was 280 – 580 V, while at 200 μs, the needed voltage was 400 – 860 V. The value of 280 V was the minimum found in that study over all test conditions. In other tests[721], a restrike voltage of 160 – 240 V was found immediately after arc extinction, with the value again rising with time; however, it appears that the conditions needed to elicit these low restrike values would not be common in actual distribution systems. Thus, Kauffmann's assumed value falls somewhere within the experimental range, but the range is quite broad.

Case histories[722] indicate that arc faults in 480 V systems tend to last for minutes-to-hours and cannot be expected to self-extinguish or to trip circuit protection devices. Smolinski[705] found that sustaining an arc in a 240 VAC circuit is not easy, but is possible, and it could be sustained in circuit where the fault current was limited to as low as 30 A. Experience indicates that in 208 V systems there is a mixed probability as to whether an arc will self-extinguish or not[723]. As mentioned above, Fisher was able to sustain arcing at 146 V, but not at 120 V. Because of his and other studies, it has often been claimed that it is impossible to sustain arcing in 120 VAC circuits, but this is not true. Bruning[724] demonstrated that circuit parameters are crucial—a self-sustained arc is impossible for most circuit parameters, but there are conditions (inductance is especially critical) under which it becomes possible.

A limited amount of work has been done on arcing in higher-voltage busbar systems; for example, Klaus and Schau[725] reported brief results on experiments in 3 – 15 kV systems.

Most arc faults originate as phase-to-phase or phase-to-ground faults, then escalate to 3-phase faults in 5 to 15 ms[726]. In the case of *insulated* busbars in 480 VAC systems, tests indicate that it is very hard to sustain arcing[727]; similar results at higher voltages are not available. In the same vein, a phase-ground fault has a good chance of not escalating to a 3-phase fault on insulated busbars[723]. In general, single-phase arcing is much more difficult to sustain than 3-phase arcing, since on a single-phase line the current passes through zero twice a cycle, during which time production of arc plasma ceases and the breakdown strength of air can recover. But on a 3-phase bus, there is no interval when all current flow ceases, thus production of arc plasma also does not cease. Bus arcing faults in secondary systems of the ungrounded, delta-connected type (3-wire) are exceedingly rare, in comparison to the currently prevalent 480Y/277 V grounded system (4-wire)[714]. However, the latter is sensibly preferred due to its better performance in regards to transient overvoltages.

In the case of non-insulated busbars, arcing failures may be induced by an ongoing, non-electrical fire. This can take place in one of two different ways: (1) deposition of conductive soots into the busway; or (2) discharging of ionized gases into the busway.

Because of magnetic repulsion effects, an arc fault across a pair of busbars moves *away* from the source; the speed of motion is greater for higher arc-fault currents. During the travel, typically little damage is done because of the non-sustained nature at one place. Burndown damage is normally found once the arc stops moving upon encountering an obstacle. Stanback[716] conducted experiments to quantify the amount of metal destroyed in arc faults in single-phase 277 V-to-ground busbar faults. The natural magnetic effect propelled the arc to the end of the bus way, and the total amount of metal lost from the busbars and from the steel enclosure was measured. The empirical rule developed was:

$$V = kI_{arc}^{1.5}t$$

where V = volume of metal destroyed (mm^3), I_{arc} = arc current (kA), and t = time (s). The constant k = 0.025 for aluminum busbar, = 0.012 for copper busbar, and = 0.011 for steel enclosures. Studies have determined that the damage to a *switchboard* from bus arcing is proportional to the energy released[728]. Only cosmetic damage normally is seen for energies < 100 kJ; conversely for energies > 700 kJ, destruction is comprehensive. In examining 3-phase arc faults in circuits carrying from 380 to 726 V, the authors found that arc power has a rise time of about 7 ms and stabilizes to its ultimate power at about 15 ms. Thus, for event durations >> 15 ms, the arc energy becomes directly proportional to duration.

There are no systematic studies of ignition potential from distribution system arcing faults. A fairly detailed report has been published on an office building fire which led to 5 fatalities[729]. An electrician attempted to replace a 200 A fuse in a 480 VAC, 3-phase distribution panel without disconnecting the power. Apparently his fumbling created a violent arcing fault, which quickly escalated into a 3-phase fault, the failure of each phase being heard as an explosion. The fire originated in an electrical closet, then quickly ignited carpeting and wall coverings along the building's corridor, thereby trapping a number of occupants.

If aluminum wire or connections (lugs) are used, then special precautions are needed, lest the probability of failure rise dramatically. Pure (uncoated) aluminum lugs may lead to rapid failure. The current good practice is to use lugs that are first coated with copper or nickel, then flashed with tin or silver. Aluminum distribution wiring systems using these types of lugs are considered to be as reliable as all-copper systems[730].

INSULATED DISTRIBUTION CABLES

The nature of arc faults in underground distribution ducts was examined by Koch and Carpentier[731] in Montréal, where a three-phase 600/347 V distribution network is used. A modest overvoltage was used, comprising 635/367 V. Phase conductors were stranded aluminum, insulated with XLPE (cross-linked polyethylene); a bare-copper neutral was used. They found that arc behavior is governed by whether the interior of the duct is clean and dry, or not. For clean, dry conditions, phase-to-neutral or phase-to-ground arcs self-extinguished in only a few cycles, and very little damage was sustained. When dirty, moist conditions were created, arcing escalated to phase-to-phase and finally to a 3-phase fault. These arcs kept re-igniting and burned for up to 5 minutes, when the experiments were terminated due to gross overheating. Because the arcing was repetitive, rather than continuous, it would not have been possible for overcurrent protection on either the secondary or the primary to activate. The arc faults pyrolyzed large amounts of wire insulation, apart from what could be directly incinerated in the arc. The pyrolysis products were found to be quite flammable, and this accounts for a number of *manhole explosions* which the authors investigated. Oxygen supply within the duct was not sufficient to allow the pyrolysis products to burn, but burning was possible once they were ejected into manholes. The authors also report that use of direct-burial cable, without enclosure in a duct, does not eliminate the problem if arcing occurs close to a manhole or a transformer vault. Case histories are known where arc-fault induced explosions occurred with direct-burial cables running at the low voltage of 208/120.

As part of their study, Koch and Carpentier provided an estimating rule for the arc fault current of insulated distribution cables:

$$I = 120 + 0.64I_{sc}$$

where I_{sc} = bolted-short current (A). Schau[732] explored arc fault currents of 3-core, insulated distribution cables at 416 V. He found that the arc current was 69% of the bolted-short available current when the latter was 5 kA, dropping to 60% for 15 kA. Additional studies were reported by Ohnishi et al.[733]

SERVICE DROPS AND HIGH CURRENT CAPACITY CONDUITS

The service drop is the wiring that goes from the secondary of the power utility's transformer to the meter and panelboard of the user's building. This wiring is particularly vulnerable to starting fires if a fault condition occurs, since the protection given to it is very limited. Basically, the only protection that normally exists are the power utility's fuses on the primary side of the transformer. But since the transformer may be sized to feed quite a number of service drops, the fuses have to have a high rating and may allow very sizable fault currents to flow in the service drop of one particular user. The damage to be expected depends on whether the fault occurs in overhead/underground wiring, or in a service entrance conduit in the building itself. In the former case, damage is usually limited to the wiring. But the latter situation, while less common (since wire in conduit has fewer opportunities to be damaged) can be much more serious. Failure of wire insulation inside a steel conduit feeding the electric meter[734] can lead to a 'cutting-torch action,' similar to a welder's metal-cutting operation (see Figure 42). The progress rate of the electric arc cutting the

metal conduit has been timed at about 1 mm s^{-1}. Any nearby combustibles can then easily be ignited by the molten steel, as documented in several cases[734].

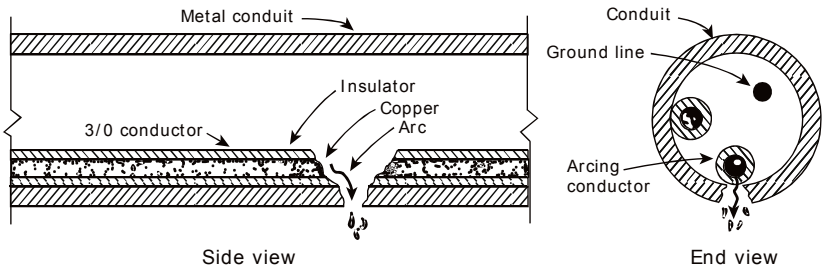

Figure 42 Arcing damage inside a service entrance conduit (after Sanford)

Another series of tests was conducted by the Kearney Co., in which ¾" (nominal 20 mm) and 1" (nominal 25 mm) conduits carrying AWG 8 copper wires or AWG 6 aluminum wires were tested[735]. In their tests, a 480 VAC power supply was provided, with resistors in line to limit current to 240 A. The fault comprised a stripped-bare wire across which were wound layers of 22 AWG copper wire, and then the assembly was wrapped with paper masking tape. The test program included steel (EMT) and PVC (ENMT) electric conduits and also schedule 40 PVC pipe. Using THW copper wires, no external damage was found with the EMT conduit and with the ¾" PVC pipe, but both sizes of the ENMT conduit showed external burn damage. Using RHW copper wires, a 75 mm long hole was melted through the ¾" EMT conduit, but no destruction of the 1" EMT conduit. Both sizes of the PVC pipe and the ENMT conduit showed external burn damage. With aluminum USE wires, all three conduits of both sizes showed external burn-through damage. Ignitability of external combustibles was not examined in the tests.

An unusual case of a circular hole of about 25 mm blown out of a service entrance conduit elbow fitting ('condulet') was studied[736]. It was found to be due to the high temperatures caused by internal arcing, combined with the low melting point of the aluminum alloy.

HIGH VOLTAGE INSULATORS

Arcing along high-voltage insulators is termed '*flashover*' by electrical engineers; this term is unrelated to its usage in fire science to denote a stage of a room fire. Electrical flashover typically occurs in wet or rainy weather, when a semi-conductive path can form along the surface of the insulator. It is facilitated by pollution, since pollutants in the atmosphere lower the resistivity of the water film. The process entails small leakage currents initially. Because of non-uniformities in this layer, preferential dry bands are established which have a higher resistivity than the rest of the layer. Local arcing along these dry bands occurs first, and this can then lead to a complete discharge path being established, electrode to electrode. The latter is designated as flashover. Electrical flashover resembles arc tracking in some of its basic features. In ceramic insulators, the material itself is not subject to charring, although pollution can deposit a film on the insulator which contains ionic dissolved solids. This film is not a perfect insulator, and when a low enough resistivity is attained, surface tracking can occur. The breakdown strength of a semiconducting pollution strip[737] is much lower than the breakdown strength of air: 50 – 70 kV m^{-1}, as opposed to 3 MV m^{-1}. Newer insulators made of silicone rubber or other elastomers show a slightly different behavior. In the case of silicone rubber, a strong role is played by oil that exudes from the material and, when present, keeps the surface hydrophobic[738]. Breakdown is facilitated by conditions that destroy this surface oil film. Rizk[739] has reviewed numerous theories for flashover along insulators. One of the simpler theories for flashover in AC circuits gives:

$$E = 102\bar{r}^{1/3}$$

where E = breakdown field strength (V m^{-1}) and $\bar{r}$ = resistance of pollutant film, per unit leakage length (Ω m^{-1}).

Electric wires and cables

In the US, testing of wires and cables is most commonly done under UL standards. A large number of different standards have been issued by UL for wires and cables of various types. The ones of most general interest include: UL 4[740] (armored cable), UL 44[741] (thermoset-insulated), UL 62[742] (specifications for flexible wires/cables), UL 83[743] (thermoplastic-insulated), UL 444[744] (communications cables), UL 493[745] (underground cables), UL 719[746] (nonmetallic-sheathed cables), UL 758[747] (appliance internal wiring), UL 817[748] (appliance cords and extension cords), UL 854[749] (service entrance cables), UL 1581[750] (general wire/cable fire tests), UL 1666[751] (vertical fire propagation test for cables in shafts), UL 1685[752] (vertical cable tray fire propagation test), UL 2196[753] (cables passing a fire-resistance test). The Steiner Tunnel test for plenum cables used to be UL 910[754], but in 2002 was withdrawn in favor of NFPA 262[755].

MODES OF IGNITION OF WIRING

It is no surprise that electric wiring* faults in buildings lead to fires. Yet, the mechanisms by which ignition occurs are not trivial and have only been explored in recent years. It is convenient to consider that ignition of electric insulation (or other nearby combustibles) can occur due the following causes:

- arcing
- excessive ohmic heating, without arcing
- external heat sources.

* 'Electric wiring' is considered here in the most general sense, encompassing wires, cables, and all other devices forming the current path.

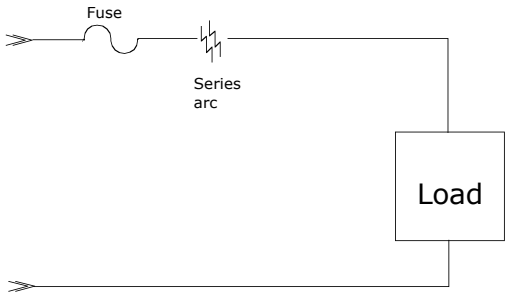

Figure 43 Series arc

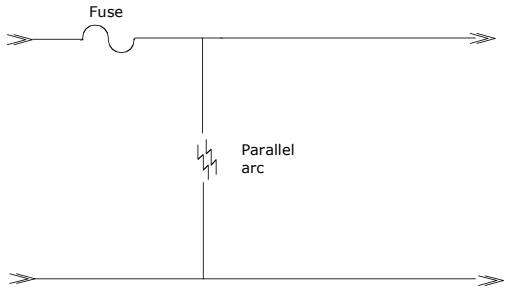

Figure 44 Parallel arc

ARCING

Topologically, an arc in a single-phase circuit* can be identified as a series arc (Figure 43) or a parallel arc (Figure 44).

A series arc cannot exist without a load. As Figure 43 indicates, if the load is turned off, then current flow through a series arc cannot occur. The presence of the load also means that it will be very rare that a series arc blows the fuse or trips the circuit breaker protecting the circuit. In a steady-state analysis, the presence of the arc *decreases* the current being drawn through the circuit, so if the circuit interruption device was appropriate to the load, introducing an arc will not trip it. Arcs in AC circuits have a highly transient characteristic, however, so if the load is sufficiently reactive (e.g., a large motor), the combination of the erratic waveform of the arc and the reactive load could possibly trip the interruption device, but this cannot be counted on.

In the case of branch circuits (as contrasted to service entrance wiring), it is also unlikely that a parallel arc will trip the protective device. There are three factors that come into play here: (1) the intermittent nature of current flow through the arc; (2) considerable resistance of branch circuit wiring; and (3) the time response characteristics of circuit interruption devices. All of these issues are considered in detail below.

* Some authors consider a third form of arc—line-to-ground—which is possible when the circuit contains a ground in addition to a neutral. The topological arrangement is identical to that of the parallel arc, since the load is not in series with the arc. Three-phase circuits can also exhibit phase-to-phase arcing.

The causes of arcs can be many, but the primary ones are:
(1) carbonization of insulation (arc tracking)
(2) externally induced ionization of air (created by flames or an earlier arc)
(3) metal-to-metal contact, i.e., short circuits
(4) poor connections.

The first three mechanisms are discussed in detail below; poor connections have been discussed in the *Electric outlets, plugs and connections* section. A sustained electric arc can ignite many substances, and general arc characteristics have been discussed in Chapter 11 and earlier in this Chapter under *Electric transmission and distribution systems.* Protective devices for detecting arc fault conditions are discussed in Chapter 12.

Carbonization of insulation (arc tracking)

In 120 VAC circuits, it is difficult to sustain arcing in air, but not difficult to sustain arcing over a carbonized conductive path. This is sometimes called 'arcing-across-char.' The mechanism has been known in electrical engineering for a very long time, but how a carbonized path gets established across an insulating material is not a trivial question. There turns out to be more than one way of creating such a path, with the most common being:

- applying an arc directly at the surface of the insulation, for example, by placing two electrodes on the insulator and applying a high voltage across them; this procedure is used in certain test methods;
- heating the insulation to excessive temperatures, as discussed earlier under *Electric outlets, plugs and connections*;
- combined effects of moisture and pollutants on the surface;
- fungal growth.

Carbonized insulation comprises a resistance which may be low enough to pass significant current and lead to ignition, yet not trip a circuit breaker. The basic principles of the arc tracking process have been discussed in Chapter 7. Color Plate 95 shows wire damage formed due to arcing across carbonized insulation[570] on an NM electric cable in a 15 A, 120 VAC branch circuit. Arcing went between the phase and the neutral conductors; the wire in between is the ground wire and this was cut afterwards, it was not involved in the arcing. Note that the statement made in Sec. 6-10.1 of NFPA 921[756] that arcing-through-char is "always a result of fire" is not correct, since carbonization of insulation can be produced by mechanisms other than fire†.

In a more elaborated scheme, UL considers that four mechanisms can cause carbonized insulation[757]:
(1) gradual breakdown of insulation due to repeated overvoltages;
(2) high voltage electrical tracking across the surface of solid insulation, due to repeated transient overvoltages;

† Referring to the 2001 edition; this statement may be removed in the next edition.

(3) deposition of contaminants and moisture on the surface;
(4) thermal decomposition of the insulation due to heat sources. These may include high-resistance series faults, break-arcs, or an existing fire impinging on wiring.

Electric insulation can carbonize due to fungal growth, since the extensive vascular system of the fungus provides a conductive string of paths[758]. This mechanism can only take place in wet environments. Fires due to carbonization of insulation are commonly seen on electrical devices near aquariums (Color Plate 96), especially ones using salt water, but whether fungal contributions are important to this ignition process has not been elucidated.

Hagimoto created a charred layer on a synthetic rubber surface, then used various metal electrodes for creating further arcing along the charred surface[525]. He found that in all cases the arcs were intermittent, with a very low on/off ratio, with brass showing a lower ratio than copper or iron. It was considered that the electromagnetic force tending to move the arc away from the source was at least one factor accounting for the intermittence[759].

Yereance[223] considers arc tracking to be a major source of residential fires of electrical origin and claims that the time period for arc tracking to lead to a fire can range from a few hours to forty years, but his study lacks specificity or details. He points out that common items such as cooking oil vapors, lint, and cat fuzz have been found not to be contaminants leading to arc tracking, but fails to identify ones that are. Béland, who unlike Yereance, conducted laboratory studies, agrees that arc tracking can happen in domestic wiring, but considers it rare, rather than common[760]. In testing, Béland examined the possibility that salt water at 120 V could cause a carbonized path when two electrodes are placed onto a Bakelite plastic surface. This proved possible to do for electrodes 2.5 mm apart, but not at 12.6 mm. In his arrangement, Béland required a minimum of 70 V for a carbonized track to occur; this is much higher than the 6 V documented in Chapter 7. He also found that results varied according to the particular type of Bakelite used. Material used for making circuit breakers was much more resistant to arc tracking than material used for switch plates. He also concluded that PVC was not able to exhibit arc tracking, which contradicts most other researchers.

Few illustrations are available for arc tracking in building wires. Welte[761] reported that prior to the 'B-grades' (NM-B and UF-B) being introduced in 1985*, it was not rare for electricians to come across house wiring cable that had carbonized. Neither damage, nor lightning, nor electrical overloads were considered to be the cause, but rather an intrinsic cable failure mechanism. Burnt cables were recovered showing that they were burned from the inside out (Figure 45). Welte reports[762] observing several accidental arc tracking fires that were either buzzing, without a visible flame, or were exhibiting localized flaming. After introduction of the B grades, instances of this type of failure became rare.

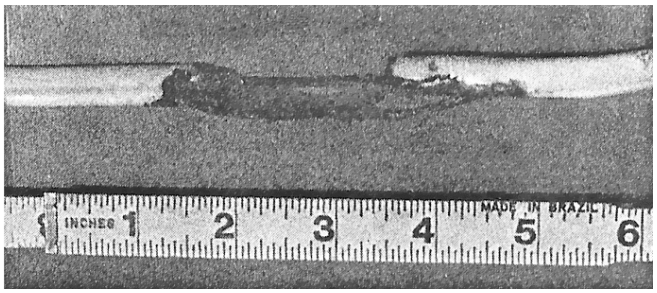

Figure 45 Non-metallic 12 AWG building cable which ignited "from inside out" due to arc tracking
(Courtesy *Air Conditioning, Heating & Refrigeration News*)

Reiter[763] reports investigating several fires that appeared to originate due to cable degradation of 60ºC-rated cables in attic spaces. Carrying of high currents and burial in thermal insulation were considered to be contributing causes.

Noto and Kawamura conducted experiments using the IEC 60112[764] apparatus and were able to obtain arc tracking on PVC-insulated cables[765] with a 100 V power supply. Using four different test arrangements, all on cables having 1.6 mm copper conductors, they were able to create arc tracking in all cases; however, only two of the four arrangements led to ignition. Ignition was preceded by intermittent arcing at ca. 5 s intervals. The PVC cables which ignited continued burning until the circuit was de-powered, at which point flaming stopped. Both plain and shielded cables could be ignited, but the ability to ignite proved to be dependent on exact details how the salt water was applied to a damaged cable location. The authors also did some experiments with flat plaques of PVC materials of various compositions. They discovered that calcium carbonate, an FR additive often added to PVC compositions as an HCl scavenger, actually promotes arc tracking failure, since early outgassing of HCl is helpful in forestalling arc ignition.

PVC insulated wire becomes semiconducting when charred. In an early study, Soma[766] examined the resistance of insulation of stranded-wire power cords when exposed in a furnace to various temperatures. Up to 200ºC, little change in resistance was found. But at 300ºC the resistance dropped dramatically. For higher temperatures, resistance further fell, until at 600ºC the resistance dropped to only 3 Ω. Tests by Hagimoto et al.[767] showed that leakage resistance of a power cord, originally ca. 10^{12} Ω prior to heating, dropped to 5×10^{5} Ω when heated for 1000 h at 180ºC and down to 10^{2} Ω at 190ºC. At a temperature of 250ºC, resistance values ca. 10^{5} Ω were reached in only 10 h. These results suggest that serious damage is already incurred at 180º.

* The 90ºC rated cables were introduced to replace the older 75ºC rated ones primarily due to thermal failures that were being experienced in wiring to incandescent lighting fixtures.

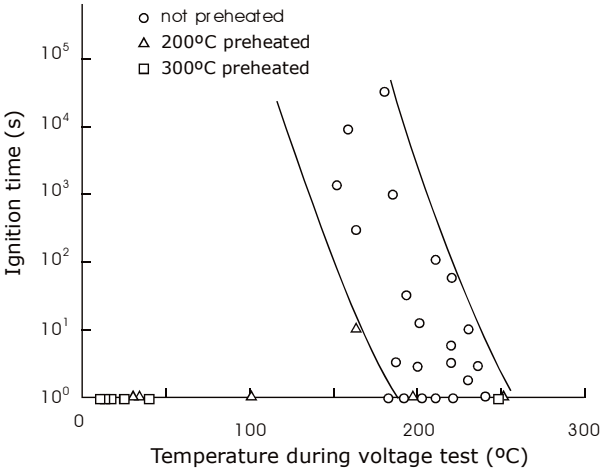

Figure 46 Effect of preheat temperature and test temperature on ignition of PVC wire insulation when subjected to 100 VAC across 1 mm insulation thickness

Even lower temperatures were found sufficient by Nagata and Yokoi[768,769]. When virgin PVC insulation was heated to about 160ºC, ignition occurred if a potential difference of 100 VAC was presented across an insulation thickness of 1 mm, which represents a common value of wire insulation thickness. If the insulation had previously been preheated to 200 – 300ºC, then ignitions occurred when the preheated insulation was raised to only very mild temperatures during the voltage test—from room temperature to 40ºC (Figure 46). To explain these results, the authors used the measured resistivity/temperature relations and applied thermistor theory to the material[770]. This showed that negative resistance characteristics are found once the applied voltage exceeds some rather modest threshold value and that the consequence is a thermal runaway of the material. In such a runaway, electrical resistance drops as temperature increases. This causes an increased current flow, which raises the temperature, which lowers the resistance, and the process escalates.

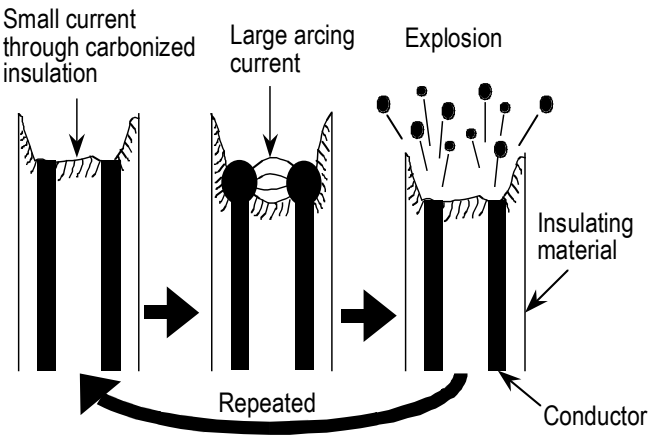

Figure 47 The discontinuous nature of an electrical cord or cable arcing fault (courtesy Hagimoto et al.)

When a Neoprene extension cord is heated to 336ºC with the exclusion of oxygen, this results in the carbonization of the insulation[771]. The conductivity of the insulation then becomes low enough so that arcing across the insulation is possible. The authors were also able to ignite cloth in a smoldering mode and carbonize the insulation of a Neoprene-insulated coiled cord, by simply covering the coiled cord with enough cloth while drawing 12.5 A through the cord. Temperatures over 300ºC were recorded. In similar experiments[772], they also obtained short circuits of PVC-insulated cords, when coiled three times, covered with a towel, and drawing 12.5 A. The wire size of the conductors was 0.75 mm^2 (18~19 AWG).

Hagimoto et al.[773] conducted laboratory studies simulating parallel-arcing faults of electrical cords and cables. They identified that the process typically proceeds in a repetitive, but irregular fashion. The basic steps are illustrated in Figure 47:

- initial current flow occurs due to a carbonized layer
- the current flow increases and results in local arcing
- the arcing causes melting of metal and expulsion of the molten pieces
- once the molten pieces are expelled, current flow drops
- continued current flow through carbonized material eventually leads again to a sizeable current flow.

The process repeats indefinitely. The authors tested four different sample types, as detailed in Table 70. The current waveforms, as determined during a 1 s duration measurement interval, are shown in Figure 48. (Note, of course, that the actual current values will depend on the resistance of the particular circuit tested).

The authors then examined the implications of the discontinuous nature of the arcing fault waveform on the time

Table 70 Construction of 2-conductor cords/cables tested by Hagimoto et al.

Specimen	Insulation material	Construction	Conductor
A	Neoprene	flat cord	0.18 mm Ø × 50; tot. area 1.25 mm^2
B	PVC	dumbbell-shaped cord	0.18 mm Ø × 50; tot. area 1.25 mm^2
C	PVC	2 insulated conductors; round jacket	0.18 mm Ø × 50; tot. area 1.25 mm^2
D	PVC	2 insulated conductors; flat jacket	1.6 mm Ø

required to trip a 10 A circuit breaker, Figure 49. It is clear that for the same peak value of current, a much longer time was needed when the waveform was not sustained. While the arcing waveform is irregular, Hagimoto et al. did find that the arcing frequency was correlated to the peak current, as shown in Figure 50. Arcing frequency was defined as $= \frac{\text{number of arcs}}{2 \times \text{number of cycles}} \times 100$. That higher currents should decrease the arcing frequency is not surprising in view of the mechanism described. Higher currents lead to more material being expelled, and this means that a longer time is required to re-create surface conditions suitable for arcing.

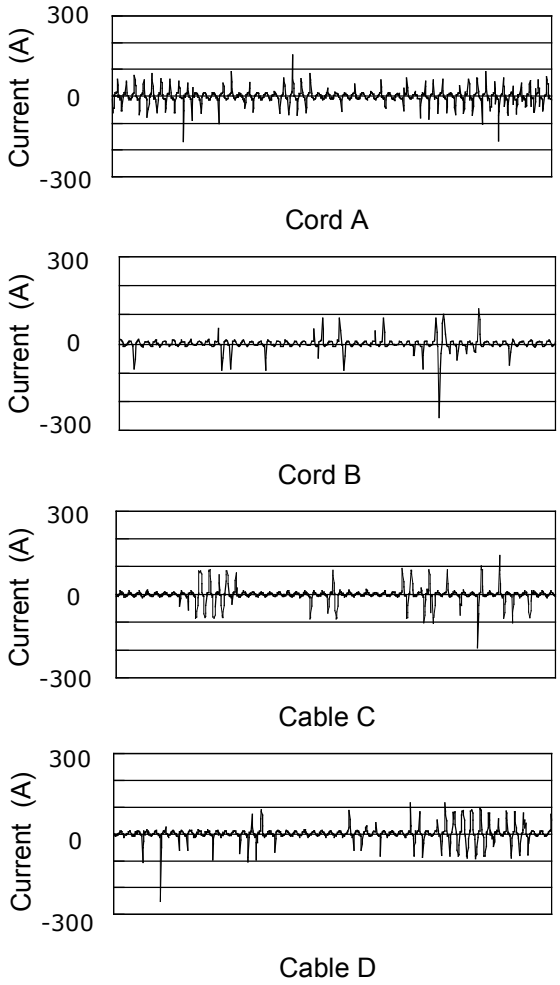

Figure 48 Current waveforms for four different specimens during 1 s measurement time
(Courtesy Hagimoto et al.)

Externally-induced ionization of air

The intrinsic dielectric strength of air is high (roughly 3 MV m^{-1}, except for very small gaps), but breakdown can occur at much lower values if the air space is ionized by some means. Two such means are flames and pre-existing arcs. If a serious arc-fault occurs, a large amount of ionized gases will be ejected. These can travel a certain distance,

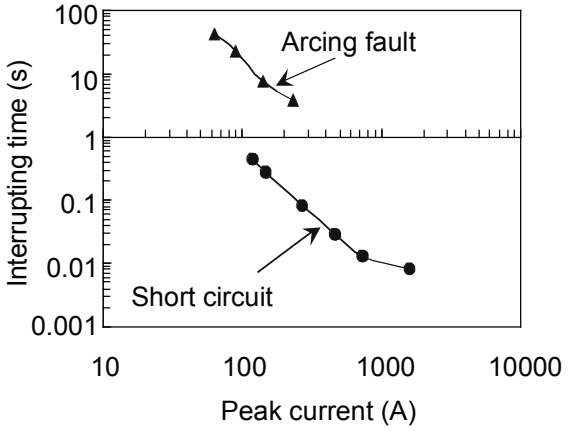

Figure 49 Interrupting characteristics of a 10 A circuit breaker for arcing faults and short circuits on Cord A
(Courtesy Yasuaki Hagimoto, NRIPS)

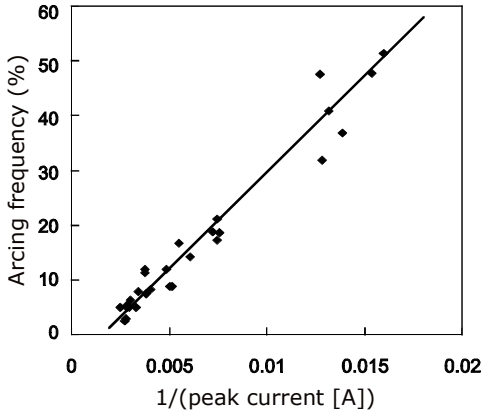

Figure 50 Arcing frequency, as determined by peak arcing current
(Courtesy Yasuaki Hagimoto, NRIPS)

and if they encounter another circuit, they can readily cause a breakdown and new arcing at the second location[706]. The decreased breakdown strength of air due to presence of flames has been documented in laboratory studies by Mesina[774], who showed that the dielectric strength of air drops to ca. 0.11 MV m^{-1} in flames. Mesina's study, however, only encompassed conditions at 1600 V and higher. A similar study was reported by Scott and Dolgos[775]. They conducted tests in an enclosure where explosions were ignited in a 9.8% methane/air mixture and the breakdown strength measured in an arc gap between two 12.5 mm brass sphere electrodes. Their results (Figure 51) show a somewhat higher than standard breakdown strength in normal air (4 MV m^{-1}) and a strength of 0.19 MV m^{-1} in the atmosphere undergoing a methane/air explosion. Bossert and Hurst[776] reported some similar data showing the reduced breakdown strength in various fuel-gas/air explosions. Their results

showed curves, rather than straight lines and also showed that some gas explosions, e.g., acetylene/air result in a lower breakdown strength than methane/air explosions. The fire does not have to be large in order to lower the breakdown strength of air. Baldo et al.[777] placed a Bunsen burner into 1.0 – 2.5 m long arc gaps and found that the breakdown strength was reduced by 30 – 50%.

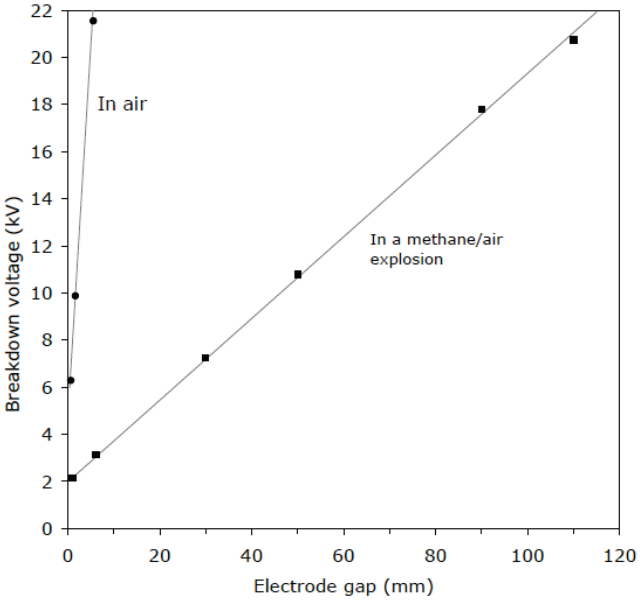

Figure 51 Breakdown strength in a methane/air explosion

There have also been limited studies in the fire investigations field[778] (see also Color Plate 97 and Color Plate 98), but many of the details of flame-induced arcing have not yet been elucidated. Arcing induced by local flaming may then cause further ignitions, either locally or elsewhere in the electric wiring. Thus, by far the most common situation for arcing to be encountered in fires is when the arc is caused by an ongoing fire[829].

It is often claimed that when evidence is found of arcing at multiple locations along a branch circuit conductor run and wires have physically broken apart at the arc locations, the initial arcing had to have occurred at the place most distant from the supply. Bernstein[779] points out that this is not true for circuits exposed to an intense fire—arcing can then occur more or less simultaneously along the entire branch circuit conductor run.

Short circuits

The term *short circuit* is commonly applied to the situation where a low-resistance, high-current fault suddenly develops in a circuit. This can take two forms: (1) a *bolted short* where a good metal-to-metal contact is made across a full-thickness section of metal; (2) an *arcing short*, where initial metal-to-metal contact is not sustained and current flows through an arc. In a bolted short, heating is not localized at the fault but distributed over the entire length of the circuit. A bolted short can readily be created by mis-wiring a circuit and then turning on the circuit breaker. The circuit breaker then typically trips before anything ignites.

An arcing short results from a momentary contact of two conductors. This causes melting of the material around the contact area. Magnetic forces tend to push the conductors apart, and the liquid bridge between them then gets broken. Electric breakdown across the gap created is then visible as the conductors separate. After an arcing short, large-diameter conductors can often be seen with a notch on the surface; smaller-diameter wires may be severed entirely; both results are illustrated in NFPA 921[756]. Color Plate 103 shows an arc created[570] by making a direct metallic short circuit across a 240 VAC line.

Color Plate 104 shows conductor damage that took place when a direct short circuit was created in a 240 VAC circuit[570]. In this case, both conductors were heavily damaged, but did not melt sufficiently to create a gap in the copper. Arcing ceased once metal was lost and remaining copper conductors became effectively further spaced.

In 120 VAC branch circuits protected by 15 – 20 A circuit interruption devices, it is exceedingly difficult to ignite a fire by means of short circuits. Short circuits will usually trip the circuit protection device, or blow out enough metal to clear the fault, or both. The amount of molten material ejected is usually small and it is difficult to ignite anything with it except 'tinder' type materials. UL testing showed that, upon creating a short circuit, wire insulation is usually 'blown away,' rather than getting ignited and burning[780]. Ettling tried igniting PVC wire insulation by creating short circuits[781], but his only successes were when a large overcurrent was created, not from bolted shorts or parting arcs.

Experiments have been performed, however, that illustrate the potential of tinder to get ignited from shorts. Hagimoto et al.[782] slowly crossed over two bare wires to make contact, with cheesecloth being placed below the location of the arcing short as an ignition target. Two types of wires were used, 1.6 mm solid conductors and 50×0.18 mm stranded. In their experiments, they used two different circuit breaker types, thermal-only and thermal/magnetic. Each was rated at 20 A. The thermal/magnetic breaker tripped in all cases, and in no case was there an ignition of the cheesecloth. Arc 'notches' were small and no wires melted through during these tests. The current at tripping ranged from 360 to 820 A. The thermal breaker did not trip in 40 trials, and tripped only in 4 trials. In two of those, the contacting wires became welded; in the remaining 38 trials, the wire melted through and broke. In every case where the thermal breaker was used, the cheesecloth target was ignited by ejected molten copper. The authors measured the current and voltage across the arc and determined that all cases of ignition involved arc energies > 100 J, while all cases of non-ignition had energies < 100 J. Similarly, using

I^2t as the test variable, ignitions occurred for $I^2t > 1500$ A^2 s, while non-ignition for $I^2t < 1500$ A^2 s. They also determined that, due to magnetic repulsion force, when the two wires were crossed over at an angle of 10º, an arc was more likely to be sustained longer than when crossed over at 90º. As for the types of wires, stranded wires had a tendency to sustain arcing longer than solid ones when a thermal breaker was used. The basic ignition/non-ignition outcome, however, was not affected by the wire type, nor by the angle of the wire crossing.

In similar experiments, Watanabe et al.[783] created short circuits by crossing two bare copper wires together, in a circuit protected by a 10 A circuit breaker of either the thermal-only or the thermal/magnetic type. Using target fuels of tissue paper and absorbent cotton, they were able to get ignitions when the peak current exceeded 260 A for the thermal circuit breaker, or 800 A for the thermal-magnetic circuit breaker. The corresponding I^2t values required were 250 A^2-s and 900 A^2-s. These are the minimum values seen for absorbent cotton, and ignition of tissue paper required somewhat higher currents.

Franklin[566] documented that fires are readily started in blankets and in paper, when a power cord is cut with diagonal cutters. The fires ignite from the molten copper droplets which are ejected. In such a situation, a bolted-short condition persists only very briefly, since the magnetic forces induced by the short circuit push the conductors apart, converting the bolted short into an arc. He was able to create up to 30 such short circuits on a power cord before a 20 A circuit breaker tripped. In laboratory measurements, Franklin documented that arcing across a 120 V circuit normally draws 200 – 250 A, but with some arcs as low as 150 A and others as high as 400 A. He reports that in creating hundreds of parallel arcs, currents below 100 A were never measured.

In circuits with larger circuit breakers, however, even high-density materials can ignite from arcing shorts. One such fire was documented in a Japanese investigation[784]. An arcing short occurred because a bolt pierced a power cable and made contact with a line conductor. The 100 VAC circuit was protected by a 150 A circuit breaker, but the actual current was only 4.5 A, because the bolt formed a poor ground connection. Laboratory tests replicating this arrangement produced an explosive sound, flames of about 0.4 m height, and heavy charring of nearby structural timber.

Plastic foam targets can be ignited in arcing faults of aircraft wire, described below under *Electric wiring in aircraft*.

High-voltage breakdown in low-voltage circuits

In 120 or 240 VAC circuits, arcing is normally initiated by metal-to-metal contact or by arcing across carbonized insulation. But direct arcing is possible if a high voltage is introduced into low-voltage wiring. If a sufficient high voltage is imposed on such wiring, then a breakdown of insulation can occur without previous carbonization or metal-to-metal contact. The exact breakdown voltage will depend on details of the devices (e.g., outlets) where the breakdown takes place, but experiments generally indicate[785] that 5000 – 7000 volts is needed for direct arcing; this is very similar to the 6500 V computed from Paschen's Law (see Chapter 11). This is because—unlike in HV wiring—insulation thicknesses in LV wiring are not selected simply on the basis of the voltage being carried (plus some safety factor), but rather are chosen for mechanical robustness and longevity. Extremely small insulation thicknesses would suffice were it desired just to withstand, say, 600 V.

EXCESSIVE OHMIC HEATING

Gross overloads

Excessive overload can lead to fires, but this condition is much rarer than is an arcing fault. It can arise if either a circuit breaker is faulty, or a cable is used which is of much smaller gauge than is the rating of the circuit breaker. Both of these situations are uncommon. Ampacity ratings of wires and cables are conservative enough that an overload of roughly 2× is not expected to create any significant problems, at least in the short term (long-term thermal degradation of insulation material is a separate issue). CPSC, however, has attributed some fires due to the use of 18 AWG extension cords* (rated at 10 A) in circuits protected by 20 A circuit protection devices[522]. In the case of a gross overload, CPSC found that a fire occurred where two refrigerators were plugged into a cube tap rated at 660 W; illustrating the long-term degradation issue, the fire happened only after 10 years of use. Another fire was investigated by NIST[521,786], where the cause was determined to be the use of steel-wire nonmetallic-sheathed cable in the 1948-vintage house. The branch-circuit wiring had functioned successfully until ca. 1980, when a window air conditioner was plugged into the outlet. The investigators speculated that some experimental cable had inadvertently been sold and used, and of course it did not have the same current-carrying capacity that a copper cable would have had. In addition, the 14 AWG cable was protected by a 20 A fuse, which would have been oversized even for a copper-wire circuit. Another fire originated in an attic space where a 14 AWG cable was found to be carrying 68 A. NIST investigation revealed that the homeowner had installed a 100 A subpanel, but fed it with a 14 AWG cable[786].

If a sufficiently overloaded condition persists, then cables may be able not just to ignite, but to create a propagating, self-sustained fire. Yamamoto et al.[787] investigated this situation. In testing Japanese cables, they found that for a self-sustained ignition to occur, an overload of 6× the rated

* The current edition of UL 817 requires that extension cords be a minimum of 16 AWG (rated at 13 A).

current had to occur for small gauge (3.5 mm^2) low voltage PVC cables, 5× for 600 V rated 200 mm^2 PVC power cables, and 3 – 4× for high voltage 200 mm^2 cross-linked polyethylene cables. In British tests[788] on a PVC extension cord rated at 7.8 A, fire occurred when a current of 55 A was passed through it, giving a ratio of 7×. This took 810 s to occur, and higher overloads resulted in fire occurring at shorter times. Gray et al.[789] tested extension cords rated at 5 A and found that a current of 35 A was needed for ignition, giving a ratio of 7×. At that current, ignition took 130 – 180 s. A thin (1 mm) PVC-insulated wire will ignite if sufficient current is passed through it to heat it to ca. 225ºC[768].

A test laboratory incident has been reported[665] where a PVC-insulated cable (ampacity = 19 A) was used to feed an electric heater drawing 60 A. The cable was hot, but still touchable, yet when it was accidentally stepped upon, a parallel arc resulted, and the arcing propagated about 3 m in less than 2 s. The insulation between the conductors was fully destroyed, but the rest of the material was not destroyed in the event, which comprised arcing but not flaming.

A moderate overload will not ignite an insulated wire, but it does raise the temperature of both the wire and the insulator. Old-style rubber-insulated wires used to be prone to a *sleeving* effect, whereby insulation closest to the wire is thermally degraded and shrinks back from the conductor. If sleeving is found, it can imply that overload conditions existed. For wires insulated with thermoplastic insulation* (which included the majority of today's common cable types), a somewhat different effect is found. Elevated temperatures cause copper to elongate, but the insulation to shrink. As a result, copper wires readily 'pop out' of the softened insulation (Color Plate 105). A direct metallic contact can then occur, with this short circuit being a localized place of ignition (Color Plate 106). Mazer[790] has provided some brief accounts of overcurrent experiments where ignition was preceded by short-circuiting.

Ignition in the excessive-overload mode cannot occur if the cable is in a circuit which is protected by a circuit breaker/fuse matched to the rating of the cable, since tripping would occur rapidly under 3× and greater overloads. But ignitions can readily occur if a much smaller gauge cable is used than corresponds to the rating of the circuit breaker. Béland[791] was able to get arcing to occur when nonmetallic sheathed 14 AWG cables, rated for 12 A, were used to carry very high currents (Figure 52). For the old style of cable

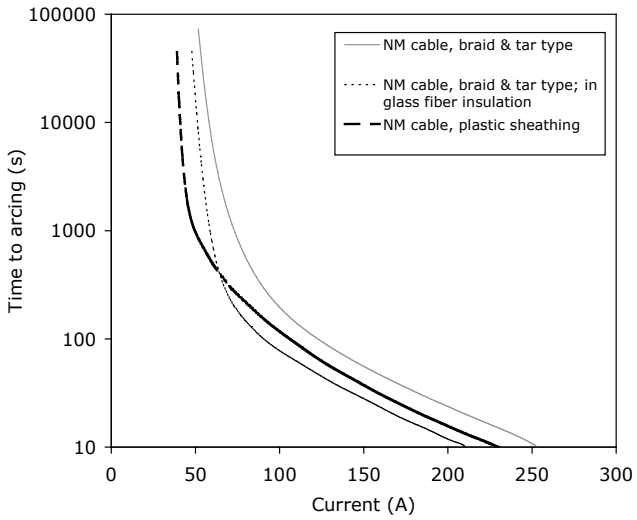

Figure 52 Time to arcing for AWG 14/2 cables with 125 V applied
(Copyright NFPA, used by permission)

which uses a braid with tar, arcing occurred at about 400ºC; for PVC constructions, at about 200ºC. In an attempt to produce an ignition of the building structure, Béland constructed a wall stud cavity, filled with thermal insulation, in which he ran an AWG 14/2 NM cable[792]. An equilibrium temperature of 370ºC was reached with 50 A. With 75 A, 520ºC was reached after 20 min, but the temperature was still climbing. Charring, but not flaming was seen, due to absence of oxygen entry into the cavity.

Excessive thermal insulation

The current required to cause sustained ignition will be less if the cable is buried in thermal insulation, where access to oxygen exists, but dissipation of heat is retarded. Béland[805] reports of a fire incident where a 12 AWG aluminum wire cable, rated for 15 A but fused at 30 A, was run for a long time at about the 30 A level, and was covered by combustible insulation. Eventually, a fire ensued. Béland also reported on arcing induced by placing an 18 AWG extension cord between a carpet and a carpet pad and running large currents through it[792]. At a borderline value of 21.5 A, no arcing occurred until the carpet was walked upon; when it was, arcing started. For a current of 27 A, arcing started in 8 min, without walking. The original data points were not provided, but Béland stated that in some cases, at a current of 40 – 50 A, it took "many days" for arcing to occur. Color Plate 107 shows a situation where a copper 14 AWG cable, rated for 15 A was run at 28 A and was covered with thermal insulation.

Theriault and Theriault[793] conducted studies on NM cables using a mockup stud cavity, framed in nominal 2"×4" studs, which was filled with mineral-wool insulation. 14 AWG cables were looped inside the cavity in various configurations to create more than one proximate path. When using

* The most common insulation for nonmetallic cable used in building wiring is PVC. The polymer is classified as a thermoplastic, i.e., a plastic which melts upon heating. Softening and melting is indeed what occurs due to medium-temperature (a few hundred °C) electric overcurrent. But if the cable is involved in a building fire (temperature of ca. 1000°C), the material typically intumesces and chars, rather than melting. The insulation normally contains not just pure PVC, but also various additives, including inorganic fillers such as calcium carbonate. These play a role in promoting high-temperature charring.

the Code-permitted 15 A current through the cables, a maximum temperature of 38ºC was recorded. Under the same conditions, but when the mineral-wool insulation was overpacked by installing twice the thickness intended for the cavity, a maximum temperature of 74ºC was recorded. This was high enough to perhaps shorten the lifetime of the cable, but not an immediate danger. The tests were repeated using 30 A, as an illustration of abusive over-fusing of branch circuits. In that case, a peak temperature of 89ºC was found using the normal insulation thickness. In the case of overpacked insulation, short circuits terminated testing in each of the tested configurations. Recorded temperatures at the time of short circuit were generally 150 – 200ºC, but these values are not necessarily indicative of temperatures at the short-circuit location, since short-circuits did not necessarily occur in those places where the thermocouples were mounted.

Table 71 Temperatures (ºC) recorded on the conductor surface of NM cables after 6 h of test in a wood-stud wall space

Wire size, AWG	No. of adjacent cables	Current (A)	No insulation	Fiber-glass	Poly-urethane
14	1	15 A (100% of rating)			173
	2				245
	3				294
	4				332
	1	18 A (120% of rating)			195
	2				308
	3				390
	4				417
12	1	20 A (100% of rating)			236
	2				267
	3				265
	4				290
	1	24 A (120% of rating)	114	131	
	2		131	206	
	3		141	211	
	4		146	215	

Heat dissipation is diminished if wires are bundled or grouped so that each wire is exposed to other wires also overheating, rather than to an environment where convective cooling is effective[772]. Several electric cables are commonly run next to each other in wiring of houses. The studies of Theriault involved some overlap and adjacency, but not much. Much higher temperatures were recorded by Goodson et al.[794] (Table 71). They conducted wall-cavity tests similar to Theriault, but Goodson used cables which were placed adjacent to each other for the entire length of the test jig. Goodson's tests used 90ºC-rated NM cables, placed in a cavity framed in by 2"×4" studs, with plywood on the other faces. The pertinent standard (UL 489[795]) does not require that a circuit breaker ever trip at its rated capacity, and only require tripping in 1 hour at 135% of the rating. Thus, Goodson conducted tests at 100% and 120% of the cable's rating, since a circuit breaker within its specifications would not be expected to trip at either of these levels. Table 71 shows that at 120% of rated ampacity, no thermal insulation, and no other nearby cables, a temperature of 114ºC was reached. This is not surprising for a cable rated at 90ºC when running a current of 100% of ampacity. Much more troubling are the results for cavities filled with polyurethane foam (for which Goodson used a foam-in-place product), since temperatures over 200ºC will lead to very rapid degradation. Goodson noted that his investigation was motivated by observing a house during construction where charring damage was already found on the insulation of NM cables. Likewise, his tests showed that for the cases of runs with 3 and 4 adjacent cables, actual charring was generally achieved during a 6 h run. His findings are especially troubling because a householder would have no way of knowing that a circuit is running at modestly overloaded conditions, since the circuit breaker will not trip. It should be noted that the NEC permits engineering calculations of ampacity derating, performed to reflect the actual thermal environment, but such calculations are almost never done except for industrial occupancies.

Prior to World War II, knob-and-tube wiring was common in the US. This form of wiring uses two separate conductors which are not grouped into a cable, but are individually strung on widely-spaced porcelain knobs. The current-carrying capacity of this form of wiring is dependent on there being unobstructed air cooling of the wires. Fires have occurred when the wires were buried in thermal insulation[522]. A similar problem can be encountered when extension cords, which are rated for exposed-air use, are buried under thermally-insulating objects.

Extension cords wrapped in cord reels or placed under rugs have much reduced dissipation of heat; see the sections below on *Appliance cords and extension cords* and *Impaired cooling*.

Stray currents and ground faults

Stray currents occur when circumstances cause current to flow through paths not intended to carry current. Ground faults are a well-known example[796,797]. They can occur if a conductor is abraded or damaged and contacts metal siding, roofing, etc. Jackson[798] described a particularly interesting case where an outlet was miswired so that the line and neutral conductors were switched. This would ordinarily not cause any problems, except in this case a heavy-duty extension cord was equipped with a separate grounding lug, intended to be fastened to an outlet plate screw. Instead, the lug contacted the 'neutral' prong of the plug, which was actually the line side. The extension cord fed a window air conditioner, and the spurious connection applied line voltage to the air conditioner housing. The latter, in turn, was

contacting the aluminum siding of the house. Current flowing over a high-resistance path through the siding ignited a wood-fiber sheathing board.

Kinoshita et al.[799] documented that only 5 A were required for ignition when a 3-conductor, PVC-insulated cable contacted a galvanized iron roof. In a limited study, voltage drops of around 1 – 5 V at each casual metal-to-metal contact were found when various metallic objects not of normal electrical function were inserted in series with a 120 V branch circuit[800]. In these laboratory experiments, it was difficult to find adventitious conductive components having enough resistance that a circuit breaker would not be rapidly tripped when the test arrangement was inserted in parallel across the line, instead of in series with a load. Nabours[801] has pointed out that fires are sometimes caused by improper wiring whereby an electrical conduit was pressed into duty as the neutral conductor, with a proper wire for that purpose not being provided. The load-carrying capacity of the conduit itself might be adequate, but connections are the weak point. On occasion, set-screw type couplings have been found where the set-screws were not tightened and the conduit itself fell out of good contact with the coupling, causing arcing at that location. CPSC has hypothesized that the Beverly Hills Supper Club fire, one of the deadliest US fires of the 20th century, was made possible by improper wiring of the neutral conductors and triggered by a ground fault that occurred[802].

An unusual mode of ignition from a ground fault is where current flows through a gas line. The current can cause overheating of the metal and lead to a rupture of the pipe[803]. Color Plate 108 shows such an outcome.

Another interesting type of ground fault was described in an incident where a downed power line contacted a corrugated steel fence[804]. Four different fires erupted in four buildings near the fence line. In each case, the fire started at the dielectric union installed ahead of the gas meter (Color Plate 109). A dielectric union is used to prevent galvanic corrosion of dissimilar metals. In this case, breakdown occurred across the dielectrics due to the high voltage (12 kV) of the power line.

In cold climates, it is not rare for individuals to thaw a frozen water pipe by attaching a welding transformer and passing current through it. Fires have resulted due the very large currents that are involved[805]. Sanderson[806] studied a case where thawing activity did not ignite the house that was being worked on, but caused ignition in six neighboring houses fed from the same power utility connection.

If a building has conductive components throughout it, such as metal lath, aluminum siding, etc., an electric fault can result in an *electrified house*. One case was already described above. Color Plate 110 shows how electrical contact with plaster mesh led to multiple ignitions of building paper and wood members. In another case[807], a 7620 VAC power line fell down and established contact with a house having aluminum siding. This ignited various locations having electrical contact to the siding. An additional consequence was that electric current also flowed through the water meter, blowing it out and creating a flood in the basement. In a similar case, a power line contacted a chain-link fence which was in contact with the aluminum siding of the house. In addition to fire damage (Color Plate 111), an explosion also resulted due to current flow induced in the gas piping.

Overvoltage and floating neutrals

All indications are that ignition from an overvoltage is rare, as concerns branch-circuit wiring. The materials used for wires and wiring devices are well able to withstand the normal surges that are a regular event in a power distribution system. To experience ignitions, one of these events is generally needed:

(a) lightning strike;
(b) a large voltage spike;
(c) accidental delivery of high voltage into low voltage wiring, or large surges on high-voltage wiring causing unexpectedly high voltages on 120/240 V wiring; or
(d) a floating neutral.

Lightning strikes can result in massive ignitions, not just of wiring, but of all sorts of combustibles. The problem has generally not been studied in connection with 120/240 V wiring systems.

Surprisingly large voltage spikes can be found on 120/240 V systems. Without any overt fault conditions, simply the operation of a motor controller can create a 2000 – 3000 V spike[808]. It seems entirely probable that repeated power line surges are responsible for substantial degradation of wire insulation and electrical components that are nominally designed for no more than 600 V operation (albeit with large safety margins). But no systematic study exists on dielectric failures—from any cause—in 120/240 V systems. As a rough approximation, a 1 mm thickness of many dielectric solids can withstand about 20,000 V. Thus, in principle, the insulation thicknesses would have to be exceptionally small or the spike voltages very large for immediate failure to occur, however, cumulative degradation effects may come into play. Also failure might occur at points of pinched insulation or at other installation abnormalities.

Occasional fire reports are encountered where, due to some malfunction in the power distribution network, high voltage

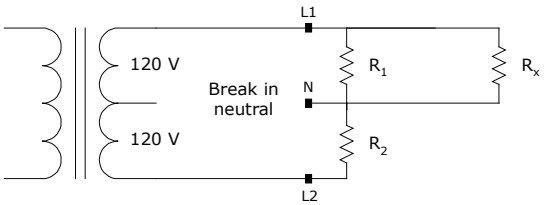

Figure 53 Floating neutral

got applied to wiring intended to carry only 120/240 V. A case is documented[809] where a utility transformer fault caused all the ground-fault circuit interrupter devices in a house to fail, along with igniting a fire due to an 'explosion' of a TV set. In another case, a faulty transformer caused the service entrance wires to ignite and burn inside a house. Such cases are rare enough that no systematic study exists.

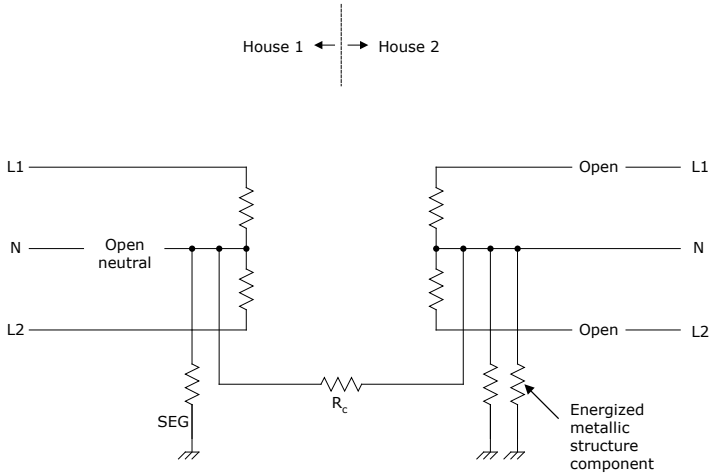

Figure 54 Ignition in house 2 (which had a pulled meter) due to open neutral in adjoining duplex house 1 (SEG = service entrance ground)

Floating neutral (sometimes called *open neutral*) problems are a bit less rare, but again, no systematic studies exist. This type of ignition occurs due to a specialized failure of 120/240 V wiring circuits[*]. In a single-phase service entrance, there are three current carrying wires: two 'hot' wires and one neutral. Figure 53 illustrates the normal feed from an outdoor transformer to the building. Inside the building, the system becomes effectively a 4-wire system, since a safety grounding wire is also run which is connected to the neutral and terminates at a ground rod[†]. All 240 V loads are directly connected across L1 and L2 and do not depend on the presence of the neutral. But 120 V loads are connected across N and either L1 or L2. If a neutral is in place, the loads will receive the intended 120 V voltage. However, if a break occurs in the neutral, the voltage delivered to 120 V loads can swing widely, in principle from barely above 0 to almost 240 V, although in practice the range is not quite as large. Figure 53 shows the circuit arrangement. The voltage present across a particular load R_x will be determined by the voltage divider action of other loads in the system, designated as R_1 and R_2. The voltage across R_x will be:

$$V_x = \frac{240}{1 + \frac{R_2}{R_1} + \frac{R_2}{R_x}}$$

Many electrical or electronic equipment can ignite if a voltage much in excess of the intended one is fed to it. Conversely, most devices will not ignite if the voltage delivered to them is too low. Electric motors, however, are an exception, and it has been experimentally demonstrated that flaming fires can result from motors running at a sufficiently under-voltage condition (see *Electric motors*).

An ignition due to under-voltage can also occur if one hot leg of a 240 V circuit is disconnected. If the circuit had any 240 V appliances and these are energized, then they can transfer power from the live leg to the disconnected leg. But the delivery will be through a sizeable resistance and much less than 120 V will be delivered.

The above discussion ignored the presence of the ground wire. According to the NEC, a 'grounding electrode' must be connected from the neutral to an earth ground at the service entrance. But, provided that the neutral is functioning properly, this ground wire serves no observable function. Consequently, there may be little to prevent its deterioration or abuse over the years. If a break in the neutral then occurs, a sizable current can flow through the ground wire. If the ground wire passes near or through combustibles, and an excess current ends up flowing through it, then an ignition might occur at that place. Fires have also been reported[810] in installations using armored cable, when a floating neutral occurred and current that would normally flow through the neutral instead flowed through the armor.

In rare cases, buildings with disconnected power (pulled meter) have sustained ignitions due to floating neutral problems[811]. Figure 54 shows how an open neutral in one house has led to an *energized neutral* in the second unit of a duplex and subsequent ignition. An open neutral exists is House 1, while the meter has been removed in House 2. Because of the break, the house-side of the neutral in House 1 has risen to a voltage substantially above 0 V. Because of high resistance in the service entrance grounds, current flows along the metallic power distribution conduit from House 1 to House 2, denoted as R_c. In House 2, the electrical conduit is touching metallic stucco mesh, which in turn has a path to ground. Consequently, a circuit is established for current to flow through the stucco mesh and ignition occurs at a poor connection along that path.

Harmonic distortion or overload

If a facility uses primarily 3-phase, non-electronic loads, then voltage and current waveforms generally remain close to the expected shape, a sine-wave. But some current-using devices are not constantly 'on' during an entire power cycle, for example:

- solid-state motor controls and variable-speed drives
- 'high-frequency' type power supplies for computer or electronic equipment
- electronic ballasts for fluorescent lighting fixtures

[*] The discussion here is based on electrical practice in North America.
[†] Mobile homes normally have a 4-wire service from pole to building.

The consequence is that the current and voltage waveforms in that circuit become distorted from a true sine-wave shape, a process termed harmonic distortion. Since the network is interconnected, this distortion then propagates to other parts of the network. The distortion is termed *harmonic* since any alteration of a sine wave produces a waveform which can be represented as the summation of a series of sine waves that includes the primary (the original sine-wave) frequency, plus additional frequencies that are harmonics (i.e., frequencies equal to 2×, 3×, etc. times the primary).

Harmonic overload of the neutral conductor can take place if a system was designed for balanced, 3-phase loads initially, but waveform-distorting devices are subsequently hooked up. In a 3-phase system, the neutral does not need to carry much load, so a small-diameter wire can safely be used *if* harmonic distortion is not present. But in distorted-waveform networks, current flows up to 173% of the phase-conductor current can flow in the neutral[812]. If the neutral is under-sized, it may overheat or melt out, leading to possible ignition. If the neutral does open up, then floating-neutral problems can follow.

A high harmonic content can also cause overheating and failure of transformers. Transformers that are especially designed to withstand high harmonic-content conditions are termed 'K-rated' transformers, with the term coming from a calculational procedure used by UL for testing transformers[813]. K-rated transformers have the drawback of a higher inrush current, which by itself can lead to other problems. IEEE Std-579[814] is a standard on the subject of harmonic distortion.

IGNITION FROM EXTERNAL HEATING

Barnes et al.[815] reported on a series of extensive tests of wire and cables and also on tests using the plaques of the polymer material alone (not made up into wires). The specimen identifications are given in Table 72. Results from a variety of ignition tests are shown in Table 73. The glow-wire tests were conducted according to IEC 60695-2-1; the needle flame tests were according to IEC 60695-2-2. Most tests were run on 1 and 3 mm samples, but the UL 94 tests were also run on 2 mm plaques. Radiant ignition results are shown in Table 74. With the exception of the PTFE specimen (which required about 35 kW m^{-2}), all other samples

NI – no ignition

showed a minimum flux for ignition in the vicinity of 15 kW m^{-2}.

Meyer et al. [816] reported on extensive small-flame tests conducted on a wide variety of wires and cables. They conducted tests in both vertical and horizontal orientation, but according to a protocol which did not follow any existing standards.

Some Cone Calorimeter data on ignition of electric cables were reported by Nakagawa[817], as shown in Table 75. The effect of FR formulations can be seen to prevent ignition at lower irradiance values. The results, however, do not indicate that the FR formulations were particularly effective in delaying ignition at irradiance values over the minimum required for ignition.

Table 75 Piloted ignition times for electric cables by Nakagawa

Wire insulation	Jacket	Ignition time (s) at specified flux (kW m^{-2})			
		20	30	40	50

PO – polyolefin
XLPE – crosslinked polyethylene

Andersson and Van Hees[818] exposed 4 types of data cables and power cables to Cone Calorimeter heating to determine heat flux levels needed to cause electric failure in the form of short-circuiting. The test cables were all multiconductor types, ranging from 24 conductors of 0.5 mm^2 to 7 conductors of 2.5 mm^2, with the insulation types used being PVC, polyolefin, and XLPE. For exposures of 1200 s or greater (but test time of 4800 s or less), 10 – 20 kW m^{-2} was needed to cause failure. For shorter times, higher fluxes could be withstood. During a 600 s exposure, typically 15 – 40 kW m^{-2} was needed for failure. Repeatability was generally very poor—identical tests often gave different results. This is presumably because short-circuiting involves mechanical contact between the conductors, but this is determined both by the stresses in the conductors and by the exact details of the melting of the polymer. Some tests were made to examine the effect of deliberately bending the cable prior to test, but the results were inconclusive. Generally, no current leakage was measured until shorting occurred. Visible damage (melting, or even insulation totally melting away in a portion of the cable) occurred in all cases before electric shorting. Ignition commonly occurred at the time of shorting, provided the heat flux was $\geq$ 15 kW m^{-2}. Sometimes ignition did not occur upon shorting and occasionally it occurred a short time before shorting. Typical ignition times for cables with a polyolefin were 103 s at 35 kW m^{-2} and 48 s at 50 kW m^{-2}. PVC-jacketed cables ignited more quickly: 21 – 32 s and 10 – 11 s, respectively. The test work involved both unloaded cables and cables carrying a 5.3 A current, but no significant difference between these two conditions was found. A few 'old' cables, one approximately 15 years old and one 20 years were also tested, but the results did not show a significant difference.

Bertrand et al.[819] ran room fire tests on PVC-insulated and jacketed cables arranged in full-scale cable trays. For tests of 1 h duration, cables short-circuited when their temperature reached 215 – 250ºC, which required a mean heat flux of only 5.3 – 5.4 kW m^{-2}. The failures occurred because at approximately 220ºC PVC softens sufficiently that mechanical stresses can move conductors into contact with each other. They then ran oven tests on individual cables and found that in a 250ºC oven short-circuiting occurred in 15 – 20 min. When tested in a 400ºC oven, however, the specimens ignited prior to short-circuiting.

Hoffmann et al.[820] conducted both radiant heat and flame tests on power cords using SPT-1 and SPT-2 type stranded, two-conductor cords. SPT-1 is 20 or 18 AWG and has 0.76 mm min. thermoplastic insulation thickness, while SPT-2 type is 18 or 16 AWG with 1.14 mm min. insulation thickness. The SPT-1 cords were also tested in a variant where a separate jacket is used, while the SPT-2 types were only tested as 'zip' cords. All radiant heat tests were at 40 kW m^{-2} irradiance, while flames were applied from a gas burner or from a wood crib. Electrical load on the cables was a 15 W lamp. When a section approximately 175 mm long was irradiated, 58% showed no electrical failure (shorting or opening), 25% tripped a 15 A circuit breaker, while 22% severed completely; less damage was recorded in another test series, where a shorter section of cord received 40 kW m^{-2} radiation. Times to failure when exposed to the radiant heat were typically 4 – 8 minutes. When a gas flame was applied to cords, 86% showed electrical failure (shorting or opening), 83% tripped the circuit breaker, while 27% severed completely. Times to failure were typically ca. 1 minute, but as short as 23 s for one type of test cord. When subjected to a wood crib fire, 100% of the test specimens showed electrical failure, 83% tripped the circuit breaker, while 22% severed completely. Failure times were longer, however, being typically 2 – 4 minutes. Severed conductors typically showed a bead at the ends (Color Plate 112 and Color Plate 113). Some cords showed arcing damage at multiple places along the length. The authors also noted that when exposed to radiant heat, some cables ignited but did not fail electrically, but did not provide details on specimen ignitions. Hagimoto et al.[821] also conducted radiant heating tests on a variety of cords and cables. They found that a wide spacing (8 mm) between conductors was helpful to avoiding initiation of arc tracking with PVC cords, but that there was little effect of the spacing on the behavior of rubber-insulated cords. Increasing the overall insulation thickness of rubber-insulated was helpful, however, and cords with 2.5 mm thick insulation proved to be resistant to arc tracking, even at the highest flux used, 40 kW m^{-2}.

Additional radiant ignition tests were reported by Factory Mutual[822,823], as shown in Table 76. The minimum heat flux values were not reported, but in most cases the heat fluxes were incremented by units of 5 kW m^{-2}. Thus, if the highest heat flux at which no ignition was observed was 20 kW m^{-2}, and the lowest heat flux at which ignition was observed was 25 kW m^{-2}, it would be concluded that $\dot{q}''_{\min} = 22.5$ kW m^{-2}.

Hasegawa et al.[824,825] examined a number of electric cables in a radiative heating apparatus where an impinging pilot was used. Minimum heat fluxes for ignition were found as shown in Table 77.

Electric cables generally behave so that, at room temperature, if a small flame applied directly to the cable, it does not lead to a propagating fire. But experience indicates that if the temperature of a PVC cable is raised to 60 – 100ºC, then propagation will occur. A limited amount of published

research also exists on the topic. In Sandia tests[826] (described in Chapter 11), where a glowing connection was simulated, it was also found that fire does not spread along non-preheated building wires. But when as little as 50 W was used to preheat a wire connection for 10 min, subsequent ignition allowed extensive fire propagation. Several studies where small-flame tests were conducted on wires/cables at elevated temperatures have been discussed in Chapter 7.

In actual fire incidents, there can be a wide variety of external heating circumstances that ignite electrical wiring. In one case studied by NIST[786], it was found that fire originated in branch circuit wiring midway between two outlets. Investigation showed that one side of the wall cavity was formed by the backside of a brick fireplace, which was being intensively used and led to ignition of the nonmetallic cable.

A European research project on large-scale fire testing of electric wires and cables also entailed collecting ignition data for a wide variety of specimens, as tested in the Cone Calorimeter[827]. Piloted ignition data at 35, 50, and 75 kW m^{-2} were reported. Ignition times at 35 kW m^{-2} ranged from 21 to 304 s, while at 75 kW m^{-2} the specimens ignited in 4 – 50 s. The authors also provided results from analyzing the data according to Janssens' thermally-thick procedure, but the applicability of the method is uncertain since the specimens may not be thermally-thick, they are invariably complex composites (including copper layers), and only 3 heat flux values were available.

CONTRIBUTORY FACTORS

MECHANICAL INJURY

Mechanical injury to wiring may be caused by any number of sources. CPSC identified[522] some interesting cases where a nonmetallic-sheathed cable had been draped against vibrating metal ducts. In time, the vibration caused the insulation to wear through and a fire to occur.

Major damage can be inflicted on wiring and other electrical installations by *vermin infestation*, e.g., rodents, snakes, insects. During the early part of the 20th century, 'rats chewing wires' became infamous as a fire cause determination by sloppy fire investigators. Consequently, this cause of fires was subsequently sometimes considered to be a myth. Yet, fires can start from rats chewing wires. It has also been sometimes considered that rodents will chew cotton-fabric insulation, but will not attack modern plastic insulations. This is incorrect, as shown in Color Plate 114. Even though ants are much smaller, the damage they can inflict can be disproportionate to their size, as shown in Color Plate 115. Fire ants are especially prone to causing damage to wiring. Both the bodies and the feces of vermin have sufficient electrical conductivity to create an electric fault; in the case of insulation chewed from wires, direct metallic contact also becomes possible.

Hosaka[828] established a flow chart of possibilities leading to ignition due to rodents (Figure 55). He then conducted laboratory experiments to quantify the phenomenon. In the first series of tests, he placed rats in a cage and supplied them with food and water *ad libitum*. He also enclosed samples of six different types of non-energized cables and 5 different types of stranded-conductor cords in the same cage. After a 10 day period, the weight of the wire insulation of the cables that remained was only about 10 – 40% of the original weight. For the cords, he was unable to measure the remaining weight of the wire insulation, since the stranded conductors were also being chewed and dispersed; using the gross weight of the assemblies, he found that the weight remaining ranged between 20 and 65%. He then conducted an arc tracking test on a partly-chewed cable containing two 1.6 mm conductors by energizing it in a 100 VAC circuit and applying one drop of rat urine to the damaged location every 30 s. Short-circuit current was limited to 10 A by a series resistance of 10 Ω. The specimen (Figure 56) showed sustained ignition in about 3.5 h.

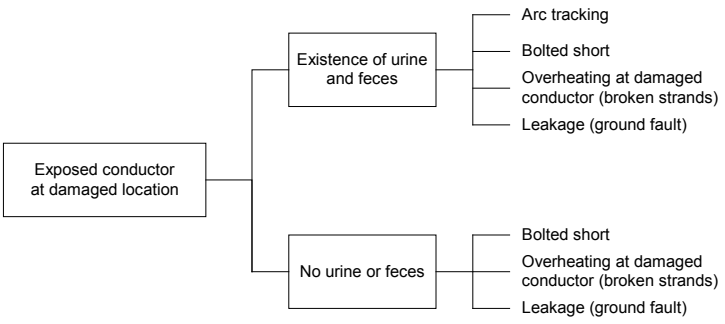

Figure 55 Flow chart of ignition possibilities upon rodent damage of an electrical cord or cable

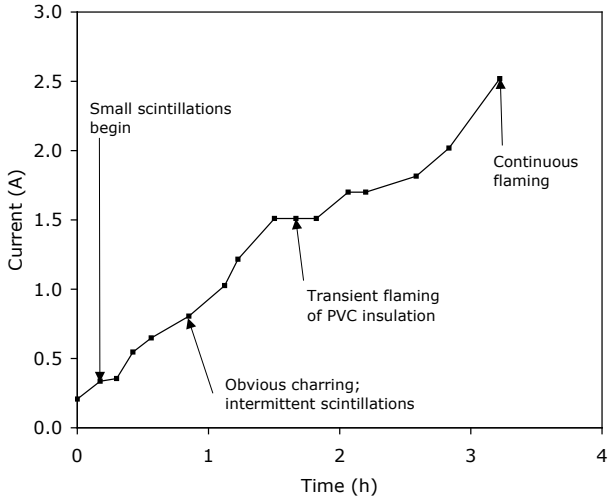

Figure 56 Arc tracking of a cable damaged by chewing of rats

Solid conductors—parallel arcing

Béland reports conducting numerous tests where cables, armored cables, and conduits were hammered until the circuit breaker opened[829]. These produced minimal mechanical sparks and could never ignite wood. In some cases loose fibers from wood fiberboard insulation could be ignited, however. He also reports that simply bringing two bare conductors together until a short resulted created even less propensity for ignition than did hammering. On the other hand, Kinoshita et al.[830] successfully ignited cotton gauze when creating bolted shorts with wires having 1.6 mm diameter solid conductors and also with ones using 1.25 mm^2 stranded conductors. In their experiments, this required a thermal-mode-only, 20 A circuit breaker; when using a 20 A thermal/magnetic breaker, ignitions were not observed. Clearly, it is difficult, but not impossible to start a fire from parallel arcing in a 120 VAC branch circuit. (See also: *Overdriven staples*).

Solid conductors—series arcing

Roberts[831] created series arcing by severing a conductor in a 14 AWG nonmetallic cable with a nail. Ignition of the cable and charring of the adjoining wood stud resulted. The fire self-extinguished after "a few minutes." This self-extinguishing might not happen if the cable were covered in a layer of dust or if other finely-divided combustibles were present. In another test, he was able to get self-sustained smoldering of the wood member, which he eventually manually extinguished. In a test using 12 AWG nonmetallic cable, he was able to get an arc which sustained itself for 1.25 h before the wire melted and the arc self-extinguished; however, in that test suitable ignition targets were not present. In none of the tests did the circuit breaker trip. Béland[829] also reported on similar experiments, but with negative results. Evidently, the probability of ignition is not so large for the severed-by-a-nail scenario.

Without an overload condition, solid conductors that are merely nicked or gouged, and not severed, are unlikely to lead to overheating conditions, much less ignition[832,833]; see however the discussion on the 'last-strand' problem for stranded conductors. If a sufficient overload is sustained, however, to cause wiring to melt, melting and arcing are expected to first occur at the reduced-section location.

Stranded conductors—parallel arcing

Nishida[834] found that cotton and paper (but not PVC) can be ignited when a single 0.18 mm strand contacts a strand from the other leg of a cable. In that case, the ignition was found to occur due to the high temperature reached by the strand and not through spark energy. A maximum of 35 J could be delivered through a short circuit of this type, but 0.3 J was found to suffice for the ignition of cotton.

The cutting of an energized electrical cord by an electric saw can result in ignition of nearby combustibles having a low thermal inertia. UL has a 'guillotine' test which simulates a sawing accident[757]. Cheesecloth is placed nearby as the ignition target. (See also: *Short circuits*).

Stranded conductors—series arcing (last strand problem)

Stranded wires used in power supply cords and extension cords are sometimes subject to abuse, leading to breakage and separation of conductor strands. This can occur due to various forms of mechanical damage, one specific case being the connection of wires into a male plug (see above). A stranded cord will overheat if strands are broken due to excessive bending and current is being carried by the last remaining strand. Color Plate 116 illustrates a cord on an electric foot warmer that failed after being used for only a few months.

Mitsuhashi et al.[835] conducted bending experiments where two types of stranded cords were repeatedly bent by 90º while under a tension load. The PVC-insulated cords were of the type SPT-1 and had 30×0.18 mm strands (rated 7 A) and 50×0.18 mm strands (rated 12 A). After the first 10% of strands were broken, the rate of breakage accelerated dramatically. It took about 900 cycles to break all except 1 strand on the 30-strand cord and about 1200 cycles on the 50-strand cord. For a one-remaining-strand condition to be

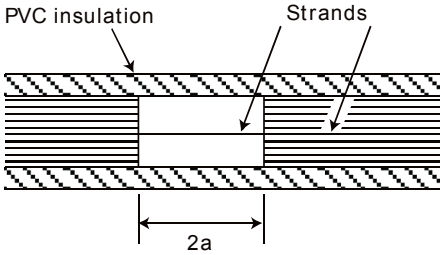

Figure 57 Geometry for last-strand failure

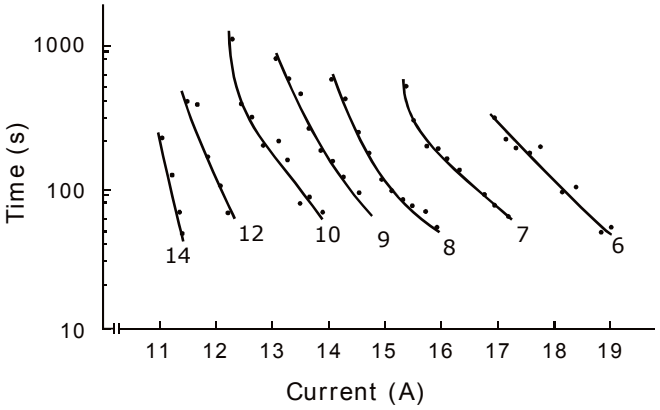

Figure 58 Relation between time and current needed for ignition of PVC to occur; numbers on curves refer to gap spacing (mm)

obtained, it was necessary to limit the tension so that the gap created at the broken strands (Figure 57) was 5 mm or less; otherwise all strands broke, rather than all-but-one. The PVC insulation was not degraded after the breaking was completed, as measured by a 5 kV DC dielectric withstand test. The authors then set up a last-strand-remaining experiment where AC current of 5 to 30 A was passed through the cord. It was found that ignition of the PVC insulation occurred only if the current was between 10 and 20 A. Currents smaller than 10 A equilibrated to steady-state temperatures of 100ºC or less and did not lead to fusing of the strand and ignition of the PVC. Conversely, currents over 20 A caused a rapid fusion of the strand, and consequently did not deliver sufficient energy into the already-broken strands to raise their temperature sufficiently to ignite the PVC.

The regions of ignition and non-ignition are shown in Figure 59. It is found necessary that the bulk copper temperature be raised above 100ºC during the overheating period, and that the last-remaining strand fuse and raise the temperature briefly to over 450ºC. The sequence of events for that strand, of course is: overheating → fusing → arcing → stopping of current flow. The ignition occurs initially at only a tiny spot, but because a certain portion of the cord has been preheated to over 100ºC, rapid flame spread can occur away from the ignition location. Conversely, if the cord has not been preheated to at least 100ºC, then only a tiny localized ignition—but no propagation—is possible. The authors did further heat transfer modeling and concluded that a gap of at least 1 mm is needed for ignition to occur.

Nagata also conducted experiments and theoretical modeling on the last-strand problem[836] (Figure 57). His experiments showed that heating of the PVC insulation proceeds in two steps: (1) gradual heating to about 100ºC due to excess current flowing through the remaining strand; and (2) abrupt heating due to explosion of the strand, with ignition of the PVC occurring at about 550ºC. His experimental results are shown in Figure 58. The least current is required at large gap spacings, since heat losses become smaller. However, as noted above, in their experiments, Mitsuhashi et al. found it impossible to create gap distances greater than 5 mm where one strand still remained. Clearly, they did not explore all mechanical deformation possibilities, so larger gap distances must still be considered as possible, although less probable. For such larger gaps, Nagata's results can offer guidance. In practice, it must not be concluded that ignitions will be limited to the current values reported by Mitsuhashi or Nagata, since other variables may well come into play; for example, in actual fires a portion of the cord is often placed against a surface rather than being suspended in air. Thus, the research results should be viewed only as qualitative guidance.

The UL standard for electric cords, UL 817[748], includes a 'mechanical drop' test which is done for 1300 cycles and an 'abrupt pull' test which is done for 5 cycles. Series-arc ignitions occur in the UL 'rotational flexing' test[757], where a stranded electrical cord is rotated enough times that one of the conductors suffers a break. Cheesecloth is the ignition target in that test.

Excessive pressure and creep of insulation

Plastics which are flexible enough to use as wire insulation show appreciable creep. That is, if a significant load is continuously applied, the plastic will exhibit cold-flow and the loaded section will permanently deform[837]. A cable which is pinched, by whatever means, might deform sufficiently over time that the insulation loses enough thickness so that failure occurs. The pinching can be an overdriven staple, an appliance leg improperly placed on top of a cord, a plastic cable tie excessively tightened around a bundle of wires,

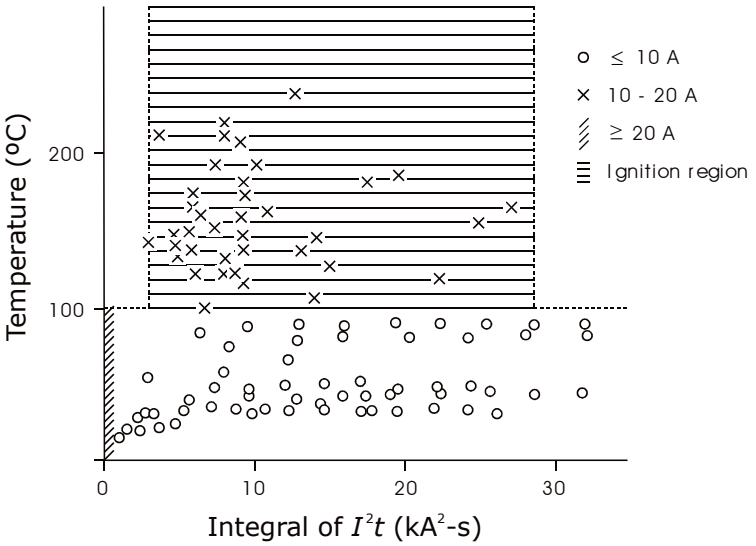

Figure 59 Ignition and non-ignition regions by fusing of the last-remaining strand

etc. CPSC[522] found a number of fires due to extension cords being pinched in doorways and other situations where a continued force was applied to the cord, but details were not documented.

The breakdown voltage of any insulator is dependent on the thickness. If the plastic insulation separating two conductors eventually gets thin enough that the breakdown voltage is lower than the actual voltage of the circuit, an arcing failure can occur. Matters are complicated by the fact that creep itself actually changes the electrical properties of the insulator, apart from the gross change in geometry[838]. Perhaps more likely is that sustained creep would cause a direct contact by a single wire strand with the opposing conductor. Such a fault would quickly be relieved by melting out of the strand but, in the meantime, high temperatures would be presented to the wire insulation. This could cause sufficient carbonizing of the insulation that arc tracking could be initiated. It has also recently been recognized[839] that excessive mechanical stress can lead to 'dielectric treeing' and eventually to gross failure. Unfortunately, as with most studies of the mechanisms of dielectric failure, few results are available below the kilovolt range.

Ignitions, in fact, are not rare when a heavy furniture or appliance item is placed on a power cord or a cord is pinched by a door. In one case known to the author, a fire took place when a heavy wooden cabinet was accidentally placed over a length of an NM-type house-wiring cable which was used instead of a cord to power some appliances. NM cables have solid conductors, so evidently the phenomenon does not intrinsically require stranded conductors. But apart from one unpublished paper[840] where an abortive attempt was made to study creep in PVC cords, laboratory studies do not exist. If the forces are such that a conductor actually breaks, then ignition may be caused largely by arcing. But if the conductors do not separate, then insulation creep is a possible—but unproven—means by which the process leads to these ignitions.

Overdriven staples

The possible ignition modes involved when staples used to secure wiring are 'overdriven' or otherwise improperly installed are not all fully elucidated, but the following mechanisms must be considered:

1. A staple is driven in so one leg contacts the hot conductor and the other the ground. In that case, immediate short-circuiting will become evident the first time that the circuit is turned on.
2. A staple fully severs one conductor, and the staple itself now bridges the two severed ends. The steel-to-copper connection resulting is likely to be a high-resistance joint, and progressive heating can be expected. See *Overheating electrical connections* in Chapter 11.
3. A staple is driven so as to nearly, but not quite, squeeze out the insulation from both conductors. This is an insulation creep situation, and breakdown of insulation can be expected to occur after a prolonged time of cold flow, as discussed above.
4. The staple pierces insulation from both conductors, and one leg of the staple contacts one conductor, while the second leg comes very close to the second conductor. The connection is exposed to an adverse environment and arc tracking eventually occurs.

In addition to the direct mechanisms, there can be at least two environmental effects:

(a) differential settlement of the structure may eventually cause a direct contact to occur where originally a small clearance existed;
(b) thermal cycling of the cable may eventually cause a direct contact to occur where originally a small clearance existed.

Tests have been reported[841] where it was endeavored to prove that a fire cannot start from an overdriven staple. However, Brugger[842] conducted a test where a staple piercing an NM cable eventually led to fire (Color Plate 120). The delayed nature of these failures was clearly identified by CPSC, who documented fires from overdriven staples in field investigations[522]. Dixon discusses a case where it took 15 hours from the turning on of power to the initiation of fire at an overdriven staple[843]. He considers that this was largely accounted for by thermal effects. A case incident of a mobile home fire is illustrated in Color Plate 121.

Perhaps the most specific case history where creep alone was involved comes from Keleher[844]. This electrician reported two different cases of creep failure. His observations are especially valuable since he was also the electrician who originally installed the wiring that failed. In both cases, the cable was 14/3 or 12/3 type NM-B, 600 volt, 90ºC rated, using THHN wire insulation. The installations were unusual, however, in that (a) the circuits were carrying 240, not 120 VAC; and (b) they were protected by 2 A, fast-blow fuses. In the first case, the electrician was called because of a blown fuse. He found failures at 5 different staple locations. In each case, no external charring was found and no mechanical damage was found. But when the cable was slit open, a 50 – 100 mm length of wire insulation was found charred. The second case was similar, except that the fault and the charring were found inside a 1/2" clamp connector (2-screw type). The wire insulation of the black wire was charred and the wire had shorted to the bare ground wire. Inspection revealed that the original installation was properly made. The higher voltage, while well within the rating, makes an insulation failure more probable, while the fast-blow fuses prevented sustained combustion and allowed the evidence to be preserved.

Driving *nails* into electric cables can lead to similar consequences as staples. In some cases, even driving the nail in is not necessary. A fire originated at a power cord that was strung over a nail (Color Plate 117). The cord spanned about 1.5 m unsupported under a desk and had been in place about a year. The investigator concluded that the insu-

lation degraded due to the hanging and vibratory forces. Copper wire melted onto a nail does not necessarily indicate an arcing event, however, as shown in Color Plate 118.

POOR SPLICES OR TERMINATIONS

CPSC found that, in a flagrant violation of both regulations and good sense, a number of fires have been caused by amateurs who made connections to building wires by simply twisting two wires together, and not by soldering or using a twist-on connector[522]. Similarly, individuals sometimes repair electric cords simply by twisting the wires together and insulating them with electrical tape. This leads to a poor connection, and Hijikata and Ogawara[845] measured the characteristics of some splices of this type at currents of 10 – 20 A. They found that the temperature of the splice increased linearly with current, typically being 50 – 95ºC for 10 A, and going up to 130 – 300ºC at 20 A. The cords were made up of 30 strands, each 0.18 mm diameter. The resistance of the splice increased less drastically with current, going from 2 – 8 mΩ at 10 A to 3 – 12 mΩ at 20 A.

On rare occasions, fires have occurred due to inadvertent presence of *process splices* in a power cable. In the manufacturing of cables, it is necessary to join conductors as a spool becomes exhausted. This is done with a splice that is not intended to be current-carrying and will normally be chopped out before packaging into shorter spools of cable for sales. But occasionally a spliced cable gets sold and subsequently is used without proper inspection. The heating process is similar to that discussed above.

DEGRADATION AND AGING OF INSULATION

Wiring is sometimes incorrectly perceived as inert and stationary and, therefore, having an infinite lifetime. If electrical insulators are made from inorganic materials (e.g., ceramic), then their lifetime is essentially infinite, provided that they are not physically damaged and that contaminants are not deposited on their surface. But for low-voltage applications, the most common insulators are polymers, which are organic substances and having a finite lifetime. Apart from mechanical insult, degradation can proceed due to the effect of heat, chemical reaction, or applied electric field. Aging consists of slow, irreversible changes in the properties of a substance. Generally, aging in polymeric materials involves on or more of these chemical mechanisms:

- Oxidation—attack of the substance by oxygen molecules. This often leads to formation of acid groups that increase the conductivity of the material. With some polymers, oxidation also leads to unwanted cross-linking, creating a more brittle material.
- Hydrolysis—interaction of the substance with hydrogen or hydroxyl radicals, with the latter commonly originating from dissociation of water.
- Pyrolysis—degradation due to heat.
- Loss of plasticizer. Many pure polymers, e.g., PVC, are unusable as electrical wire insulation, since they are hard and brittle. Consequently, organic molecules generically known as plasticizers are added which improve the physical properties. With some polymers, during aging, the plasticizer is readily lost. This can then lead to mechanical failure of the insulation due to embrittlement.

The first three of these processes modifies the polymer by breaking bonds in various ways. The consequences can be that small molecules are formed and possibly released as a vapor. The remaining segments will show a poorer performance. The consequences of these chemical changes are typically[846,847]:

(a) increase in the dielectric loss factor;
(b) decrease of dielectric breakdown strength;
(c) decreased resistance to partial discharges associated with the phenomenon of dielectric treeing; and
(d) degradation of mechanical properties.

Polymer degradation due to an applied electric field has mostly been studied theoretically and in connection with high-voltage equipment. The book by Dissado and Fothergill[848] presents the current-day theories, but it presumes a familiarity with advanced chemistry and physics of the solid state and the authors also forthrightly admit that it is difficult to apply most theories towards understanding actual field failures. Leaving aside pure theory, laboratory aging studies on various polymeric insulation materials[848] typically show that if the applied electric field is less than about 1 – 5 MV m^{-1}, then life is 'infinite.' This kind of laboratory conclusion, however, does not help interpret failures or ignitions resulting therefrom.

Natural rubber insulation used in the first half of the 20th century was exceptionally susceptible to aging, and would tend to fail in a catastrophic way—sufficient cracking would develop so that pieces of insulation could fall off an insulated wire[576]. Modern plastic insulation is more resistant to aging and does not fail by falling off in chunks, thus, studying the ways in which it does fail has been more difficult. In an interesting experiment, modern PVC-insulated cables were boiled for 15 minutes, then re-tested for electrical failure under high load, but did not indicate any changes attributable to boiling[849].

In commercial specifications, the aging problem is normally approached rather indirectly. Lifetime is normally not assessed *per se*, but a 'rating' temperature is reported. The latter is determined by a test protocol where some variable, such as ultimate strength or AC breakdown strength is measured as a function of time and 'failure' is declared when the value has dropped below a certain limit. An extrapolation is then made, commonly to 20,000 hours, and the temperature at which the material is deemed to be able to survive for that period is declared to be its rating temperature. Dakin[850] originally showed that most degradation processes can be represented reasonably well by Arrhenius-form kinetics and that, most often, first-order kinetics was realistic. The consequence is that plots of a measurable property (e.g., tensile strength or breakdown strength) can

be made as straight lines—for a specified temperature—if time is plotted on a linear x-axis and the performance measure on a logarithmic y-axis. More commonly, a decrease of the property down to a certain value is arbitrarily defined as end-of-lifetime. In that case, if $1/T$ is plotted on a linear x-axis, where T = absolute temperature (K) and lifetime is plotted on a logarithmic y-axis, again straight-line plots can be made. Bruning and Campbell[851] provide a good summary of some of the theoretical concepts used in laboratory studies of insulation aging. Mathes[852] has described the history of industrial standards (e.g., IEC 60085[853], IEEE Std-1[854]) by which temperature classes are established for electrical insulation material.

From the point of view of understanding electrical failures, this process is unsatisfactory, since no failure is actually ever evaluated. In an end-use article made from this material, mechanical strength is rarely challenged, while insulation thickness is commonly vastly greater than the minimum that would be needed if it were sized according to the limiting-value breakdown strength. This is because other factors generally govern, for example, wire insulation thickness must be sufficient so that moderate mechanical abrasion does not cause short circuits. Bajpai and Marlin[855] surveyed existing methods used to analyze aging effects in electric wiring and components and found a plethora of theories but essentially no validated studies, where actual failures under operating conditions (as opposed to extreme test conditions) would have been observed. UL has a procedure of long-standing, UL 746B[856], for the evaluating thermal aspects of aging of polymeric materials; this involves medium-term testing, along with extrapolations. But there is no known study which relates performance measures used in that standard to electric failures that result in ignitions. UL themselves have pointed out that since laboratory aging tests often involve subjecting a polymer to temperatures above its glass transition temperature, while the in-use conditions would involve temperatures below this value, the degradation chemistry deduced from accelerated aging tests may be inapplicable[857]. On the other hand, many polymers have a glass transition temperature below room temperature, so this limitation would not apply. IEC has a multipart series of standards—IEC 60216—which is similar to UL 746B; it is understood that eventually the two organizations may harmonize these standards.

There is no modern study which actually examines aging effects in connection with fire incidents. A British study[858] found that in the pre-World-War-II era there was a statistical correlation between incidence of electrical fires and age of installation. However, wires of that era were insulated with materials quite different from those in use today, thus failure modes would hardly be comparable. A recent survey of aircraft wiring does at least help to illustrate the problem, see *Electrical wiring in aircraft*. The combustion products of a fire, especially HCl released from burning PVC, can attack electrical insulation chemically and prematurely shorten its lifetime. Dervos and Vassiliou[859] found that in some circumstance even comprehensive cleaning of surfaces exposed to fire smoke failed to restore electrical resistivity to acceptable values (while creating a visually 'clean' appearance).

As shown in Table 43, deterioration due to aging accounts for about 14% of US fires originating in the electrical distribution systems of residences. The majority of the deterioration involves thermal insulation of wires and cables, with age, heating (including sunlight), moisture, and mechanical wear being the dominant deterioration mechanisms. CPSC specifically identifies moisture as being a problem in service entrance cables. When a fault occurs allowing rain to enter into the service entrance cable or conduit, resulting degradation has been found to be the cause of some fires. Voltage spikes have been proposed as another means of degradation[860]. Apart from several studies where insulation was degraded at very high temperatures (discussed below), there has been no laboratory research on other degradation factors in the context of building wires. Much military and industrial test data exists on laboratory degradation of wires, but neither the wire types, nor the test protocols there are applicable to building wiring.

Stricker[861] noted that "although cable life has not been defined, a life expectancy of 20 to 50 years is reasonable." In a short-term aging program, he then examined 90ºC and 105ºC rated PVC-insulated cables. The specimens were all heating cables, thus, sufficient lifetime under elevated temperature conditions was presumably a design objective. Eight different types were tested, some without jacket, others with PVC or nylon jackets. Significant plasticizer loss occurred for all types when conditioned at 71 – 77ºC for approximately 1 month. Stricker interpreted the plasticizer loss as the end of useful life for the cables, although further electrical or thermal testing was not done. He concluded that none of the specimens should be operated at over 71ºC; this was in sharp contrast to the 90 – 105ºC temperatures for which the cables were rated.

Sandia National Laboratories conducted several studies on the thermal degradation of insulation. Chavez[862] examined the electrical failure of two cables as a function of oven heating. Electrical failure was considered to be a short circuit or a low-resistance condition developed across the line; experiments were not conducted to actually elicit ignitions. The two cables were a 12/3 cable with cross-linked polyethylene insulation and a 12/3 cable with polyethylene/PVC wire insulation and PVC jacket. His results are given in Table 78.

Lukens[863] conducted limited testing on a 3-conductor, 12 AWG cable using polyethylene/PVC wire insulation and a PVC jacket. In short-term oven testing, no short circuits occurred in a 60 min test at 130ºC; 10% of specimens short-circuited when exposed to 150ºC for 60 min; 25% exposed to 170ºC for 30 min; and 33% exposed to 170ºC for 60 min. The test arrangement was not designed to elicit overt ignitions, since negligible current was passed through the conductors. In another Sandia study[864], the combined effects of thermal and nuclear radiation aging was examined on a series of electric cables. In complementary testing, the effect of submersion in an alkaline water solution was also explored. Neither electric failures nor overt ignitions were studied, with the only variables examined being the resistance and dielectric strength of the insulation. In yet another Sandia study[865], cables were subjected to accelerated aging at 125 – 150ºC, followed by high-temperature testing. In the high-temperature testing portion, cables were energized and failed electrically, leading to ignition of the insulating materials. The results indicated that the effect of the lower-temperature aging was small-to-insignificant. In the high-temperature tests, failure occurred at about 425ºC for a 10 min exposure, dropping to 330 – 365ºC for a 75 min exposure.

When recessed ceiling lighting fixtures are used that are intended to be buried in thermal insulation, some exceptionally high temperatures can be reached. Using a fixture carrying the IC (insulated ceiling) rating and specified for a 75 W lamp, Yarbrough and Toor[866] measured a maximum temperature of 123ºC on the building wiring connecting to the fixture. The installation, including lamp size, were in accordance with how the product was listed by the testing laboratory. Since building wiring may have a rated temperature as low as 60ºC temperature, they concluded that greatly shortened lifetimes must be anticipated in applications of this kind. A NIST study on lighting fixtures also examined the effect of over-temperatures on 60ºC-rated normal building wiring[619]. When overlamping of a fixture created 202 – 205ºC temperatures in the electrical junction box, failure occurred in less than 65 h. The wire insulation became brittle, cracked, fell away from the conductors, and this led to a short circuit.

270	47	
350	13.2	4.2
450	4.0	2.0
500	3.3	

PARTIAL DISCHARGES

Partial discharges are partial breakdowns of an electrical insulation that occur when the electric field locally exceeds the breakdown field strength, but a full breakdown from electrode to electrode does not occur[867]. These discharges convert capacitively-stored energy into a heat, mechanical, or chemical form of energy which, in turn, acts to further degrade the insulation. If the process is sustained, it may eventually culminate in a gross breakdown of the insulation. Partial discharge is generally initiated by a transient overvoltage. The problem is especially acute in circuits, such as electronic variable-speed drives for motors, that create pulse-type voltages significantly greater than the nominal sinusoidal circuit voltage.

CHEMICAL DAMAGE

Oil or other chemicals can cause damage to wire insulation, leading to failure and possibly fire.

ALLOYING DURING MELTING

Damage due to alloying due to melting can be confused with damage due to arcing, so the process of alloying must be understood. Even though copper has a melting point of 1085ºC, pouring molten aluminum (T_{mp} 660ºC) on it will lead to melting of the copper and the formation of a copper/aluminum alloy[868]. This can take place because, under optimum conditions, copper and aluminum can form an alloy (33% copper, 67% aluminum) which has a melting point of only 548ºC. Color Plate 119 shows an example of typical damage to a copper conductor from alloying.

APPLIANCE CORDS AND EXTENSION CORDS

CPSC estimates[869] that there are about 7100 fires a year in US residences originating from electrical cords and plugs, along with 120 deaths. Of these, extension cords account for 3300 fires, along with 50 fatalities and 270 injuries[870]. A CPSC field study[871] on fires originating from appliance cords led to the statistics shown in Table 79 through Table 81. In the case of appliances rated at 1500 W or more, 74% of the fires involved failures of various kinds at the male plug end; failures along the cord were only 6.5%.

A parallel CPSC laboratory study[872] identified the most common failure modes as:

- Bad crimp within molded male plug or female cord connector. This is a manufacturing defect.
- Bad mating contact with wall outlet, extension cord, or male contacts of appliance. Usually a progressive failure due to wear.
- Flexure failure of cord, commonly at entry to plug or to appliance. Normally due to heavy use. Was a more serious problem before introduction of bend-relief reinforcements.
- Tension failure at plug; cord insulation separated from molded plug. Can sometimes be due to inadequate bonding of plug to cord insulation.

- Plug blades pitted or arced, possibly due to withdrawal of plug under load. Was seen to be especially problematic with air conditioners.
- Flexure or abrasion failure of cord insulation, leading to arcing between conductors or to grounded objects.

The CPSC study focused on design and manufacturing issues, but clearly several of the failure types are likely to be caused by negligent or abusive usage. In some European countries, recessed wall outlets are used, where the male plug, when inserted, is flush with the surface, rather than protuberant. There are presumably fewer fires that result in those cases from furniture being shoved against plugs.

In a 1981 study on extension cords[873], CPSC determined that about 90% of extension cords on the US marketplace conform to UL 817[874]. But a 1999 study[869] concluded that only 28% met 'current safety standards.' This shift parallels the dominant role that imported articles (mostly Chinese) assumed during the same time period. Based on a number of fires examined in depth in the 1981 study, CPSC identified three main causes of fires from extension cords (Table 82). Improper alterations usually involved splicing of the cord. Age of extension cord was not necessarily correlated to failure, since some 35% of the incidents involved cords one year old or less.

Table 82 Factors leading to fires from extension cords

Factor leading to fire	Percent
overloading	48
physical damage or misuse	46
improper alterations	6

There has been a large number of product recalls by CPSC of improperly manufactured extension cords. By far the largest number has been due to undersized conductors. Other factors have been improperly polarized plugs, inadequate strain relief, or—in one case—use of a plastic that "once ignited, continues to burn and spread flames."

IMPAIRED COOLING

As discussed under *Excessive thermal insulation*, above, published current-carrying ratings ('ampacity' values) are based on certain assumptions of convective cooling. When the actual situation involves much poorer cooling, electric failures and possibly ignition can be anticipated. As an example, a case history[875] has been reported where a fire originated at an extension cord which was coiled upon itself and stuffed into a baseboard hot-water radiator. CPSC has explicitly warned[870] consumers not to place extension cords under rugs, since the reduced heat dissipation may cause ignition even if the cord is within its normal current rating.

Cord reels are a consumer item where an extension cord incorporates a permanently attached reel intended for storing the cord. As considered above, under normal circumstances, an overload must be exceedingly large before a cable will ignite. A fire and its subsequent investigation, however, revealed that cord reels do not comprise 'normal' circumstances. In the absence of adequate warnings, it is natural to use a cord reel by only unreeling a needed amount of cord and not the whole length. The cooling for the tightly-wound portion then becomes minimal. Tests[876] have been done on a 16 AWG cord reel, rated for 10 A. In ambient air, passing 9.5 A through the cord caused about 1ºC of temperature rise. But by passing 9.5 A through it for about 1.5 h, a fire resulted when the wire remained wound on the reel.

WIRES IN STEEL CONDUITS

Electrical branch-circuit conduits are sometimes found after fires to contain arc-fault damage. The cause of the fire might then be attributed to a wiring fault. This reasoning is rarely likely to be correct. Instead, the most common reason for arcing damage found on conduits is external heating of the conduit during fire[877]. Without providing external heat-

ing to a conduit, it is very hard to create a fault within it. Splices inside conduits are prohibited, so the only internal causes are limited to gross overloads or defective wire insulation (due to manufacture, installation, mechanical abuse, vibration, etc.). In either case, a short from a conductor to the conduit would lead to a high-current parallel arc and would likely cause quick tripping of the circuit breaker. For serious damage to occur*, it is necessary that either (1) the arcing be current-limited, or (2) an unsuitably high-rating circuit breaker be used. If an inappropriate circuit breaker was installed or some defect existed making the short-circuit current unreasonably small for the circuit, these factors would be expected to be found in the investigation after the fire. (Service entrance conduits, which effectively lack protection, are discussed in a separate section: *Service drops and high current capacity conduits*.)

If an external fire impinges on the conduit, however, the heat of the fire can char the wire insulation inside the conduit, creating a semi-conductive char through which arcing can occur locally. The resistance created is likely to be high enough that the circuit breaker will not be tripped (Figure 60)[878,879]. Color Plate 122 shows the consequence of an experiment where a propane burner was used to heat a steel conduit until the wiring inside it failed and arcing occurred.

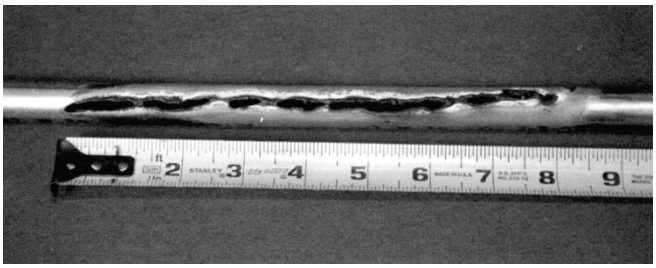

Figure 60 Damaged conduit due to arcing inside caused by external fire
(Copyright Fire Findings, LLC, reprinted by permission)

Fuller et al.[880] conducted experiments where a bare spot was created on a THHN 4 AWG copper wire which was run through a 32 mm (1-¼") EMT conduit. A 120 VAC supply was used, but current was deliberately limited to 20 – 80 A by a resistance inserted into the circuit. The authors found that three different results could be obtained:

(1) the wire would get spot welded to the conduit;
(2) a glow discharge would develop which could last indefinitely and would consume about 100 W, with a voltage drop of 0.14 to 1.4 V rms. This glow produced little heating outside the conduit and would not be an ignition source.
(3) an arc would be created. The arcs typically dissipated 1000 W, showed a voltage drop of 8 – 15 V rms, and drew 70 – 80 A. The arcs lasted less than 1 s, but they melted the zinc from the outside of the conduit. Ignition was achieved when cotton or paper was placed on the outside of the conduit at the place of the arcing.

Fuller's study involved essentially a series arc, since enough resistance was inserted into the circuit to avoid circuit breaker tripping. Under those conditions, they proved that arcs could cause lightweight kindling to be ignited. A parallel arc, by contrast, will normally present a great enough load to trip circuit breakers of 30 A or less before any significant damage is done[881]. The question then arises whether a 'poor contact' somewhere in the circuit can provide sufficient resistance for the arc to constitute a series arc. Ettling measured various poor (i.e., barely touching) contacts and found that they provided either low resistance (a voltage drop of only 1 – 5 V in a 120 VAC circuit), or else were fully open[800]. His study, then, suggests that poor contacts are unlikely to prevent a circuit breaker from functioning sufficiently quickly, but the study was not exhaustive.

ELECTRIC WIRING: CAUSE OR VICTIM?

ARC BEADS AND FIRE-MELTED WIRES

When an arc occurs in electrical wiring, portions of the conductors may melt since the temperature of an electric arc is over 6000 K (see Chapter 11), which is greatly in excess of the melting temperature of copper (1085ºC) or aluminum (660ºC). Upon cooling, the molten material often assumes a roughly-spherical shape (Color Plate 123, Color Plate 124) and consequently this re-solidified zone is termed an 'arc bead.' By contrast, the shape of the end of a copper wire that simply melted is likely to have a droopy look (Figure 61). Fire-melted artifacts are sometimes called 'globules,' as distinguished from 'beads.' An arc bead, however, does not necessarily have to be spherical (Color Plate 104). In the investigation of fires, arc beads are frequently encountered because electricity is available in most buildings undergoing a fire and if a fire is sizable, it is likely to burn wiring to the extent that short circuits occur. A single fire may generate a large number of arc beads in this manner, and such beads can be called 'victim' beads. Conversely, if a fire originated because an electric fault produced arcing, the beads from such an event can be called 'cause' beads because they actually correspond to the cause of the fire.

Visually, arc beads can often be distinguished from melt globules since they possess a sharp demarcation between a roughly-spherical bead and the cylindrical portion of the wire, while fire-melted wires do not show a sharp transition between molten/re-solidified and virgin material[756]. This criterion may not suffice for unequivocal determination and, in that case, microscopic examination is needed.

The crystal structure of copper changes with heating. Color Plate 126 shows examples of virgin and fire-exposed grain structure. Cracking often occurs along grain boundaries after a fire exposure (Figure 62). Unless heated to beyond about 300ºC, copper wire shows fine longitudinal striations

* Different considerations apply for conduits carrying large-diameter wires. In those cases, sufficient current may be available to cause serious damage before tripping of the circuit breaker.

Figure 61 Examples of melted copper wire beads caused by exposure to fire without arcing
(Courtesy Yasuaki Hagimoto)

caused by the wire-drawing process[882]. When heated to higher temperatures, fine-grain recrystallization appears, followed by the formation of some large-grain structures as temperatures over about 800ºC are attained. Shaw[883] proposed that, when examined under a microscope, arc beads exhibit a much finer, smoother grain structure than do the wires melting due to heating from fire alone. But he was rebutted by Levinson[884], who pointed out that copper melted in the presence of oxygen shows a pattern of pure copper grains interspersed with oxygen-containing material, irrespective of what was the cause of the melting. Singh[885] proposed that, if arcing was involved, there will be a pronounced CuO or Cu_2O grain structure near the end, progressively diminishing away from the end. On the other hand, if the wire was simply fire-exposed without arcing, there will be diverse grain patterns along the length, without a systematic gradient. Takaki[882] conducted more detailed experiments and concluded that arc beads commonly show three regions: (1) a surface layer containing numerous voids, (2) an intermediate layer that did not melt, but did recrystallize, and (3) a deep layer where the material neither melted nor recrystallized (Figure 63). By contrast, fire-melted beads tend to be uniformly recrystallized. Ettling[886] cautioned that no simple rule is likely to cover all cases, but also described a number of other qualitative differences that can help distinguish arcing from simple melting.

(Courtesy Kevin Lewis, Schaefer Engineering Corp.)

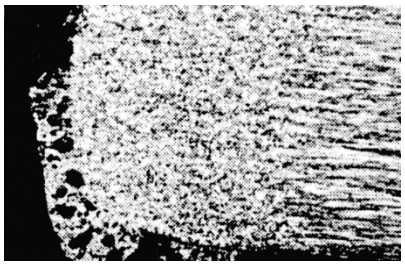

Figure 63 Arc bead showing the three metallographic zones (surface, intermediate, deep layers)
(Courtesy Akira Takaki)

The above discussion was limited solely to arc beads in copper conductors used in branch-circuit wiring. Arc beads in aluminum wiring commonly do not survive the temperatures of a room fire, while there has been no significant research on arc beads in large-diameter wires, such as used in the building service entrance. Wires that are tinned or solder-coated[884] behave differently from solid-copper wires and will also not be considered.

PROPOSED METHODS OF DISTINGUISHING 'CAUSE' FROM 'VICTIM' BEADS

If the melt feature on a conductor is due to arcing and not simply due to melting in a fire, investigators and forensic scientists have explored the notion that the two types of arc beads—'cause' and 'victim' beads—might be distinguished after the fire by some means of physical or chemical testing. If a particular bead could be demonstrated to have been the residue of an arc that caused the fire, this might enable the cause of a fire to be pinpointed which would otherwise be undetermined. Simple visual observation is not sufficient for this purpose, since two Japanese studies[887,888] showed that the following features do not discriminate between 'cause' and 'victim' beads, even when the former were not subjected to the ensuing fire:

- glossiness of the bead
- color of the bead
- shape of the bead
- surface smoothness or roughness
- size of the bead (although the very smallest beads of less than 1 mm tended to be 'cause' beads,

while the largest ones of over 3 mm tended to be 'victim' beads).

Consequently, a number of instrumental analysis techniques have been proposed, and these fall into three categories:

(i) microscopy
(ii) Raman spectroscopy and X-ray microanalysis
(iii) Auger electron spectroscopy (AES) and secondary ion mass spectrometry (SIMS).

In addition, testing for metal hardness was explored by Takaki[882], but he definitively demonstrated that all copper wires exposed to temperatures over about 250ºC showed greatly reduced hardness and this was independent of any details of arcing.

Microscopy methods

The simplest proposed methods claim that examination of a bead under a microscope (after preliminary preparation which may include cleaning or etching surfaces, and other techniques for preparing cross-sections) will suffice to make the distinction. The methods that have been suggested for differentiation are:

(1) 'cause' beads have square or rectangular pock marks, while 'victim' beads lack these structures;
(2) 'victim' beads show small surface-deposited particles, while 'cause' beads do not have these;
(3) 'cause' beads have small voids, while 'victim' beads have large ones;
(4) the number of voids or their total cross-sectional area is different in 'cause' beads than in 'victim' beads;
(5) 'cause' beads have a small dendrite-arm spacing, while 'victim' beads have a large spacing;
(6) based on examining long segments of wire and not just beads, if long segments are uniformly recrystallized, the wire suffered gross electrical overheating; this does not directly establish cause/victim status, but may be of help in assessing the sequence of events that transpired.

Method #1 was proposed by Gray et al.[789] in 1983. They presented results from one accidental fire and conducted a few experiments in the laboratory on flexible, PVC-insulated cords by passing excessive current through the cord until it shorted out and ignited (producing 'cause' beads) and by heating a cord carrying normal current in a fire until ignition (producing 'victim' beads). They then examined slices cut through the beads under a scanning electron microscope (SEM) and, on the basis of observed features, proposed that 'cause' beads show numerous square or rectangular pock marks, while 'victim' beads show few or none. It was not clear whether the pock marks observed represented impurity inclusions or merely regions of crystallization. No other investigators have reported finding these features, so presumably they were due to some rare combination of circumstances, rather than being a normal characteristic of 'cause' beads.

Method #2 was explored by Erlandsson and Strand[889]. In one set of experiments, they created shorts between copper conductors, then exposed the wires to a fire fueled by wood and PVC, the latter intended to simulate burning wire insulation. In another set of experiments, they created the short circuit within the fire environment. The 'victim' beads, when examined with SEM, showed a nearly uniform dispersion of small particles of about 2 μm size on the surface of the beads. Supplementary studies showed that particles of this type could also be created when arcing took place in an atmosphere containing pure HCl vapors, generated by evaporating liquid HCl and not by burning PVC. Small surface particles, by contrast, were absent in beads created by arcing of *bare* conductors prior to exposure to a wood/PVC fueled fire. Unfortunately, the latter test condition does not correspond to the normal creation of 'cause' beads. When the authors created 'cause' beads by shorting together *insulated* wires (by scraping away only small bits of insulation), they found that the bead surfaces contained small particles indistinguishable from those on the 'victim' beads.

A number of investigators explored voids in the bead as an indicator. Erlandsson and Strand[889] studied the cross-sections of beads created in several different ways. They found that in an air atmosphere, arc beads showed copious voids but beads formed by melting the copper by an overcurrent were without voids. In a reducing atmosphere (a gas flame), they found that a smaller number, but larger, voids were present, irrespective of whether the bead was created by arcing or simple melting. They also noted that an 'oxide wedge' could be found between the melted and the unmelted material when tests were run in air, but not in a reducing atmosphere. Tokyo Fire Department[890] conducted experiments which showed that, contrary to the findings of Erlandsson and Strand, voids can be created when copper beads are formed in an air atmosphere by an overcurrent melting process. They made beads by fusing wires with overcurrent in air and in atmospheres of N_2 and CO_2. The experiments were conducted in a tube furnace and the ambient temperature was also controlled. Voids were almost always present when beads were formed in air at 1000ºC, but almost never when in N_2 or CO_2 at the same temperature.

Method #3 was briefly explored by the Tokyo Fire Department[890]. On the basis of limited testing, they noted that voids in 'cause' beads are smaller than in 'victim' beads. They concluded that the voids in 'cause' beads are also more likely to be near the surface, while those in 'victim' beads deeper inside. They consider that the reason is because 'cause' beads tend to solidify more rapidly and oxygen has a lesser possibility of diffusing further inside, whereas 'victim' beads solidify more slowly and voids near the surface tend to migrate inwards and aggregate into larger voids inside, where the temperature is still high. Their testing was not extensive enough to draw statistical conclusions.

Method #4 was investigated by Ishibashi and Kishida[888] who examined 15 beads from fires where it was known whether the bead was the cause or the victim. They concluded that presence of voids is generally more plentiful in 'cause' beads than in 'victim' beads. Presumably this is because 'cause' beads are more likely to be formed in an oxidizing atmosphere and 'victim' beads in a reducing atmosphere, but differences did not support a firm distinction between the two types of beads. Mitsuhashi[891] created 'cause' beads by making current-limited shorts with a stranded-conductor cord and then placing the beads obtained in an oven heated to 400 – 1000ºC. The 'victim' beads were created by first exposing bare conductors to the oven-heating treatment, then covering them with PVC insulation and producing a current-limited short. Mitsuhashi counted micro-voids (0.5 to 1.0 μm) for each bead in three small areas near the center and found about double the number of voids in 'victim' beads than in 'cause' beads. But he also counted voids in 'cause' beads that were not exposed to any further heating after creation of the bead. In that case, the number of voids was roughly similar to the 'victim' beads. For forensic purposes, the method did not seem promising since, while the average number of voids was different for 'cause' versus 'victim' beads, the distributions were overlapping and a particular concentration of voids could be encountered for either case. Method #4 was also explored by Oba[892] who created 'cause' and 'victim' beads in the laboratory and, in each case, subjected them to various oven-heating regimes afterwards. Typically, 30 – 45% of the cross-section area comprised voids and this depended on the temperature of heating that was used after formation of the arc bead, but the distributions overlapped greatly and he concluded that void-area percent cannot be used as a tool for discrimination.

Both method #3 and #4 were studied by Miyoshi[893,894], who counted large voids and found that they were much more plentiful in 'victim' beads than in 'cause' beads. In his study, the 'victim' beads were created by burning a power cord in a burner flame until shorting occurred. But the 'cause' beads were created by shorting a wire together which was not subsequently placed in a fire; thus, his protocol did not attempt to simulate room-fire effects. Under these conditions, the maximum diameter of the voids in the 'victim' beads was typically 2 – 3 times larger than in the 'cause' beads. Similarly, the fraction of the total void area occupied by voids of 132 μm or larger diameter was 14% in the 'cause' beads and 72% in the 'victim' beads. Again, however, the actual distributions showed overlap and a particular void distribution could show up in either a 'cause' or a 'victim' bead, albeit with a higher probability in the one than in the other.

Seki et al.[887] focused on the presence of a dendritic crystal structure (Figure 64) in arc beads. They showed that the general presence or absence of dendrites in an arc bead cannot be used as a means of identification (Table 83),

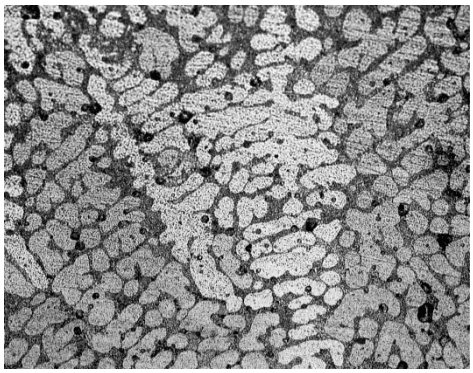

Figure 64 A copper wire bead showing a dendritic crystal structure
(Courtesy Yasuaki Hagimoto)

since it simply reflects the oxygen concentration in the bead. Near-zero O_2 concentration leads to no crystals, as does the eutectic concentration of 0.39 mass%. O_2 concentrations smaller than this produce primary crystals of Cu, while larger concentrations produce primary crystals of Cu_2O. But Seki et al., together with Lee et al.[895], proposed method #5, observing that, if a dendritic crystal structure is created, the spacing between the dendrite arms reflects the ambient temperature at which the bead solidified. In their view, a 'cause' bead will solidify at a near-ambient temperature (< 400ºC) and therefore have a small dendrite-arm spacing while a 'victim' bead will solidify at a fire-gas temperature (> 400ºC) and show a large spacing (unless it re-melts in the fire). On the other hand, the rate of cooling and the temperature of the environment prior to the formation of the bead were found not to affect the spacing. In support of their thesis, the authors produced experimental curves showing the spacing as a function of ambient temperature at solidification and of oxygen concentration, separately for Cu and Cu_2O dendrites. Based on their photographs, however, assigning a characteristic dendrite arm spacing to a particular bead appears to be a highly subjective determination. The authors performed extensive testing, but the description of their results does not make it clear if categorical classification of results as 'cause' or 'victim' was successful. In any case, the tests were primarily exposures in a small electric furnace and creating 'cause' beads which would then be subjected to a room fire was not undertaken. The method cannot be applied at all if the bead does not exhibit dendritic crystal structures and, as shown in Table 83, most beads do not.

Table 83 Dendritic crystal structure observed by Seki et al. in test arc beads

Bead	No dendritic crystals	Dendritic Cu crystals	Dendritic Cu_2O crystals
Cause	57%	38%	5%
Victim	92%	8%	0%

Method #6 was proposed by Levinson[884], who noted that if a substantial length of wire exhibits uniform recrystallization, this is most likely due to electrical overcurrent, rather than thermal heating from a fire, since the latter would be unlikely to heat a wire uniformly. Levinson carefully avoided claiming this distinction can be used as a proof of the origin of a fire, however, since the fire itself may have created conditions leading to an overcurrent.

Raman spectroscopy and X-ray microanalysis methods

On the basis of a very small number of tests, Tokyo Fire Department[890] noted that carbonaceous material is likely to be found inside 'victim' beads, but not inside 'cause' beads. Masui[896] used X-ray microanalysis to examine for the presence of carbon in arc beads that he created by (a) causing a series-arc failure in a cord; or (b) by first charring the wire insulation with a burner flame, then causing a series-arc. His results were only exploratory, but they did show a negligible amount of carbon in the first type of bead, which would correspond to a 'cause' bead. The analysis showed the second bead type to have nearly as high a local concentration of carbon as a pure carbon control sample. The second bead type, however, only partially represents a 'victim' bead in that insulation was charred prior to arcing, but the bead was not subsequently exposed to a fire.

Lee et al.[897,898] carried this idea further by examining the constitution of carbonaceous inclusions. They did not collect any data on what fraction of beads contains carbonaceous inclusions, but rather studied beads that did have these inclusions with Raman spectroscopy to distinguish between amorphous and graphitic carbon. This can be done on the basis of Raman spectra since amorphous carbon shows a broad peak at 1350 – 1360 cm^{-1}, while graphitic carbon has a sharp peak at 1580 cm^{-1}. The authors created 'cause' and 'victim' beads in the laboratory and found that 100% of the 'cause' beads always contained amorphous carbon but 27% of 60 samples also contained graphitic carbon. In all of 20 'victim' beads tested, amorphous carbon was detected; in none of them was graphitic carbon detected. The authors then examined 8 beads from actual fires where the status of the bead was established by other means. They were able to find graphitic carbon in 3 of the 5 'cause' beads. The authors hypothesized that the effect occurs because PVC is bodily conveyed into the interior of an arc bead. In their view, graphitic carbon is created inside the bead only if the sequence of creating the 'cause' bead is such that PVC insulation is slowly charred due to an electrical fault before final failure leading to arcing occurs. In a 'victim' bead or in a 'cause' bead where the fault rapidly leads to ignition, time required to form graphitic carbon is not available. 'Cause' beads of the latter type will occur when a large, rapid overcurrent melts the insulation and quickly creates a short circuit. It is not clear how the authors envision that carbon migrates into the copper, since they state that temperatures are only 110 – 250ºC when PVC is being charred. In any case, the method has a rather low probability of identifying a 'cause' bead of only 27 – 60%.

AES, SIMS, and ESCA methods

A number of techniques exist that allow the concentrations of certain elements in a metallic sample to be determined. These include Auger electron spectroscopy (AES), electron spectroscopy for chemical analysis (ESCA), and secondary ion mass spectrometry (SIMS). With any of these, a depth vs. concentration profile can be made by progressively etching away portions of the surface and examining a lower layer. Erlandsson and Strand used AES in connection with their experiments discussed above to quantify the chlorine present in the surface particles attached to the bead, but, as mentioned above, the presence of chlorine was found not to be uniquely associated with 'victim' beads and was equally-well found in 'cause' beads, if the 'cause' arcs were created by shorting together insulated, rather than bare, wires.

In 1980, MacCleary and Thaman postulated[899,900] that an arc bead formed without a pre-existing fire ('cause' bead) would be formed in an oxidizing atmosphere, while one that occurred after a fire was already ongoing ('victim' bead) would be formed in a reducing atmosphere. Consequently, they believed that profiles of the oxygen concentration, as a function of depth below the surface of the bead, would enable identification to be made. Their patent[900] envisions that AES, ESCA, or SIMS can be used for this purpose, but their own work they used only AES. Because of the limited sensitivity of their technique, they took the derivative of the signal data as the analysis variable and only sought relative magnitudes, not an absolute calibration of oxygen concentration. Figure 65 shows three samples they analyzed. The 'cause' bead was created by short-circuiting two conductors after preheating them for 15 s. The 'victim' bead was created by a small fire which short-circuited an NM cable. The 'overload' bead was created by producing a current-limited overload which heated the cable for some time (unspecified) before the conductor fused and arced. The authors also showed results from four beads taken from real fires where the fire cause was known. Their proposed scheme for identifying beads was to discard the first 5 nm of the surface (since it would likely reflect ambient oxidation of the copper) and to evaluate the remaining portion:

- if the concentration is generally low, the peak is found at 20 nm or less inside the surface, and concentrations beyond the peak become quite small, then this is a 'victim' bead;
- if the concentration is generally high, the peak is found at a depth of 20 – 200 nm, and the concentration decays slowly at greater depths, then this is a 'cause' bead;
- if the concentration is very high, and oxygen is detected to 2000 – 4000 nm, then this is a 'cause' bead where arcing was preceded by prolonged overheating.

The authors also pointed out that the method cannot be used if a re-melt occurred. To detect the latter, they proposed that a bead be cut in half and an AES scan be made across the diameter. If four, rather than two, peaks are found across the diameter, then a re-melt is indicated. Robertsson et al.[901] attempted to validate the MacCleary/Thaman method, but found that the oxygen profiles could not reliably distinguish 'cause' from 'victim' beads.

Satoh et al.[902] used AES and SIMS to obtain O, C, and Cl profiles on four specimens: a 'cause' and a 'victim' bead from actual fires and a 'cause' and a 'victim' bead produced in the laboratory. The 'cause' bead was created by short-circuiting a stranded-conductor cord, then exposing it in a burner flame, while the 'victim' bead was produced by placing the cord into a burner flame until it shorted. Depth profiles were obtained by etching the surface down with a cesium ion beam (for the SIMS) or an argon ion beam (for the AES). They plotted both the AES and the SIMS data in a way as to normalize the remaining elements to Cu, which was taken to have a constant depth profile. From these preliminary plots, they concluded that the primary feature of a 'cause' bead is an oxygen profile that rises to a peak at about 1000 nm beneath the surface, and only then proceeds to fall. By contrast, 'victim' beads showed O, C, and Cl concentrations that were all similarly-shaped decay curves, without any appreciable rising portion. By comparing AES and SIMS results, they concluded that AES is much less sensitive and incapable of good resolution deeper than about 1000 nm; thus they concluded that SIMS is the preferred technique. In a later study[903], they used only SIMS to examine 10 beads recovered from fires where the cause/victim identity of the beads was known (Figure 66). The fires however were all small and none had reached the fully-involved room stage. One of the beads was so heavily surface-damaged that it was considered not appropriate for analysis. Of the remaining 9 beads, all were correctly classified by adopting the following rule:

- if the (absolute) oxygen concentration at the 3000 nm depth is $<10^{17}$ atoms/mm^3, then it is a 'cause' bead;
- if the concentration is $>10^{17}$ atoms/mm^3, then it is a 'victim' bead.

They cautioned, however, that the results must only be viewed as preliminary. They hypothesized that the distinction arises because the environment temperature is high when a 'victim' bead is formed and this allows a greater amount of oxygen to diffuse into a piece of copper that has been preheated. It must be noted that this is the exact opposite of the MacCleary/Thaman classification, where low—not high—oxygen concentration denote a 'victim' bead, although Satoh et al. analyzed concentrations at much greater depths into the bead, while the MacCleary/Thaman technique had sufficient sensitivity to characterize only a shallower region. Satoh et al.[904] continued the research with 65 additional samples from real fires and then found that there was only a 39% agreement between their proposed technique and the conclusion from that particular fire investigation.

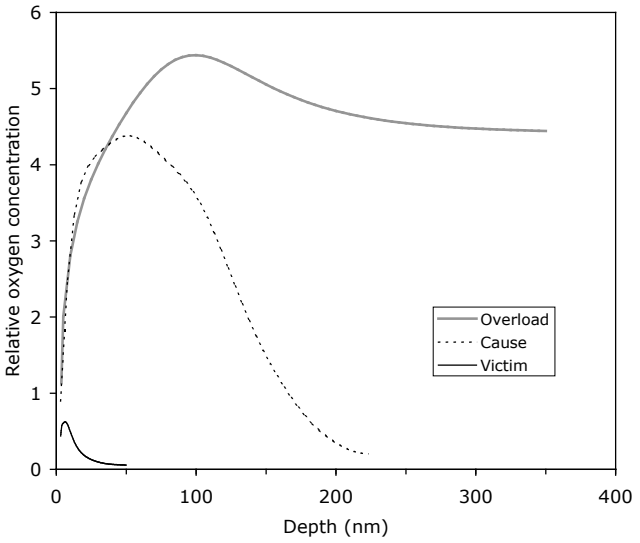

Figure 65 Oxygen concentration profiles shown in the patent by MacCleary and Thaman

MacCleary and Thaman did not pursue further the ideas of their patent, but since 1989 a method has been promoted by Anderson[905] that is similar to the MacCleary/Thaman idea in that it is proposed that AES depth profiles of certain elements can be used to establish the cause/victim status of an arc bead. Anderson noted that ambient air contains significant amounts only of oxygen and nitrogen. If an arc occurs between two wires in ambient air, then only oxygen can dissolve into the bead while the bead is in its molten state (nitrogen does not dissolve into copper). However, if the arc occurs in an atmosphere where there is an ongoing fire, then a number of other atoms will be found in the atmos-

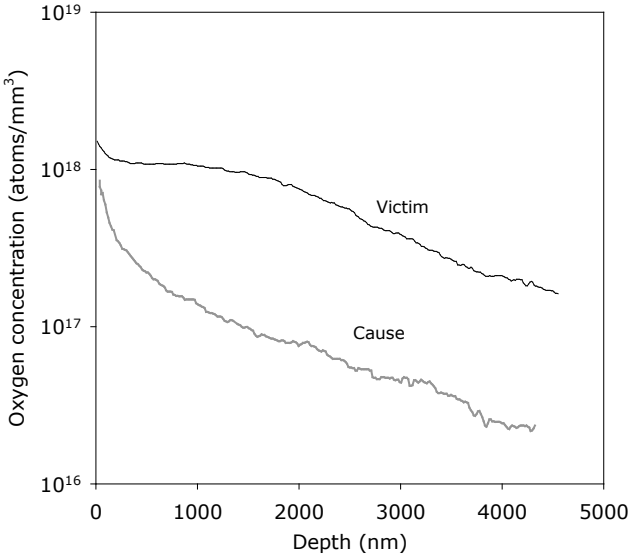

Figure 66 Oxygen concentration profiles, as measured by Satoh et al.

phere; these will also dissolve into the bead. Apart from oxygen, Anderson used carbon, chlorine, sulfur, calcium, zinc, iron, phosphorus, and chromium atom profiles. He did not propose any quantitative criteria for distinguishing between 'cause' and 'victim' beads, relying instead on a subjective evaluation, with apparently some emphasis placed on the carbon profile. Thus, a sizable concentration of carbon would indicate a 'victim' bead, while a lack thereof would suggest a 'cause' bead. Figure 67 shows a bead presented by Anderson[912] as a 'cause' bead, while Figure 68 shows a 'victim' bead.

The basic notion, however, that non-oxygen atoms will become available for incorporation only into 'victim' beads lacks foundation. In most practical cases, wires are insulated by a polymeric material, typically PVC. The polymer is in contact with the conductor and may be vaporized regardless of whether the arc bead was the first event of the fire, or if it occurred much later in the fire. Thus, it is not clear why a more copious presence of carbon or chlorine atoms would suggest a 'victim' bead. Similarly calcium carbonate is a common filler for plastics used in electrical wiring, so calcium may also be anticipated from either destruction of wire insulation as part of the initial arcing or from events much later in the fire.

One of the pivotal assumptions of the MacCleary/Thaman and Anderson theories is that the elemental profiles are frozen into the bead once the bead has cooled. Consequently, it is considered that once the arcing has stopped, further exposure to the fire atmosphere will not affect distribution of elements to be found within the bead (except possibly at the very surface, which is to be removed and discarded in their testing procedure). The principle is that the solubility of gases is much greater in liquid copper than in solid copper and, thus, the gases will be trapped after the bead solidifies and this distribution will be frozen in place and available for later study. Howitt[906] argued against this, but the basic concept that a substantial amount of oxygen can be dissolved in molten copper is correct[907,908]. Some gases can enter into copper while it is hot but not molten, however. This is the reason that stranded copper wires recovered from fire scenes often crumble to bits in the process of examination—the material has turned into copper oxide and no longer has mechanical strength. Howitt also conducted tests[909], but using energy-dispersive X-ray spectrometry (EDS), instead of AES. He was criticized by a laboratory offering AES services[910] for using a technique that is much less sensitive, but this does not seem germane, since his results showed adequate sensitivity. More problematic is the fact that a depth profile was not established, only a concentration within a relatively thick sub-surface layer. Howitt analyzed 13 samples obtained under various combustion and no-combustion conditions and noted that no systematic differences in C or O concentrations could be found that would be attributed to the presence of a pre-arc fire.

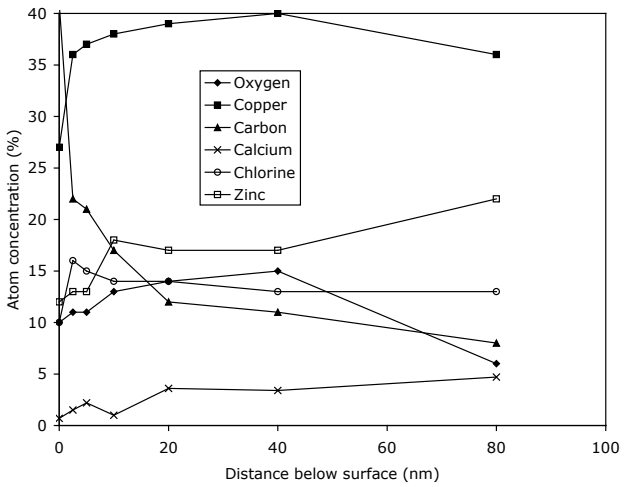

Figure 67 A 'cause' bead, Anderson's Case (graphs of results published by Anderson in the form of tables)

The use of Anderson's method for forensic purposes would require a quantitative protocol for analysis, specifically, concerning how the depth profile should be considered. Argon-ion sputtering is used in the Anderson method to remove the outer layer ("environmental cap" in his terminology). In his scheme, the cap comprises all the layers until a region is reached which has at least 60% copper. Consequently the disregarded environmental cap is stated in his reports as having widely-varying thicknesses: 2.5 nm[914], or 5 nm[911], 5 – 10 nm[912], or 5 – 20 nm[913]. But once the "environmental cap" has been removed, Anderson relies solely on a qualitative judgment that a 'victim' bead shows a profile where C, Cl, and Ca atoms are abundant to a greater sub-surface distance than in a 'cause' bead[914]; he does not appear to have been able to establish any quantitative criteria for making this distinction.

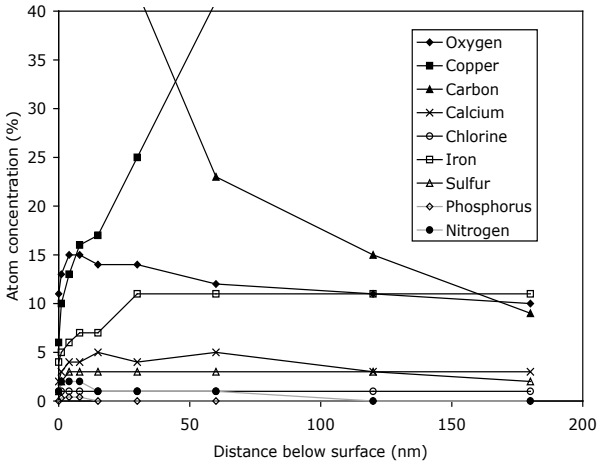

Figure 68 A 'victim' bead, Anderson's Case 3 (graphs of results published by Anderson in the form of tables)

Béland[915] pointed out that there is a significant statistical problem with the method even in a single laboratory: tests conducted on different portions of the same bead give substantially different results. An AES spectrometer can be operated in a raster-scan mode to characterize surface areas; however, no statistical technique has been demonstrated for obtaining characteristic averages in this way. He also pointed out[916] that Anderson's published work did not include even elementary descriptions of the tests performed, such as the exposure times for the specimens. Anderson claimed[913] that, in a fire litigation case, he was able to correctly distinguish 'cause' from 'victim' beads but Béland[916] argued that this was not done 'blind.'

Ettling[917] examined Anderson's data[905] and found numerous problems and inconsistencies. In his view, the basic problem is that in real fires—as opposed to Anderson's laboratory tests—a bead will most likely remain in a fire environment for an extended time, regardless of whether it is a 'cause' or a 'victim' bead. Thus, laboratory studies where a bead is created and then quickly removed from a fire environment do not present relevant information. Ettling also noted that in Anderson's study, the oxygen content of a bead formed in air was higher than for a bead formed in oxygen. No explanation was given by Anderson in his paper for this (nor did Anderson provide any description in his paper of specimen preparation or exposure procedures). Another questionable result was a bead from a 'victim' arc occurring near a gypsum wallboard which showed high amounts of sulfur. Electric arcs in branch circuit wiring do not normally vaporize gypsum wallboard, and there is negligible calcium sulfate liberated even as hydration water is lost during a post-flashover stage of fire. Thus, Ettling concluded that presence of sulfur is likely to indicate contamination to a hot bead, rather than being a useful tool for unraveling the early history of the fire.

Ettling also analyzed Anderson's later paper[912] where he presented AES results on beads recovered from three fires. In one case (Figure 67), the very deepest layer tested, 80 nm, showed zinc to be about 2/3 as plentiful as copper. Ettling points out that, at high temperatures, zinc oxidizes in air so readily that only zinc oxide should be available in the air, and the latter is unlikely to migrate into the bead. Thus, he concluded that this large amount of zinc came from a gross surface contamination of the bead. In another of Anderson's example cases (Figure 68), a power cord bead was examined from a failed electrical cooking pot. For layers below the "environmental cap," copper was the most abundant element, with iron being next. Anderson claims the iron came from the failed element, but would require that both the cord and the element be arcing at the same time, and that a huge fraction of the iron end up in the other bead. Equally problematic is that if the iron came from the heating element, no chromium or nickel (from the resistance wire itself) was recovered.

Henderson et al.[918] attempted a direct validation of Anderson's theory by preparing specimens under two conditions. The 'cause' beads were prepared by shorting together 18 AWG stranded copper wire in air; the 'victim' beads by placing the insulated, energized wire in a fire and waiting until an arc occurred. They found that the carbon profiles overlapped, and that there was no way to unambiguously differentiate between the two sets of results. Béland ran a similar set of experiments[915] and obtained the same conclusion in comparing the chlorine profiles of 'cause' and 'victim' beads.

Reese[919] pointed out that in dwellings, when a fire originates in branch circuit wiring and a bead is found, the event commonly involves arcing-through-char, not a simple metal-to-metal short. The latter would be likely to cause rapid tripping of the circuit breaker and would only rarely start a fire. Thus, while wire beads can be created readily in the laboratory by simply shorting two bare conductors against each other, this type of event is not common in accidental fires. If a fire originates from an electrical fault where charring occurred first, followed by shorting, then the AES test result will presumably be a false negative, since it will be formed in an environment containing reaction products from the charring of wire insulation. Fitz[920] pointed out a more fundamental logical concern with the AES scheme. In addition to arcing-through-char, a short circuit can happen due to radiant heat flux falling onto a thermoplastic cable or cord from an ongoing fire. When the insulation softens sufficiently for the conductors to make contact and produce a short circuit, there may not be any combustion or combustion products in the vicinity of this arc. This effect particularly may occur inside appliances, in engine compartments, or in wall cavities subjected to external heating. Thus, a positive AES result ("this bead was the cause of the fire") will be reported, despite the fact that the bead was the victim and not the cause.

For a laboratory technique that has been offered for forensic purposes, it is also a serious concern that the basic details of the phenomenon being utilized have not been studied scientifically. The non-copper elements identified in an AES spectrum must originally start out as atoms or molecules somewhere else. Through processes of transport and reaction, they end up embedded in the bead, but the chemical history that takes them there has not even been conjectured. Likewise, after they have entered the bead, no theory has been offered to provide a quantitative understanding of the depth profiles and of the lateral concentration variations in the bead.

Only one published study could be found supportive of Anderson's claims. Metson and Hobbis[921] performed an AES analysis on a single bead removed from the wall cavity of a fire scene, but suggested that reference to Anderson's work suffices to establish validity of results.

VIABILITY OF PROPOSED SCHEMES

Most of the proposed methods have been pure empiricisms, without any theoretical basis. Obviously, these could only be validated by a preponderance of empirical data. But some others refer to a theoretical principle, even though an actual quantitative theory has not been offered by any researcher. The relevant principles are necessarily based on some hypothesis that the chemical or the thermal histories of 'cause' and 'victim' beads form distinctly different populations. Concerning chemical histories, there have been only two hypotheses: (1) 'Cause' and 'victim' beads are uniquely associated with oxidizing and reduction atmospheres, respectively. In turn, the oxygen content of the bead will uniquely reflect this. But as Robertsson et al.[901] observed: "The oxygen content in the surface layer of a melt bead does not only depend on the type of damage but also on the thermal pre- and post-history of the electrical damage." In other words, once a bead is created—either a 'cause' or a 'victim' bead—it may remain for a long time in atmospheres that range from oxidizing (good supply of oxygen), to reducing (buried in oxygen-depleted, glowing or smoldering rubble). (2) The atmosphere surrounding a 'victim' bead will contain material that originated from decomposing solids nearby, while that around a 'cause' bead will not. Adequate amounts of this material (carbon, etc.) will then be found in the bead. This hypothesis is refuted, however, when it is considered that 'cause' arcs can and do occur in environments where the insulation already has been substantially degraded. Conversely, a short-circuit due to molten wire insulation can occur during a fire in a protected environment where there are no local combustion products and a minimum of pyrolysis products.

Thermal histories of arc beads can be diverse, but it is hard to envision any aspects that innately separate 'cause' from 'victim' beads. The temperature of an arc itself is vastly higher than the temperature of flames, but this is no help in making a distinction, since both arc temperatures and flame temperatures will have been attained at some time for beads of both types. Any bead can be expected to remain in a fire for a long time after it was formed—or a short time. An extended period of very high conductor temperatures, due to gross overload, may also precede the formation of an arc, irrespective of whether it is a 'cause' or a 'victim' arc. Remelting of an arc bead, of course, is universally agreed to eliminate any chance of deducing its prior history. One research group proposed that 'cause' beads, once formed, are likely to solidify at fairly low temperatures, while 'victim' beads will solidify at high temperatures. This presumes that fire heating will not be rapid, once a 'cause' bead initiates a fire. The hypothesis is questionable and, in any case, has not been experimentally examined apart from the authors' work.

Most of the techniques described in the literature have clearly been identified by their authors as being exploratory, initial investigations and not as finalized, validated methods. The one exception is Anderson's method, which he has claimed is sufficiently developed to be suitable for forensic purposes. But evidence does not support the idea that this method is ready for such usage. The main problems with the method are: (1) apart from the knowledge that oxygen and some other elements can dissolve into molten copper, there has been no chemical or metallurgical study that examines the details of the process and establishes a theoretical basis for concentration distributions to be expected in the solidified bead; (2) no quantitative criteria for distinguishing 'cause' from 'victim' beads have been developed; (3) even if post-fire contamination does not occur, subsequent and repeated heating in the fire environment makes interpretation of results uncertain; (4) the method is intrinsically subject to producing false positive and false negative results. False positives would indeed appear to be a problem, judging from Anderson's report[922] that he determined 1/3 of all the arc beads that he examined to be 'cause' beads. In the normal course of events, 'victim' beads should outnumber 'cause' beads by a huge fraction, since many fires cause extensive arcing, while generally there will only be one arc—at most—responsible for starting a fire.

In view of the above considerations, there is not much promise with any of the methods that have been proposed for distinguishing between 'cause' and 'victim' beads since:

(1) Most of the methods have been offered without any supporting theory. But the few theories that have been offered are inconsistent with the knowledge of the variety of behaviors that are found in room fires.
(2) With a few exceptions, the methods have been put forth as qualitative and subjective, without means of quantification.
(3) The methods typically have been based on studies using an extremely small number of experiments. In the few studies where sufficient samples were used to enable statistical conclusions to be drawn, the 'cause' and 'victim' bead populations showed sufficient overlap that only trends, not categorical distinctions, could be drawn. In the only study where comparison was made to a fairly large number of real-fire beads of known identity, the results were unacceptable (39% success).
(4) Almost all of the fire exposures for the laboratory-created beads have been very different from real room fires.
(5) None of the methods has been independently validated, although several validation attempts have been made and led to conclusions of irreproducibility.
(6) Most researchers proposing the various methods have suggested them in the spirit of ideas meriting further research, but Anderson has argued that his method is robust enough that it already should be accepted for forensic purposes. However, his

method does not appear to be more promising than any of the other methods.

In addition, serious doubt exists that any method could be developed in the future which is robust and reliable. This could only be possible if chemical or thermal exposure conditions were invariably different during the formation of 'cause' versus 'victim' arc beads. But distinctions of this kind have not been discovered.

Electric wiring and equipment in motor vehicles

The automotive environment presents increased possibilities of ignition, since electrical wiring and devices can be damaged both by collision and by vibration. Until the last few decades, automobile manufacturers used circuit protection devices only to a limited extent and it was not rare to encounter circuits that are totally without protection, or have inadequate protection. Short circuits by means of a relatively poor (high resistance) connection can also be more of a problem in motor vehicles than in house wiring, due to a ten-fold difference in voltages. For example, in one incident[923], a 5 A current was drawn due to a screw improperly driven into a cable bundle. At a 12 V supply voltage, this high-resistance short represents 2.4 Ω and the current will not trip a 10 to 30 A breaker. But if the voltage were 120 V, then the same 2.4 Ω resistance would draw 50 A and would be expected to trip a household 15 or 20 A breaker. Franklin[924] reported on tests conducted by General Motors, who documented that a faulty door lock switch can start an armrest fire and not blow a 20 A fuse used to protect the circuit. An arc in such a device can draw 12 to 24 A, and such arcs have been documented to be able to burn as long as 60 s prior to melting out a conductor.

Arc tracking is generally considered to be a lesser problem at low voltages, but a countervailing issue in motor vehicles is that the environment can contain pollutants (corrosives, soot, etc.) that promote arc tracking. Certain 1984-1993 models of Ford vehicles had ignition switches which were found to be a cause of fires (Color Plate 125). Investigations[925] determined this to be an arc-tracking problem inside the switch, exacerbated by the fact that the polymeric insulation between the metal contacts was grease-coated.

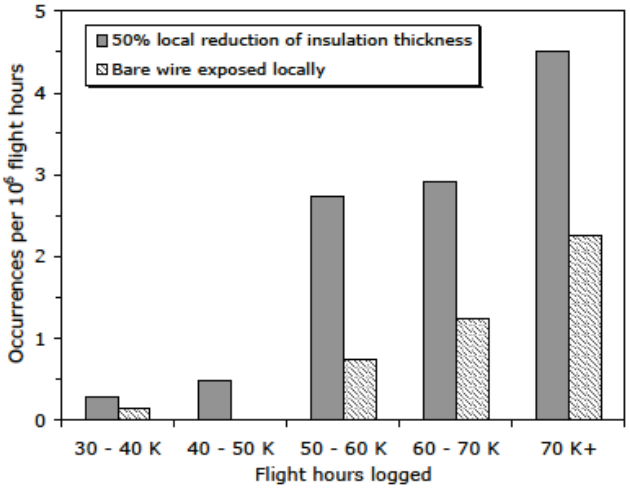

Figure 69 Aging of aircraft wiring

If the main ground strap going from the battery to the chassis develops a corrosion-caused high resistance, a fire can result if excessive current then flows through other paths to ground. A case of this type was documented by Sloan[926]. Battery acid is a relatively good conductor, thus, under unusual circumstances, battery acid can drip onto two exposed conductors and cause a temporary short. This short can then be the cause of an ignition[927].

As of the present time, the automotive industry is actively planning to raise system voltages from 12 volts nominal (14 V charging) to 36 volts nominal (42 V charging). The effect of this on ignition potential is yet to be determined.

Electric wiring in aircraft

The US National Transportation Safety Board[928] analyzed accidents or fires in commercial airplanes due to wiring faults from 1983 to 1999. The incidents identified involved:

- improperly routed wiring bundles shorted to various metallic objects (4 incidents)
- explosion in fuel tank due to degraded insulation from tank float switch wiring
- an excessively tight bend in a wiring bundle caused arcing; accumulated lint contributed to fire
- clearance was too small between electric wiring and hydraulic line; hydraulic fluid got ignited
- electrical arcing, not otherwise identified by NTSB (considered to be arc tracking by many private experts)
- unidentified electrical ignition event associated with fuel-level sensor wiring caused explosion in fuel tank. This was the famous TWA 800 flight of 17 July 1996.

Most of the above problems were due to faulty inspection or maintenance. An exception is arc tracking, which has been researched in depth during the past few decades.

One practical survey on degradation done on fuel tank wiring in Boeing 737 aircraft is at least illustrative[929]. Figure 69 shows that failure rates progressively increase as more aircraft hours are logged. The results imply that a useful service life of around 50,000 hours might be construed for these components.

Arc tracking was first noted in the aerospace industry around 1960. In the earliest research study[930], Elliott found that PVC cables carrying 28 VDC would readily undergo arc tracking. He also observed that electrolysis of water produces oxygen, which erodes copper and produces copper hydroxide and cuprous oxide. In a DC circuit, the process leads to conductive dendrites growing from the cathode to

the anode. Each dendrite can carry about 1 mA. The growth of dendrites is unique to DC circuits and does not occur when the polarity is changing. Arc tracking is especially problematic in aircraft, since each time an airplane descends from a high altitude into a warmer lower altitude, the chilled parts of the airplane may condense moisture.

The specifications for wiring in aerospace applications are different from that for building or electronics uses. It is essential to minimize both space and weight, whereas material cost is relatively secondary. For wiring, these objectives can be met if the insulation is made much thinner than found in other industries, down to about ¼ of such comparative thickness. Weight reduction is also helped by increasing the temperature rating to 200 – 260ºC, compared to normal ratings which are below 100ºC. Aromatic polyimide (Kapton™) and various types of fluorinated polymers (Tefzel™, Teflon™ etc.) were a suitable design solution[931]. Kapton has very good dielectric strength when dry and undegraded; unfortunately, due to its high water absorption factor, it proved to be highly prone to arc tracking. Color Plate 127 shows an example of mild arc tracking on Kapton aircraft wiring[932]. In cases of severe tracking, the whole bundle can be destroyed, not just individual wires[933].

Published research on arc tracking has mostly been due to FAA, NASA, and their contractors. The FAA ran tests on wires with various insulation types to determine their propensity for arc tracking[934]. In their tests, bundles of wire were coated on one end with powdered graphite, then an arc was deliberately created there. The test then consisted of determining whether 'dry' arc tracking would be observed to propagate or not. Tefzel (MIL-W-22759/16), PVC/nylon (MIL-W-5086/1), and cross-linked ETFE (MIL-W-22759/41 and also a proprietary grade) samples did not lead to arc tracking. Nor did an experimental construction comprising Teflon inner wrap/polyimide middle wrap/Teflon outer wrap. But Kapton (aromatic polyimide, MIL-W-81381/12) did, see Color Plate 128.

Ignition of electrical wiring occurred during 9 NASA space missions, of which 3 involved arc tracking. Consequently NASA sponsored three workshops on wiring for spacecraft applications[935-937]; in each, arc tracking of Kapton-insulated wires was a predominant concern. The most important technical conclusions to emerge from the workshops were that:

- circuit protection devices usually do not protect against arc tracking;
- the higher the voltage the easier it is to initiate arc tracking;
- arc tracking occurs less readily in vacuum than in air;
- the probability of an arc re-strike over a carbon path is proportional to the available Volt×Amp product. For three different wire types evaluated as improved replacements* for existing MIL-W-81381 Kapton-type wiring, the 50% probability of restrike was at V×A products in the range of 100 – 130 VA (tests run in air). Numerous restrike results were documented at circuit voltages as low as 20 V.
- for bends in the wire, arc-tracking probability is inversely proportional to bend radius;
- wires of 4 AWG (5.189 mm) or larger are unlikely arc track, due to heat sink effect of copper mass.

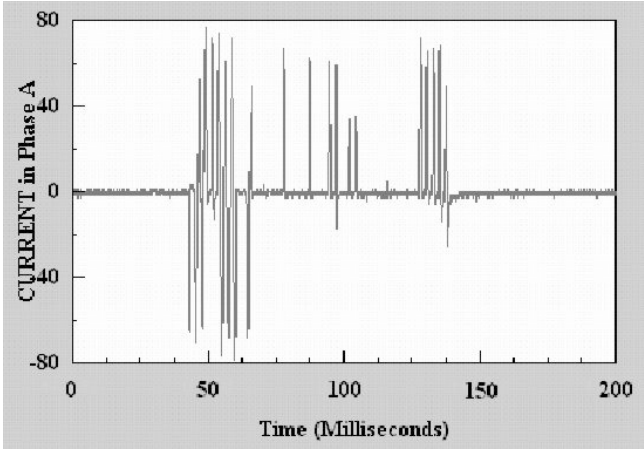

Figure 70 Waveform of flashing event

The workshops also documented that Kapton arc tracking problems have been severe in US Navy aircraft, and remediation measures within the Navy have been going on since the late 1980s.

Because of these problems, commercial aircraft makers have generally switched to XL-Tefzel (crosslinked ETFE) or TKT (MIL-W-22759, Teflon/Kapton/Teflon composite) in the mid-1990s; Airbus was still reported to be using Kapton wiring as of 1999[929]. Even though it contains a Kapton layer, in the TKT composite it is encapsulated between two other layers and the resultant composite does not show the problematic behavior of MIL-W-81381. Additional test data on composite wire insulation has been presented by Berkebile et al.[938]

A detailed laboratory investigation was conducted of arc tracking and other failure modes on exemplar aging aircraft wiring subsequent to the TWA 800 disaster[932]. An experimental arrangement patterned after Section 27 of the ASTM D 3032 wet-arc tracking test was used, with 3-phase, 208 VAC at 400 Hz being supplied. With this power supply, the study identified three stages of progressive electrical failure:

(1) Scintillations. These show up as pinpoints of light at damaged areas of insulation. During some scintillations, buzzing or crackling sounds could be heard. Peak

* The three systems were: (1) Kapton/extruded, crosslinked ethylene tetrafluoroethylene; (2) PFTE extrusion/Kapton/PTFE dispersion; and (3) modified PTFE tape/TPT tape/modified PTFE tape/PTFE dispersion.

current spikes are only about 20 A, consequently no circuit breakers trip.

(2) Flashing. These were noted as a white flash and audible popping, and tended to occur after scintillations had been going on for some time. They are isolated events, with seconds or minutes passing before the next event (Figure 70). The events last about 0.5 ms and show 8 kW peaks, with 4 J being dissipated. Arc voltages of ca. 100 V and peak currents up to 65 A were measured.

(3) Strong arcing. A bright flash that lasted up to 1 s or more, with intense hum or crackling. Arc power levels were ca. 10 kW, with peaks up to 15 kW; energy dissipated was ca. 5 kJ. Circuit breakers often tripped, since the circuit topology produces parallel arcing.

A series of tests was conducted by Cahill[939] to examine the potential of electrical faults for igniting kindling fuels. In her tests, bare sections of 20 AWG aircraft wires were intermittently touched. This tripped the 7.5 A breaker in only 1 of 25 trials, but ignited adjacent polyurethane foam (non-FR) in several trials.

Electronic components

Researchers at VTT conducted limited testing to examine the ignition behavior of electronic circuit boards subjected to power supply overvoltage or reversed polarity conditions[940]. Electric failures and smoke were readily produced, but flaming ignitions were less common and were barely sustained. Tantalum capacitors readily 'exploded,' but this did not lead to flaming fires or subsequent ignitions. In a few cases, the printed circuit board itself ignited, but flaming only lasted 25 – 70 s. See also: *Television sets and computer monitors*.

Engines, diesel

The operating temperatures on the metal surfaces of a small, 1-cylinder diesel engine have been measured[941]. These were found to be very much dependent on the engine rpm's. At 700 rpm, no temperatures exceeded 150ºC, while at 1400 rpm peak temperatures of 400ºC were measured on the muffler, and temperatures around 300ºC on the exhaust manifold. Larger diesel engines, in particular those that are turbocharged, may show exhaust component temperatures over 600ºC under heavy load conditions. These can readily act as ignition sources for many kinds of combustible liquids. For this reason, some heavy equipment designs use a firewall between the engine and the hydraulic pump. An incident has been reported[942] where diesel fuel was being accidentally sprayed onto the exhaust manifold of a diesel engine. Ignition occurred only upon shutting down the engine. The engine was equipped with a high-speed cooling fan and the air flow created by this fan helped limit the residence time of the fuel in the vicinity of the manifold. If the air intake for a diesel engine happens to become contaminated with flammable vapors, a runaway condition can be precipitated, due to this unexpected source of fuel delivery. Some two-stroke diesel engines can runaway if the air intake is occluded. This vacuum condition can cause motor oil to be sucked into the chambers and burned.

Ethers

Ethers are organic compounds where two functional groups (which may be aryls or alkyls) are linked together by an oxygen atom. Common ethers include diethyl ether ($C_4H_{10}O$), vinyl ether (C_4H_6O), furan (C_4H_4O), tetrahydrofuran (C_4H_8O), ethylene oxide (C_2H_4O), and 1,2-propylene oxide (C_3H_6O). Some cyclic ethers are linked by two oxygen atoms, e.g., 1,4-dioxane ($C_4H_8O_2$). The explosion hazard of ethers comes from their propensity to react with atmospheric oxygen, forming first a hydroperoxide, then further reacting to form polymeric 1-oxyperoxides. 1-Oxyperoxides are substances containing the group (O–C–OO–). Ethers can be photosensitive, with light serving to accelerate the generation of peroxides.

Diethyl ether, also called ethyl ether, or just "ether," was the first anesthetic to achieve widespread use; however, it has been replaced in modern medicine by anesthetics which have fewer medical side effects and are not as seriously flammable. It is used very widely in the chemical, plastics, and pharmaceutical industries. Some of diethyl ether's unusual problems stem from its boiling point (34ºC), which is barely above room temperature. The high density of diethyl ether vapors sometimes allows vapors to accumulate in low spots or to creep along the floor until they come in contact with a source of ignition. It has been reported[943] that diethyl ether vapors are susceptible to ignition if discharged into the air at high pressure, but the mechanism is not documented. The thermal decomposition kinetics has been discussed by Seres and Huhn[944].

The combustion of diethyl ether is specialized, since, apart from showing normal flames and cool flames, it can also show green flames in a certain temperature/pressure region[945]. The green-flame combustion can occur at 1 atm pressure and temperatures of 330 – 370ºC. At subatmospheric pressures, diethyl ether is also unusual in that it exhibits two, discontinuous regions of flammability. For instance, at 20ºC and 0.5 atm pressure, mixtures of 1 – 7.5% are flammable, as are ones of 20 – 27%, but mixtures between 7.5 and 20% are not. The lower-concentration region corresponds to normal flames and green flames, while the higher one to cool flames. According to the Bureau of Mines, at 25ºC and 1 atm, the limits of flammability of diethyl ether are considered to be 1.9 – 36%. Flame propagation does not occur[946] at pressures below about 0.2 atm. Cool-flame ignition, by itself, does not injure persons or ignite other combustibles such as paper. However, once diethyl ether is ignited in the cool-flame mode, it can transition to regular burning with normal, hot flames; this can lead to explosions and general fire involvement. Glass bottles of diethyl ether have been documented to explode spontaneously in storage[947]. Diethyl ether is an electrical insulator, which allows electrostatic charge buildup that may re-

sult in incendive sparks being formed. Shipping containers for diethyl ether normally contain stabilizers, which involve an oxidized metallic surface such as cuprous oxide or stannous oxide.

Diethyl ether is one of the easiest to ignite vapors, but its AIT has historically proven very difficult to measure accurately, and early studies showed extreme disparities. The first reliable studies are considered to be those of White[947], who used a heated-tube method and reported 187ºC. In a later study[948], however, he considered the value of 227ºC, obtained by Tizard and Pye, to be a more accurate determination. Later, Hsieh and Townsend[949] reported on experiments where they had no difficulty in observing autoignition at 200ºC, but did not explore lower temperatures. Mullins[950] gives the AIT as 186ºC in air and 178 – 182ºC in oxygen. In a 1965 compilation[4], the Bureau of Mines listed the AIT as 160ºC in air. A 1985 Bureau of Mines compilation[127] gives a value of 195ºC in air and 180ºC in oxygen, but another table in the same publication lists 160ºC in air. Neither compilation provides information as to the origin of the data. NFPA 325 considers the AIT in air to be 180ºC. Powell[17] specifies that the AIT is 102ºC, but without giving any details, and this should be considered a spurious value. Bull et al.[951] reported on experiments where a 7.2% diethyl ether/air mixture was heated by a 114 × 114 mm vertical aluminum plate. Cool, blue flames were first observed at a plate temperature of 267ºC, while a hot-flame ignition took place at 591ºC. On the other hand, Powell[17] reports that using a much smaller brass plate (26 × 16 mm), ignition was found to occur at 225ºC. Additional data in Chapter 6 indicate that diethyl ether is one of the few substances for which hot-surface ignition temperatures are only barely higher than the AIT.

A vapor cloud explosion of dimethyl ether took place at BASF, in Ludwigshafen, Germany in 1948 that killed 207. *Petroleum ether* is a chemical misnomer and the product is not an ether at all; it is a mixture of low-boiling-point hydrocarbons and is synonymous with petroleum naphtha. See also: *Ethylene oxide*; *Organic peroxides*; *Propylene oxide*.

Ethylene

Ethylene (C_2H_4) is a gas widely used in the chemical and plastics manufacturing industries. The limits of flammability are unusually wide: 2.7 – 36%. The UFL rises drastically with increased pressure, leading to potential hazards in processes where ethylene is used under pressure. In oxygen, the upper limit rises to 79.9%. The minimum oxygen concentration for combustion is 10%; this is lower than the 11.5% – 12% value found for most hydrocarbons. Its very small MESG value of 0.65 mm (British) to 0.69 mm (UL) places it among the most difficult to protect of gases from the point of view of designing explosionproof instrument enclosures. The double bond (C=C) is not strong and ethylene is prone to decomposition, in which carbon, methane and hydrogen are the main products. In the presence of certain catalysts, e.g., anhydrous aluminum chloride, ethylene can undergo explosive oligomerization[26]. Ethylene is also used for artificially ripening fruit and a number of explosions have taken place when flammable atmospheres were inadvertently created. Britton et al.[952] reviewed the ignition hazards of ethylene that are potentially encountered in chemical production facilities.

Ethylene glycol

An ethylene glycol/water mixture is the most common form of antifreeze agent and is used in transportation vehicles of various sorts. The antifreeze mixture will not ignite and burn by itself, but if it is spilled on a hot surface, the water fraction can first be driven off, with the residual glycol igniting at that point. Spills of the antifreeze on electrical parts can start an electrolysis action which has been reported to start fires in aircraft[953]. Under such circumstances, a period of many hours may be needed after the spill before ignition can occur.

Ethylene oxide

Ethylene oxide (C_2H_4O) is used in very large quantities as an intermediate in the chemical manufacturing industry; it is also used as a sterilization gas for surgical equipment. The molecule has the shape of a 3-membered ring and is a member of the chemical family of oxiranes. In air, its minimum spark ignition energy of 0.06 mJ is exceptionally low, thus nearly-imperceptible sparks can lead to ignition. The spark energy required to ignite ethylene oxide vapor decompositionally (in the absence of air) is vastly higher. Energies in the range 100 – 1000 mJ are typical, but depending strongly on pressure and temperature[962]. Ethylene oxide is considered stable if pure and at low temperatures, but is notorious for fire and explosion incidents under other conditions, e.g., leakage into contaminated atmospheres or ignition by localized heat. Pure ethylene oxide vapor can be readily ignited at 125ºC by electric spark[954]. Ethylene oxide reacts with most organic compounds, thus, care must be taken not to use inappropriate gaskets or seals. The flammable range of ethylene oxide is quoted as 3 – 100%, which is, of course, exceptionally broad. At 1 atm, there are two regions of combustion: between 3% and 65% C_2H_4O, a normal luminous flame is seen; for mixtures over 65%, a pale-blue flame occurs; for 100% C_2H_4O, a nearly-invisible decomposition flame is found[963]. The pale-blue flame and the decomposition flame are not cool flames, which also occur, but which do not lead to propagating-flame conditions. A pressure limit of 0.7 atm is reported[26]. Gustin[955] reviewed case histories for a number of explosions involving ethylene oxide.

Surprisingly small amounts of ethylene oxide vapor in air can lead to explosion if rapidly compressed. Griffiths and Perche[956] showed that less than 1% vapor suffice, under mild compression conditions where compression raises the gas temperature to 567 – 617ºC. In addition, they hypothesized, but did not demonstrate, that compression in oxygen-free environments can also lead to ignition.

Britton conducted a large number of decomposition-explosion tests using ethylene oxide/nitrogen mixtures in an 0.55 L sphere[962]. For near-ambient pressures, a temperature of ca. 500ºC was needed for explosion, dropping to about 450ºC at 13 atm. A value of $E \approx 260$ kJ mol^{-1} appears to reasonably capture the process, both for Britton's own data and for Japanese work that he cites. During decomposition, detonation can occur at low temperatures. Chen and Faeth[957] found that there were two distinct pressure regimes, within which the limits were insensitive to the actual pressure. At pressures of 2 – 12 atm, detonations in 100% ethylene oxide were observed for temperatures over 80 – 120ºC; at pressures over 20 atm, the minimum temperature dropped to as low as 28ºC. These results indicate that setting up processes to operate at pressures over 12 atm is inadvisable, unless reliable chilling can be provided.

Pure liquid ethylene oxide is considered highly stable, but, in the presence of other substances it is subject to polymerization, isomerization, and decomposition reactions. Polymerization in the presence of moisture produces tetraethylene glycol or low-molecular-mass polyethylene gly-

Table 84 Common names for pure explosives

Common name	Chemical name	Alternate names
AN	ammonium nitrate	
AP	ammonium perchlorate	
BTF	benzotris[1,2,5]oxadizole, 1,4,7-trioxide	benzotrifuroxan; hexanitrosobenzene
CP	5-cyanotetrazolpentaamine cobalt III perchlorate	
DADNPh	dinitrobenzenediazooxide	diazodinitrophenol
DATB	2,4,6-trinitro-1,3-benzenediamine	
DDNP	diazodinitrophenol	
DEGN	2,2'-oxybisethanol, dinitrate	diethyleneglycol dinitrate; dinitroglycol
DINA	N-nitrobis(2-hydroxyethyl)-amine dinitrate	diethanol-N-nitramine dinitrate
dinol	dinitrobenzenediazooxide	diazodinitrophenol
DIPAM	2,2',4,4',6,6'-hexanitro[1,1-biphenyl]-3,3'-diamine	diaminohexanitrophenyl; hexanitrodiphenyl
DNP	2,4-dinitrophenol	
DNPA	2-propenoic acid, 2,2-dinitropropyl ester	2,2-dinitropropyl acrylate monomer
DNT	1-methyl-x,x-dinitro-benzene, where x,x denotes one of 6 possible isomers	dinitrotoluene
EDNA	N,N'-dinitro-diaminoethane	ethylene dinitramine
EDNP	ethyl 4-4-dinitropentanoate	
Explosive D	ammonium picrate	Dunnite
hexyl	dipicrylamine	hexanitrodiphenylamine; 2,2',4,4',6,6'-hexanitrodiphenylamine
HMTD	hexamethylenetriperoxidediamine	
HMX	octahydro-1,3,5,7-tetranitro-1,3,5,7-tetrazocine	octogen
HNAB	hexanitroazobenzene	
HNS	1,1'-(1,2-ethenediyl)bis-[2,4,6-trinitrobenzene]	2,2',4,4',6,'-hexanitrostilbene
NC	partially nitrated cellulose	nitrocellulose; guncotton
NG	1,2,3-propanetriol, trinitrate	nitroglycerin
NM	nitromethane	nitrocarbol
NQ	nitroguanidine	Picrite
PA	2,4,6-trinitrophenol	picric acid; trinitrophenol
pDNPA	2-propenoic acid, 2,2-dinitropropyl ester polymer	dinitropropyl acrylate polymer
PETN	2,2-bis[(nitrooxy)methyl]-1,3-propanediol, dinitrate	pentaerythritol-tetranitrate; penthrite; TEN
PGDN	1,2-propanediol, dinitrate	1,2-propylene glycol dinitrate
RDX	hexahydro-1,3,5-trinitro-1,3,5-triazine	Cyclonite; hexogen; trinitrotrimethylene-triamine; Research Department Explosive
TATB	2,4,6-trinitro-1,3,5-benzene-triamine	1,3,5-triamino-2,4,6-trinitrobenzene
TATNB	1,3,5-triazido-2,4,6-trinitrobenzene	triazidotrinitrobenzene
TATP	triacetone triperoxide	
tetryl	N-methyl-N,2,4,6-tetranitro-benzenamine	N-methyl-N,2,4,6-tetranitroaniline; tetranitromethylaniline
TNA	2-methoxy-1,3,5-trinitro-benzene	methyl picrate
TNB	1,3,5-trinitrobenzene	
TNM	tetranitromethane	
TNRS	lead styphnate	
TNT	2-methyl-1,3,5-trinitrobenzene	

cols, while polyethylene oxide is produced under dry conditions. Exothermic activity for 5 g samples of pure ethylene oxide held in a glass vessel[958] was found to commence at around 80ºC. The polymerization process requires a catalyst, with either acids or bases being able to serve that role[959]. Iron oxides promote the isomerization of ethylene oxide, although the action is not that of a simple catalyst[962]; the two most hazardous forms[960] of iron oxide are γ-Fe_2O_3 and γ-FeO(OH). Isomerization produces acetaldehyde with the release of 115 kJ mol^{-1} of heat. Acetaldehyde has a much lower AIT than does ethylene oxide, and if acetaldehyde has been formed due to catalytic isomerization, the resultant mixture can show a large drop in AIT[962]. The presence of water greatly lowers the temperature at which exothermic activity occurs. Detectable heat release was found at 200ºC for pure ethylene oxide, but at 50ºC for 10% ethylene oxide/90% water mixture. Even a 1% addition of dimethylamine to ethylene oxide was found to reduce the threshold to 33ºC[962]. June and Dye[961] studied the lower limit in ethylene oxide/nitrogen systems for decomposition explosions, and provided data as a function of moderately elevated pressures and temperatures.

Ethylene oxide soaking into porous pipe insulation is a special problem. Exotherms are found below 100ºC with certain insulations[1663]. Porous insulation exacerbates the self-heating problems of ethylene oxide since it captures a certain amount of moisture from the air, which is then available to react with the ethylene oxide. Britton considered the case of ethylene oxide polymerizing into one of the glycols and conducted oven-cube tests on glycol-soaked insulation to determine the temperature below which runaway self-heating is unlikely to occur. He concluded that for practical insulation thicknesses, pipe temperatures below 60ºC were acceptable[1663].

The liquid is more stable than the gas, but under extremes of pressure and temperature, liquid ethylene oxide can show a flaming decomposition[962] and has been considered as a rocket monopropellant and gas generant at one time. The decomposition products are primarily CO and CH_4, but C_2H_4, H_2, and minor amounts of C_2H_6 can also be produced. The primary reactions are[963]:

$$C_2H_4O \rightarrow CH_4 + CO$$
$$2C_2H_4O \rightarrow C_2H_4 + 2CO + 2H_2$$

For pressures up to 1 MPa, it is recommended that process temperatures be held below 75ºC; for higher pressures, progressively lower temperatures are needed[964]. The mixing of ethylene oxide and water is an exothermic reaction. A case history is reported of an explosion which occurred when water was added to a tank car which was about 15% full of ethylene oxide[965]. The analysis of the incident indicated that the two liquids (which are 100% miscible) did not, in fact, mix but rather stratified due to the filling procedure. A reactive lay-

Table 85 Common designations for explosive mixtures

Designation	Component	Percent
Amatol 80/20	AN	80

er was formed which heated strongly and drove the rest of the system to explosive decomposition.

In 1997 there was a rash of ethylene oxide explosions and it was speculated that at least some of them were associated with catalytic combustion systems used for air pollution control purposes[966]. In older times, it used to be prescribed that copper should not be used in ethylene oxide systems, since small amounts of acetylene impurities were common and there was concern of creating highly explosive copper acetylide. Ethylene oxide currently produced is free of these impurities and consequently the advice is outdated[26].

Explosives

Explosives are classed by UN[1650] as Class 1 Dangerous Goods. This class is subdivided into 6 divisions; in addition, a letter designation is appended to the Division number which denotes a 'compatibility group.' All transportable Dangerous Goods are also assigned a "UN No." For pure chemicals, a UN number identifies a unique compound. But most explosives are not pure chemicals, and they are assigned group numbers. These are determined by both the composition and the functional nature of the item. Each UN number belongs to a single Division, but there are many UN numbers in each Division. Explosive substances are assigned UN Nos. 0000 through 0500, but not all numbers are currently in use. Dangerous Goods of classes other than Class 1 are assigned numbers 1000 and higher. National regulations are typically based on the UN scheme, but with local variations.

Since the chemical names of most explosives are lengthy, in the explosives profession there has arisen a standard set of abbreviations or common names; a selection is given in Table 84 and Table 85. Some additional designations exist in Europe that are not common in the US.

Each year, BATF attends about 1500 bombing incidents, 500 attempted bombings, 400 fire-bombings, and 180 attempted fire-bombings[967]. The explosives used in these incidents are shown in Table 86. The deaths and injuries from incidents[968] are shown in Table 87.

Table 86 Explosives used in bombings and attempted bombing incidents in the US during 1993 – 1997

Explosive	Percent
flammable liquid	30
"chemicals" (homemade devices producing gas from domestic materials)	26
pyrotechnics, flash powders	17
black powder	10
smokeless powder	8
match heads	2
commercial high explosives	1.1
military explosives, except C4 and TNT	1.1
blasting agents	0.2
C4 and TNT	0.1
other	5

The oldest explosive is *black powder* (gunpowder) and for many centuries it was the *only* available explosive. Black powder normally contains 75% potassium nitrate, 15% charcoal, and 10% sulfur. Since it is a physical mixture made up of the three different materials, the method of preparation greatly influences the properties of the finished product. Furthermore, the nature of the ingredients themselves, e.g., what type of tree was burned to produce the charcoal, is also important. Maltitz[969] has written a book devoted solely to practical details, while Urbański[256] gives a more scientific review. The ignition temperature is typically cited as 300ºC, but this is preceded by several 'pre-ignition' steps. The process begins with melting of the sulfur at ca. 115ºC, then at ca. 150ºC the molten sulfur reacts with the hydrogen in charcoal to form H_2S. The H_2S reacts with the potassium nitrate to form potassium sulfate. The exothermicity of this reaction then leads to progressive melting of the KNO_3. Black powder still has significant uses in manufacture of fireworks, although it has long been replaced as a military propellant by smokeless powder. It sees use among enthusiasts of antique weapons, since these could not withstand the pressure created by smokeless powder. Some 'black powder' coming from China in recent years includes sodium chlorate, which produces a much more energetic (and dangerous) propellant[970]. Urbański[256] warns that substituting potassium chlorate for potassium nitrate in black powder will produce a mixture "exceptionally sensitive to impact and friction, and therefore too dangerous to manufacture." Even without this substitution, he notes that black powder is "highly sensitive to impact and friction." The wheel-lock weapon invented in the 16th century used a spark from a serrated wheel moving against iron pyrite to ignite black powder, clearly demonstrating that a modest mechanical spark suffices. A spark flying off a match head[315] has also been documented to ignite black powder. The energy required for spark ignition of black powder is 45 mJ, and one explosion in a black-powder manufacturing facility was attributed to low ambient temperatures, which caused low humidity levels and a high propensity towards static electrification[1436].

Stecher[443] supplied some very old values for ignition/explosion temperatures of a number of explosives, determined by an unspecified method (Table 88).

Urbański[256] has given ignition temperatures for various explosives (Table 89), obtained under short-term heating. For explosives lacking long-term stability, room temperature may effectively become their ignition temperature when they have sufficiently decomposed.

Hikita[971] reported T_{ig} and the activation energy, E, for a number of explosives in air. He also determined that, for the substances studied, there was no effect of oxygen concentration on the ignition temperature. Kayser[972] reported results from the NOL Thermal Sensitivity Test, which uses a sealed 'microbomb' to determined 'threshold' temperatures for the initiation of explosion. Both of these sets of data are given in Table 91.

Table 91 Properties as determined by Hikita and Kayser

Substance	T_{ig} (ºC)	E (kJ mol^{-1})	$T_{thres.}$ (ºC)

a – unspecified details
b – confined by 0.08 mm lead foil
c – only confined by a layer of 0.05 mm Mylar tape

The sensitivity of explosives to various forms of energy input varies a great deal, and even rank-ordering is not assured. Table 90 shows results for some common explosives[973]. The minimum detonating charge test uses lead azide as the detonator. The two drop-hammer tests, in principle, measure the same impact effect. Explosion temperature results were determined as 5-s exposures in an open cup. The friction test is a qualitative test at Picatinny Arsenal. Most of the tests rank-order explosives similarly, although with significant exceptions; however, the explosion temperature is clearly unrelated to the other results. A compilation of Bureau of Mines data from their versions of the card gap test and the projectile impact test has been published by Watson[974].

The Bureau of Mines (BM) reported ignition data on a series of explosives in a spark discharge test apparatus where the voltage was fixed at 5 kV and the capacitance varied[90]. In addition, confined and unconfined conditions were examined. Unlike most other procedures, the results were reported as P = 0% values, i.e., the highest energy for which no ignition will occur. Larson et al.[975] measured a number of explosives confined by thin foils at Los Alamos National Laboratory (LANL). In their study, they consistently found that greater thicknesses gave higher MIE values, thus only their thinnest foil results are presented here. Most recently, Skinner et al.[976] reported on a series of tests conducted at the New Mexico Institute of Mining and Technology (NMIMT) where the only confinement was a layer of Mylar tape. Some comparative results of these studies are given in Table 92. The agreement varies widely, but the two newer studies tend to agree better. Larson et al. also examined the effect of heated specimens on the MIE. At 175ºC, the MIE values typically dropped to about 50% compared to room temperature, although for a few specimens there was almost no decrease.

Several conclusions emerged from the Bureau of Mines study:

(1) The minimum spark ignition energy for unconfined mixtures usually increases greatly when the substance is pulverized to smaller than 100 mesh size.
(2) For confined conditions, the size of granules generally does not affect the minimum spark ignition energy needed.
(3) There is generally no relation between the confined and the unconfined results.

Table 93 Friction and impact sensitivity for various explosives (values given are for 50% probability level)

Substance	Friction sensitivity (kg)	Impact sensitivity (kg-m)
barium styphnate	1.7 – 2.0	0.113 – 0.122
CP	0.9 – 1.3	0.066 – 0.105
HMX	6.2	0.160 – 0.176
PBX of HMX (96% HMX, 4% FPC-461)	7.2	0.17
LX-15	> 36	> 0.250
LX-16	7.7	0.12
PETN	7.0 – 8.1	0.124 – 0.170
RX26BB (HMX/ TATB, 50/50)	13	> 0.250
TATB	> 36	> 0.250

(4) The above results pertain to 25ºC conditions; in separate testing, it was shown that for nitroglycerin under confined conditions at 60ºC, the minimum energy is greatly lower (0.056 J).

The values reported for lead azide are highly dependent on the test conditions. In other studies, MIE values have been lower, e.g., 0.002 mJ to 0.04 mJ. Dusts of black powder require 30 mJ for capacitive spark ignition, at the 50% probability level, while lead styphnate ($C_6H_3N_3O_9Pb$) requires[977] 0.052 mJ. A minimum ignition energy of 0.1 J has been reported for RDX[90]. Static electricity can readily cause explosion of detonators. Dale[67] and Demberg[978] described several accidents. In examining non-electric detonators using lead azide as the primary charge and various charges of secondary explosives, Demberg found that all incidents occurred within 72 h of manufacture. It was concluded that the most likely cause was electrostatic charge picked up during packaging, given the very high sensitivity of lead azide to electrostatic initiation. It was also concluded that safer detonators would result if fine particles of lead azide were eliminated from use.

Friction and impact sensitivities for a number of explosives were reported by Wang and Hall[979]. For friction sensitivity testing they used the Koenen/BAM test, while for impact sensitivity a drop-hammer test having an 0.5 m hammer drop distance and a 20 mg quantity of test substance. The results are shown in Table 93.

Table 94 Flash points for explosives

Using an adiabatic calorimeter, Gross et al.[980,981] determined the kinetic parameters of some common explosives (Table 98). Values from various sources[976,982,985] are shown in Table 100. The latter data are more current, thus can be expected to be more reliable than the work of Gross et al. Note however that Janswoude and Pasman[983] demonstrated that explosive substances typically do not show a behavior consistent with single-step Arrhenius kinetics over the entire temperature range of interest. Instead, as temperatures increase, the effective values of both *E* and *QA* fall.

Flash points for a number of explosives have been reported in the Russian literature[984]. The values shown in Table 94 were obtained in an open-cup, dynamic test method.

The minimum energy density (kJ m^{-2}) for shock initiation has been obtained for some explosives. Values are given in Table 95[985]. The term *critical energy fluence* is commonly used in the explosives field as a synonym for minimum energy density. The measuring techniques and the calculational formulas for obtaining these values are given by Walker and Wasley[986]. Results for liquid explosives (e.g., nitromethane; liquid TNT) are generally found not to obey a critical energy fluence relation[987].

The radiant ignition times of HMX, RDX, and tetryl at high irradiance values (> 300 kW m^{-2}) using a CO_2 laser has been reported by Vilyunov[234].

Table 96 Critical diameters for detonation of some pressed explosives

Explosive	Density (kg m^{-3})	Grain size (mm)	Critical diameter (mm)

	850	0.07 – 0.2	10.5 – 11.2

Table 97 Critical diameters for detonation of some liquid explosives

Explosive	Density (kg m^{-3})	Critical diameter (mm)
glycerol dinitrate	1520	8.0
nitric acid	1390	110.
nitroglycerine	1600	2.4
nitroglycide	1320	7.
nitromethane	1140	18.
nitromethane/acetone, 84/16	1080	80.
tetranitromethane	1640	16.

Critical diameters for detonation (not to be confused with critical diameters for decomposition) have been tabulated[90] for a number of explosives (Table 96). A larger compilation has been provided by Dobratz and Crawford[985]; they include information on effects of confinement, but not on grain size. Some critical diameters for liquid explosives (Table 97) have been presented by Dremin[988]. Heats of combustion, explosion, and detonation are shown for some explosives[90,989,990] in Table 99.

Table 99 Heats of combustion, explosion, and detonation for some explosives

Explosive	OB (%)	Heat of combustion (MJ kg^{-1})	Heat of explosion (MJ kg^{-1})	Heat of detonation (MJ kg^{-1})
NG	+3.5	6.76	6.69	6.22
PETN	–10.1	8.20	6.13	6.26
RDX	–21.6	9.53	5.72	6.08
HMX	–21.6	9.42	5.68	6.19
Pentolite	–42.0	11.67	4.09	
Tetryl	–47.4	12.24	3.90	4.77
TATB	–55.8	11.89	3.12	4.26
TNT	–74.0	15.15	2.78	4.57

Many explosives are prone to self-heating caused by decomposition, if stored above room temperature. For example, some limiting storage temperatures[232] are: mercury fulminate 50ºC, nitroglycerin 60ºC, PETN 65ºC, tetrazene 75ºC, although of course both the time and the quantity stored should also be taken into account. But others, such as tetryl, TNT, etc., are greatly more stable.

The US Department of Transportation regulates shipments by categorizing explosives as Forbidden, Acceptable, or New. Forbidden explosives include:

- materials showing a self-accelerating decomposition temperature (SADT) of 50ºC or less
- explosive mixtures or devices containing a chlorate and an ammonium salt or an acidic substance
- nitroglycerine, diethylene glycol dinitrate, or other liquid explosives, except as authorized by DOT
- leaking or damaged packages of explosives
- unstable, condemned or deteriorated propellants
- certain toy torpedoes
- fireworks containing yellow or white phosphorus
- initiating explosives, when dry
- all other substances identified as Forbidden in Par.172.101 (Hazardous Materials Table).

Table 98 Reaction properties determined by Gross and coworkers for some common explosives

a – varies widely for actual product

Although it is common for flammable gas/air explosions to cause fires, it is uncommon for explosions of solid explosives[180]. Forest fires have been repeatedly ignited by shooting enthusiasts using tracer, incendiary, or armor piercing ammunition. Numerous ignitions have been documented[991] due to use of Chinese bullets that have a steel 'penetrator core.' Firing high-power rifle bullets into cases of sporting ammunition causes only modest hazard. Hampton[992] fired 2 to 3 shots into various cases of ammunition and observed puffs of smoke. Some individual cartridges were found to be fired within, but there was no evidence of propagating explosion. He concluded that the hazard of mass detonating upon firing into ammunition cases is minimal. The *Handloader* magazine has published a book giving numerous details on essentially all commercially available powders for handloading of ammunition[993].

See also: *Ammonium nitrate and ANFO*; *Cellulose nitrate*; *Dusts*.

Fabrics

Fabrics predominantly occur in draperies, other decorative applications (e.g., bunting), bedding, clothing, and as the cover material for upholstered furniture. Textiles can also be found in rugs and carpets, but these are generally treated as a separate commodity from the point of view of ignition testing and characterization.

An early study[994] provides US statistics on the ignition of clothing fabrics (Table 101). In 36% of the cases, a flammable liquid was involved as an 'intermediary material.' Gas ranges accounted for 65% of the kitchen range incidents. In another US study[995], the activities of victims leading to ignition were identified (Table 102).

Table 102 Activities of victims whose clothing got ignited

Activity	Percent
cooking	12.1
playing with matches	10.5
using matches or lighter	10.5
falling asleep with smoking material	7.6
working/repairing machine	6.1
smoking	5.8
tending open fire (not leaves or trash)	5.4
burning leaves or trash	4.8
sleeping	4.8
playing near open fire	2.8
cleaning with flammable liquid	2.7
helping another person	1.3
other	15.7

The US Federal standard regulating the flammability of apparel fabrics does very little to prevent injury from flammable fabrics. During 1965 – 1970, a Federal program was in place whereby 434 fabrics associated with burn injuries were tested[996]. Of those, only 5, or 1.2% failed the CS 191-53 (16 CFR 1610) method; this method is described in Chapter 7.

Fabrics are sometimes divided into those made of natural versus synthetic fibers. Cotton, wool, linen, silk and hemp are the dominant natural fibers, while synthetic fibers include nylon, polyester, acrylic, and a host of others. Rayon and cellulose acetate are made by chemical modification of natural materials, thus, they do not fully fall into either category. The earliest form of rayon fabrics were based on cellulose nitrate (see *Cellulose nitrate*). These were extremely flammable and such fabrics have not been made since the 1930s. The cellulose used today in making rayon fabrics is not nitrated.

Because of their light weight, the ignition of both charring and melting fabrics tends to involve complications. Most synthetic fibers (apart from acrylic and high-temperature fibers, e.g., Nomex) are thermoplastic. These types of fabrics generally show melting, drooping, and other large-geometry deformations prior to igniting. Thus, they may move out the igniter flame, if ignition is from a flaming source. If ignition is by radiant heat, the motion may change the effective heat flux that subsequently seen by the specimen.

Charring fabrics (e.g., cotton, wool) generally do not deform greatly prior to ignition. However, if heated slowly, they char and blacken, then possibly ignite in a glowing mode, prior to going into flaming ignition. In some unpublished testing on cotton fabrics using a hot air stream, the author found that the response to temperature of the test specimens was approximately as follows:

225 – 245ºC light brown
260 – 290ºC medium brown
300 – 340ºC dark brown/black
355 – 365ºC glowing ignition

Glowing ignition is readily recognizable as an abrupt turning red of a previously black place on the material. Often glowing ignition is highly localized, preferentially occurring at an edge or where fabric yarns have broken due to charring-induced tension. The temperature noted above is *not* the temperature of the glow, but the surface temperature of the material an instant before the glow appears; actual glow temperatures would be several hundred degrees higher. Under slow heating conditions, transition from glowing to flaming is highly unpredictable. In some cases, flaming occurs after only a slight additional heating (i.e., a surface temperature of 370 – 400ºC). But it may occur much later, when the surface is substantially hotter, or not at all, if the fabric is sufficiently consumed by means of glowing combustion. The above sequence of events appears to be relatively insensitive to the weight of the cotton fabric; however the temperatures reported should not be construed as minimum values.

Table 103 Ignition temperatures for fabrics measured in a modified Setchkin furnace

GIRCFF No.	Fabric type	Pilot ignition (ºC)	Auto-ignition (ºC)
4	cotton	280-290	280-297
9	cotton	297-290	297-308
18	cotton	278-294	301-311
5	cotton	301-311	301-327
10	cotton	339-351	429-443

Fabrics are perhaps the best example of a thermally-thin material. Thus, studies on fabrics may reveal, at least qualitatively, fire physics pertinent to other thin materials.

Charring or glowing of fabrics can be affected significantly by impurities present in the fabric, especially alkali metal ions. When cotton and similar fabrics are ignited in a flam-

IGNITION TEMPERATURE

The ignition temperatures of fabrics, despite being studied by numerous investigators, are poorly known. The problem comes from the fact that very diverse results have been reported for the same fabric type, and it is not readily possible to ascribe these differences to peculiarities of the test method or the experimental technique. Consequently, the present section comprises a compilation of data from some of the better-known or more extensive literature sources, but none of the reported values should be viewed as definitive or as recommended.

The AIT[443] of several fabric types was reported by NIST in 1947 using a test method which was only described very sketchily, see *Wood* for details. The values given were: cotton 240ºC, nylon 475ºC, silk 570ºC, viscose rayon 280ºC, wool 205ºC. In 1949, Graf[997] reported on the autoignition temperatures of a number of fabrics. His typical values were: cotton 250ºC, linen 240ºC, rayon 300ºC, silk 232ºC, and wool 240ºC. His experimental technique, however, was poor (see *Wood*).

Wulff et al.[1032] conducted ignition tests in a modified ASTM D 1929 Setchkin furnace, with the modifications as described in Chapter 7. These results are shown in Table 103. For piloted ignition, there was little difference among the cotton specimens. But for autoignition, the differences were surprisingly large, apart from the FR cotton which would well be expected to diverge from other cotton specimens. The 'GIRCFF' numbers refer to a textile industry research program; the physical characteristics of these specimens have been studied in some detail[998], but ignition temperature differences are presumably due to chemical, not physical factors.

The NFPA Handbook[999] lists ignition temperatures for a number of FR fabrics and of fabrics that intrinsically resist high temperatures. These are shown in Table 104, but the measurement technique used to obtain the values is unknown. The temperature given for FR cotton seems questionable. Einsele[1000] and Rieber[1001] reported the ignition temperatures for a number of fabrics, using unspecified test methods (Table 105). Rieber's data for cotton are dubious, since a higher value is listed for piloted ignition than for autoignition.

Khattab[1002] studied the autoignition temperature of 25 × 25 mm fabric samples using a tube furnace. He found that higher ignition temperatures were recorded in the horizontal orientation than in the vertical (Table 106).

Horrocks et al.[1003] studied the autoignition temperatures of a number of fabrics in a vertical tube furnace, with the presence of an updraft. Their tabulated AIT values (Table 107) are notably high, as compared to values determined in other studies; this is presumably due to effects of the updraft.

Normal cotton fibers are about 95% cellulose. Davies et al.[199] conducted thermal analysis tests on cellulose purified from cotton (see *Cellulose*) and found that in a DTA apparatus autoignition occurs at 350ºC for a heating rate of 20ºC min^{-1}, going down to 290ºC at 1ºC min^{-1}. Repeating the experiments for cotton treated with a durable FR agent, they found[1004] an autoignition temperature of 310ºC at the 20ºC min^{-1} heating rate; a drop in ignition temperature is common for FR agents that work in the condensed phase. The ignition temperature of fabrics was studied by Mórotz-Cecei and Beda[1005] in a modified thermal analysis instrument which had been equipped for spark ignition, giving the results shown in Table 108.

Robinson et al.[1006] tested fluff created by grinding up rubberized cotton fabric and testing 'small samples' in a fur-

nace. No exothermic behavior was found at a furnace temperature of 200ºC; at 210ºC smolder could be initiated, but without visible glowing; at a 220ºC furnace temperature, glowing ignition was observed. The ignition temperature of white cotton terry-cloth towel was determined[1007] using the LIFT test to be 302ºC; as normal for reporting results from that test, the value is determined by a computation based on a theory and not by direct measurement.

FLAME IGNITION

A large number of studies are available on the flame ignition of fabrics, because burn injuries from clothing items most commonly occur when a flaming ignition source ignites the garment. Because of heat-sink effects, time to ignition is usually found to be proportional to the fabric's 'basis weight,' which is the mass per unit area (g m^{-2}). Exceptions commonly involve napped-surface fabrics such as terry cloth which are effectively 3-dimensional structures and less well idealized as being simply a plane sheet. Fabrics with napped or brushed surfaces may ignite much more readily than their weight might suggest, but such ignitions are sometimes only partial, that is, only the nap burns off and the base fabric fails to ignite.

A large ignitability study was performed at NIST on 58 fabrics in a wide variety of fiber types. The specimens were oriented at 45º and ignited by a small, diffusion flame from a butane burner. Apart from five that did not ignite (2 nylon, 1 polyester, 1 silk, 1 wool), the results are shown in Figure 71. The straight-line relation shown is:

$$t_{ig} = 0.0128\, w$$

where t_{ig} = ignition time (s) and w = basis weight (g m^{-2}).

A major study at FMRC[1008] gave the following conclusions concerning fabric ignitions from small flames of a laboratory burner:

- For most fabrics, ignition times did not change with fabric angle, for angles between 0º (horizontal) and 62º. The only exceptions were knit-brushed and terry cloth fabrics, which were much slower to ignite in the 0º position. (But note below that other researchers have disagreed).
- Ignition times were insensitive to flame height and burner tube diameter.
- For premixed flames, the equivalence ratio (normalized fuel/air ratio) had a significant effect, with fastest ignitions being near stoichiometric conditions.
- Ignition always occurred fastest when the luminous tip (for diffusion flames) or the tip of the inner cone (for premixed flames) was contacting the fabric. Ignition times increased when the flame was held closer or farther from the fabric than this distance.
- Premixed flames ignited fabrics about 2.5× faster than did diffusion flames. For very quickly ignitable fabrics (ignition times < 1 s with a diffusion flame), the ratio climbed even higher.
- Ignition times from a paper match were similar to ignition times when using a diffusion flame burner.
- A sizable fraction of thermoplastic-fiber fabrics tested melted but did not ignite when using a premixed flame burner; most of them did ignite when using the diffusion flame burner.
- Fabrics which had dissimilar front and back surfaces tended to show different ignition times for flames applied to back versus front.
- The presence of a skin-simulating heat sink close to the rear face of the fabric had only slight effects on ignition time.
- Fabric porosity did not affect the results.
- Over the range of RH values studied (15 to 85%), no effect was found of equilibrium relative humidity on the ignition time for thermoplastic fabrics. A minor effect was found for cotton and part-cotton fabrics, but this effect can become important in any particular test if the performance is otherwise borderline.

The FMRC ignition time data for cotton fabrics, when using a premixed methane flame could be predicted on the basis of the fabric weight as:

$$t_{ig} = 0.0055\, w$$

in other words, ignition was about twice as quick as found in the NIST tests for a diffusion flame. The FMRC correlation is restricted to cotton fabrics, since few thermoplastic specimens ignited when using the premixed flame burner.

Weaver[1009] conducted ignition tests using the CS 191-53 (16 CFR 1610) method (described in Chapter 7) with the modification that the flame was applied for varying lengths of time in 1-s increments. In his tests on cotton fabrics, he found a similar proportionality between the ignition time and the fabric weight. Corduroy and terry were the excep-

tions to the general trend, igniting much faster than expected from their weight. Apparel cottons typically ignited in 1 – 2 s; twills, ducks, and denims ignited in 4 – 6 s; only one specimen out of 65 required more than 6 s for ignition.

Ward and Jaeckel[1010] tested a variety of fabrics by applying small flames to specimens oriented vertically, horizontally, and at 45º. For thermoplastic fabrics, ignition generally took much longer in the 45º orientation than for vertical or horizontal specimens. For cotton fabrics, the effect was unclear, since not enough data were collected. Not surprisingly, on the average, ignitions were fastest for the vertical orientation. In some tests, a flame is applied to the face of the cloth, while in others it is applied to the bottom edge of the fabric. A study[1011] showed that ignition times are roughly twice as long when the flame is applied to the face, as opposed to the edge. In some cases, ignition times are slightly different depending on the orientation of fabric, that is, whether the warp or the weft direction is placed vertically[1003]. Holmes[1012] pointed out that size of flame does not make much difference when igniting cellulosic fabrics, but that thermoplastic fabrics have a higher probability of ignition from a *smaller* flame, since a smaller flame is less likely to cause melting and retraction sufficient for the fabric to move away from the hot zone.

Durbetaki[1013] ignited clothing fabrics from the gas flame above a burner and examined the effect of the angle of the cloth. His results (Table 109) show that, with most fabrics, when the burner gas stream was not directly perpendicular, longer ignition times were found. For terry cloth, quickest ignition was at a 30º angle. This is due to the high pile structure of the cloth, which can 'capture' the gas stream.

Table 109 Results for fabric ignition times (s) from a gas flame

Fabric	Angle of cloth from horizontal			
	0º	30º	45º	60º
cotton denim, 296 g m^{-2}	4.0	5.1	7.3	--
cotton terry cloth, 265 g m^{-2}	3.7	1.0	1.9	2.6
batiste, 65% polyester/35% cotton, 86 g m^{-2}	1.2	1.8	3.1	3.8

Irjala[1014] conducted several Nordtest tests on bed linens. Her results are summarized in Table 110. The Nordtest NT Fire 037[1015] is a horizontal-test method that has three parts: cigarette ignition is tested in the horizontal orientation by placing the specimen on a mineral fiber board, placing a lighted cigarette on top, and covering it with (a) a cotton sheet; or (b) an absorbent cotton pad. Flaming ignition is tested by applying a butane flame for 20 s; ignition is reported if flaming continues for 150 s after removal of butane flame. Nordtest NT Fire 029[1016] is a 45º test slightly similar to CS 191-53. A flame is applied to the surface, near the bottom for varying lengths of time. If no ignition occurs for a 20 s application, ignition time is reported simply as greater than 20 s.

Injury from clothing textiles is often very serious because it takes a relatively long time for pain to be felt after the ignition of a fabric. Studies at FMRC[1017] showed that lightweight cotton fabrics ignited from a small flame in 1 – 2 s, but it took another 4 – 11 s before the wearer would have registered pain. By that time, flame spread may well have engulfed a large part of the garment and serious injury might be unavoidable. It has been suggested that this happens with cotton fabrics because, even though the thermally-thin assumption is generally reasonable, flaming commonly occurs on the outside of the fabric first, and does not break through to the inside until a sizable area has become flame-involved[1018].

A significant fraction of clothing ignitions occur when the victim, especially an elderly woman, is wearing a billowy-sleeve garment and is doing cooking on a gas stove. To address this issue, a possibly unique set of experiments[1019] was conducted by Gillette Research Institute. In these experiments, various fabrics were constructed in the shape of

acrylic	35.5 – 58.1

a sleeve and moved over a gas burner, maintaining various heights above the stove and times of exposure. Enough test runs were made so ignition propensity could be expressed as a probability of ignition. Fabrics which tend to melt and shrink performed well: polyesters showed nearly 0% probability of ignition, with nylon ranging 5-25% for a 15 s exposure. Wool showed a 30% probability for a 15 s exposure, while acrylic and acetate/nylon blends showed around 40%. Cotton, FR cotton*, and cotton/polyester blends showed very poor ignition performance, with most specimens showing an 85-100% probability for a 10 s exposure. Even at a 5 s exposure, these fabric types fared badly, with only a few heavyweight trouser fabrics showing less than 50% probability of ignition. Trousers, however, are rarely ignited on stovetops in actual incidents.

For applying ignition data to fire cases, it must be noted that ignition propensity is not the only factor affecting burn injury. Lightweight fabrics have the highest propensity to ignition. They also have the highest flame spread rate. However, their heat content is also the lowest, which means that at any given location such a material will present a briefer heat flux history to the skin, than does a heavier, slower-to-ignite material. In principle, a fabric could be so lightweight that it could burn up fully, yet not cause serious injury. In practice, Webster et al.[1020] estimated that a fabric would have to be 11 g m^{-2} or lighter in order to burn up without causing injury. This is not a viable weight for clothing textiles, since even a lightweight muslin is ca. 35 g m^{-2}.

In addition, it must be emphasized that while most thermoplastic fabrics are capable of being ignited by a small burner (e.g., as in the NIST study), this does not indicate that they will cause an appreciable burn injury. Arnold et al. conducted full-scale tests on dresses and concluded that nylon, polyester, and certain FR fabrics cannot sustain combustion, even when ignition is attempted with a large paper fuse[1021]. The question whether ignition leads to self-sustained combustion is a crucial feature of fabrics flammability, but is not incorporated into any standard test or regulation for fabric flammability. Based on further experimental work, Kadolph et al.[1022] proposed a rating scale (Table 111); her ratings are very similar to experimental observations of Krasny et al.[1023] and of Chouinard et al.[1024] These studies indicate that thermoplastic fibers which melt and pull away from the source of heat (such as nylon or polyester) are associated with low injury potential from garments. Conversely, acrylic fibers were found to be the most hazardous fiber type both by Kadolph and by Krasny. These plastic fibers, instead of melting and shrinking back, intumesce and burn in place.

Full-scale mannequin tests conducted by Bercaw and Jordan[1025], however, gave somewhat different results. Their testing, which used single-layer A-line dresses, gave the results shown in Table 112. Perhaps the most usable data are those obtained from NIST's Mushroom Apparel Flammability Test (MAFT) since they are measured quantitatively; some results[1026] are shown in Table 113. In some cases, an individual may wear cotton underwear, with a nylon or polyester outer garment. In that situation, there is no benefit from the melting behavior of the outer garment, and the two-layer combination can cause severe injury. Other heat transfer measurements were made by Chouinard et al.[1024], who measured the total heat transferred (as opposed to the heat transfer rate) to sensors located 6 mm

* It is noteworthy that the same FR cotton fabric which showed ignition behavior indistinguishable from non-FR specimens in the stovetop burner test showed "no ignition" results in Bunsen burner tests conducted at FMRC.

away from the back side of various fabrics. They determined that for cotton, acrylic, and wool fabrics:

$$q'' = (1.5 \text{ to } 2.1)W$$

where q'' = energy fluence (kJ m^{-2}), and W = basis weight (g m^{-2}).

The melting temperature of melting fabrics is invariably lower than the ignition temperature, and this is the main reason that melting fibers show relatively good performance with regard to burn injury. Table 114 shows some melting temperatures for various fibers[1001,1027]. But melting temperature alone does not determine whether the material will stay in place or fall off and the latter, as mentioned above, is an important factor.

Table 114 Melting temperatures of different fibers

Fiber	Melting temperature (ºC)
acrylic[a]	235 – 320
diacetate	255
modacrylic	160 – 190
nylon	160[b] – 260
polyester	252 – 292
polypropylene	164 – 170
PVC	100 – 160
triacetate	293
a – acrylics often shows no clear melting point b – value appears to be unreasonably low.	

Most ignition test methods used for fabrics are a variant of a Bunsen burner test, but there has been a very large variety of similar, but non-identical tests published by various standards bodies. The two mandatory Federal standards in the US concerning the ignitability of garment textiles are discussed in Chapter 7. Villa and Krasny[1028], Krasny[1029] and Carroll-Porczynksi[1030] reviewed a large number of other US and UK test methods. Vlot[1945] has reviewed laws and regulations governing the flammability of textile products from numerous countries.

RADIANT IGNITION

Radiant ignition occasionally occurs with garments, but is more important in other applications, e.g., theater curtains. Thus, a fair amount of research exists on this ignition mode. Wesson[1031] compared the piloted-ignition times for black and white fabrics using flame radiation and tungsten lamps. Since white fabrics have a low radiant absorptivity in the visible spectrum, but high in the infrared, the results (Figure 72) show that white fabric ignites more quickly when using a flame source than a tungsten lamp source. For black fabric, there was no detectable effect of radiation source. Wesson further showed that if the absorbed irradiance, rather than incident irradiance, were plotted on the x-axis, all of the data would collapse onto a single line. This data treatment will generally be impractical, however, since it requires having the complete spectral absorptivity curves of the test materials, along with the spectral characteristics of the radiant source. Wulff et al.[1032] studied the absorptivity of 20 different garment fabrics under two conditions: tungsten lamp source and infrared heater. For both sources, absorptivities were very low, typically 0.2, and higher than 0.26 in only 10% of the cases. This could be attributed to the diaphanous nature of most fabrics, with transmissivity typically being much greater than absorptivity.

Table 115 Piloted ignition times for terry cloth tested horizontally in the Cone Calorimeter

Heat flux (kW m^{-2})	20	30	45	60
Ignition time (s)	51	17	6.3	4.3

Table 116 Piloted ignition times (s) for fabrics tested at various heat fluxes in the Cone Calorimeter by Scudamore et al.

Fabric	Weight (g m^{-2})	Flux (kW m^{-2})			
		20	30	40	50
acrylic	400	52	28	16	19
wool	392	24	15	11	9

The piloted ignition of cotton fabrics exposed vertically to a radiant heat source was studied by Rangaprasad et al.[1033], who found a minimum heat flux for ignition of 12.6 kW m^{-2}. A white cotton terry-cloth towel was tested for piloted ignition in the LIFT test[1034]; it gave a minimum flux for ignition as 10 kW m^{-2} when tested with a non-combustible ceramic fiber backing board. Vodvarka[1035] conducted studies to determine the minimum radiant flux needed for autoignition of a muslin cotton bedsheet when exposed to quartz lamp radiation. He found a minimum flux of 40 kW m^{-2} was needed, but this dropped to 29 kW m^{-2} when a mattress was placed behind the bedsheet so it no longer received convective cooling on the unexposed face. Simms[1036] reported that 16 kW m^{-2} was needed for the autoignition of cotton cloth, provided that the exposed area was large (greater than about 0.05 m^2). For an exposed area of 50 × 50 mm, the value rose to 33 kW m^{-2}.

Ohlemiller conducted Cone Calorimeter tests on terry cloth and obtained the results shown in Table 115. Scudamore et al.[1673] tested two fabrics for piloted ignition in the Cone Calorimeter. The specimens were oriented horizontally, but further test details were not specified. The results are shown in Table 116. Holbrow et al.[1037] tested the autoignition of various fabrics in the Cone Calorimeter. The specimens were backed with 13 mm thickness of ceramic fiber blanket. Their results are shown in Table 117.

Mowrer[1038] explored the autoignition of several fabrics using the Cone Calorimeter in the horizontal orientation. Fabrics were desiccated then stretched over a dead air space. His results are shown in Table 118.

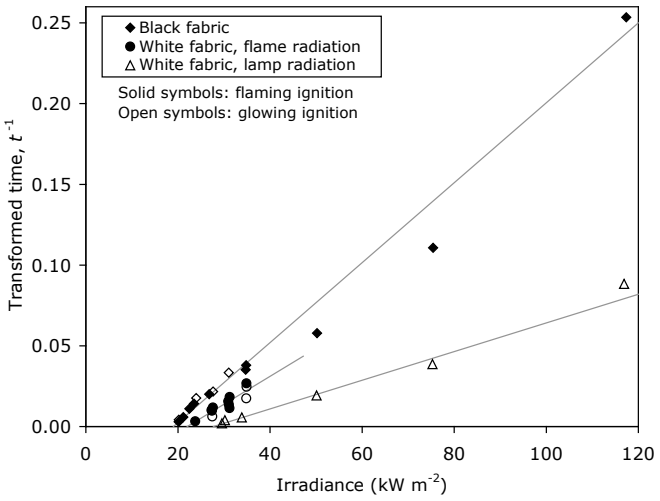

Figure 72 Effect of fabric radiant absorptivity (color) and radiation source type on the piloted ignition of cotton fabrics

Researchers at Japan's NRIFD reported an interesting study on fabrics in the Cone Calorimeter[1039]. They used the horizontal specimen orientation and the stretcher frame developed at NIST for testing fabrics over a dead-air space. Fabrics in the range of 70 to 538 g m^{-2} were tested. All fabrics ignited at a heat flux of 50 kW m^{-2}, one fabric (a 70 g m^{-2} nylon) did not ignite at 35 kW m^{-2}, while 4 fabrics did not ignite at 20 kW m^{-2}: the above nylon; a 77 g m^{-2} FR nylon; a 115 g m^{-2} polyester lace fabric; and a 118 g m^{-2} FR polyester lace. In addition, at 35 kW m^{-2}, the non-FR polyester lace ignited in only 1 of 3 trials. These results appear to be related to basis weight, since the 4 fabrics failing to ignite at 20 kW m^{-2} were the 4 lightest fabric samples examined. Times to ignition at 50 kW m^{-2} were very short (< 7 s) for most specimens, except the lightest and the heaviest. The specimens taking more than 7 s to ignite were the two lightweight polyester lace fabrics, plus a 409 g m^{-2} rayon and a 538 g m^{-2} FR rayon. Details of the ignition are not provided, but it may be that the very lightweight thermoplastic lace fabrics shrink and melt together at the edges, and only ignite there. If so, this would explain a long time to ignition, since the effective thickness of such a molten glob would be much greater than for the initial fabric.

The NRIFD researchers conducted all their tests with an unusual arrangement: underneath the fabric they placed a layer of aluminum foil (Figure 73). Thus, the tested specimens were a fabric-foil "sandwich," which was then stretched over the dead-air space in the specimen holder. This was done because they reported[1040] getting generally no ignitions without a foil backing; it is not clear how many fluxes or specimens were tried in the no-foil condition. The interpretation of such results is not necessarily obvious. Fabrics are porous substances and the lightweight ones are visibly porous. Possibly radiation reflected from the foil then serves to simultaneously heat the back face of the specimen. The flow of pyrolysis gases is also clearly affect-

ed, although this is harder to interpret. In any case, it is not very clear whether such results are applicable to any end-use situations.

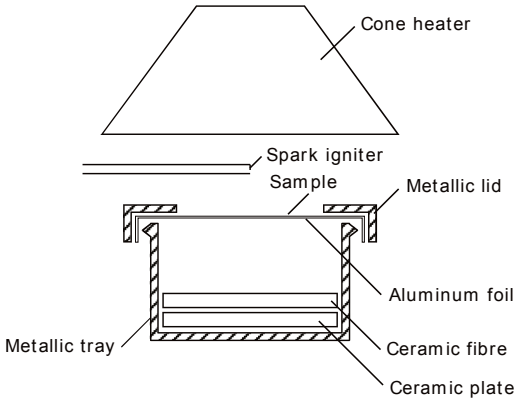

Figure 73 Arrangement for testing fabrics in the Cone Calorimeter used by researchers at NRIFD

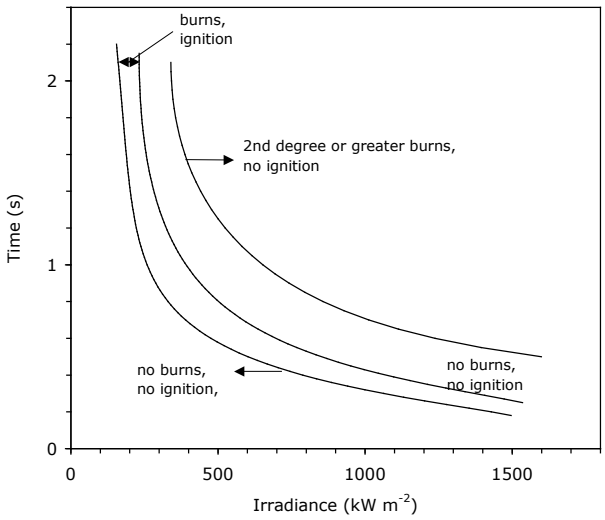

Figure 74 Regimes of radiant ignition found by Mixter for shirt fabric + underwear fabric system

Schopee et al.[1041] tested fabrics for autoignition with an unusual radiant heat apparatus where the specimen was simultaneously exposed by heaters from both sides. Their results are given in Table 119.

Wu et al.[1042] tested the ignitability of protective Army clothing by radiant heating. In their tests, two-layer (Nomex/Kevlar outer layer, aramid waffle-weave underwear) samples were tested on top of a block which has thermal properties roughly similar to human skin. At a flux of 84 kW m^{-2}, without a pilot there were no ignitions during the maximum exposure time of 10 s. Using a gas pilot, no specimens ignited for a 4 s exposure, but when exposed for 6 – 10 s, ignition did occur, but flaming was not sustained upon removal of the pilot.

Ward and Jaeckel[1010] studied the ignition of fabrics placed vertically 7 mm away from a radiant heater of unspecified heat flux. They found that cotton and FR cotton (but the FR cotton specimens ignited much faster than the non-FR) ignited in a few seconds, while cellulose triacetate, secondary cellulose acetate, acrylic, polyester/cotton blend, and all thermoplastic fiber fabrics did not ignite at all.

The clothing of electricians sometimes ignites when a high-current electric arc is caused in switchgear. Doughty et al.[1043] used an electric arc test apparatus to determine the energy needed to ignite cotton apparel fabrics of the kinds commonly used by workers. Their results are given in Table 120.

Under intense radiant heating, a fabric may be so rapidly pyrolyzed that sustained flaming becomes impossible. Mixter[1044] studied this phenomenon by exposing fabric systems comprising a cotton shirt fabric on top of an undershirt material to radiant heating from a carbon arc. Figure 74 shows that four regimes were found in this work:

- at lowest fluxes—no ignition, no burns
- at higher fluxes—ignition, burns
- at higher yet fluxes—no ignition, no burns
- at highest fluxes—no ignition, but burns occur.

This phenomenon, which is relevant only to very high heat fluxes, has not been studied for other fabric systems, so the results of Mixter should be viewed only as indicative. Burns are avoided in the third regime due to the endothermicity of the pyrolysis process.

CONVECTIVE HEATING

Hinkley et al.[196] conducted experiments on vertically-oriented white cotton fabric (120 g m^{-2}) by impinging an air stream from a hot-air blower onto the fabric. Their results are given in Table 121. Air flow velocities were not measured. It was found that fabrics ignited convectively by a hot air stream ignite substantially faster when oriented horizontally than when oriented vertically, but a general quantification of the effect was not undertaken[1045]. In another study[1046], it was found that cotton fibers (not woven into fabric) autoignited in a hot air stream at less than 370ºC.

Table 121 Autoignition of cotton fabric from a hot-air blower

Distance from outlet (mm)	Hot air temp. (ºC)	Ignition time (s)
25	876	3.1
51	849	3.5
76	705	5
102	545	17
114	470	N.I.

OTHER FORMS OF HEATING

It is extremely unlikely that a cigarette would ignite (either flaming or sustained smoldering) an item of clothing[317,1047]. This includes even fabrics which fail the CS 191-53 test. It was also found that a variety of contaminants (laundry softener, oily soil, cigarette ashes, and an ethanol/water mixture) placed on fabrics could not induce flaming from a cigarette[1048]. Smoldering which can later turn into flaming was found possible only in massed layers of fabrics, such as in storage. Smoldering ignition of folded denim clothing has been reported upon placing a lighted cigarette within the folds; in one test smoldering transitioned to flaming at 28 minutes[304].

Large burning wood brands (38 × 38 mm) readily ignite denim, burlap, gunny sack, and similar heavy cotton fabrics[1049]. For somewhat smaller wood brands, ignition probability is highly dependent on wind conditions. Lighter fabrics, such as broadcloth cotton shirt fabrics and wool fabrics, tend to burn through without sustained ignition, unless backed by some insulating material. Even with backing, they tend to resist ignition from smaller wood brands. However, it is rare that brands this large would land on persons. The hazards of burning wood brands only a few mm in size appear to be negligible. Molten copper ejected from a high-current electric fault has caused ignition of workers' clothing[1050]. Impact sparks and welding sparks (slag) have been documented to ignite clothing of workers, leading to fatal injuries. Molten material from arc welding will readily burn holes through clothing, but actual flaming ignitions are rare, and no laboratory study appears to exist of this topic.

Table 122 Hotplate ignition temperatures of some fabrics

Fabric	Temp. (ºC)
cotton	400
acetate	525
nylon 6	530
triacetate	540
acrylic	560
polypropylene	570
wool	600
modacrylic (Teklan - polyacrylonitrile/ polyvinylidene chloride, 50/50)	690

Table 123 Glow-bar ignition temperatures of some fire-improved fabrics

Fabric	Weight (g m^{-2})	Temp. (ºC)
cotton	155	< 820
FR cotton	155	820
Nomex (aromatic polyamide)	170	800
Nomex	220	850
Kynol (phenolic based)	240	790
Fypro (modified polyamide)	145	860
polybenzimidazole (PBI)	165	930

Hot-surface ignitions of fabrics have been studied by several workers. Sayers[1051] tested a number of fabrics by dropping specimens onto a hotplate. His results are given in Table 122 and these are not too different from ignition temperatures determined by other means. Kaswell[1052] tested some fire-improved fabrics by pressing a glowing metal bar against the fabric; his results are given in Table 123. Ward and Jaeckel[1010] attempted igniting various fabrics with a heated metal bar of an unspecified temperature. They found that cotton, FR cotton, secondary cellulose acetate, and cellulose triacetate specimens ignited, while wool and thermoplastic fiber fabrics did not.

Ignitions of fabrics from electric burners has been studied[1053]. No fabrics ignited when exposed to a burner at 370ºC (visible radiation is not seen at this temperature). For the two higher temperatures used, results are given in Table 124. Ignitions, when they did occur, took from 1 s to 30 s, with the exception of a single specimen that took 56 s. The results indicate that 100% thermoplastic fabrics are unlikely to ignite from an electric burner, but that cellulosic and part-cellulosic fabrics will usually ignite if brought into contact with a burner running at its high-heat setting. They may also ignite if held a short distance above such a burner.

Data on thermal exposures to parachutes from burning-aircraft fireballs have been analyzed by Thielman[1054], who also reports some tests on nylon, Nomex, Kevlar, and

Table 124 Ignition of fabrics from electric burner

Fabric	Maximum height above burner (mm) at which ignition occurs	
	510ºC (dull red)	590ºC (bright red)[c]
cotton, plain-weave, 306 g m^{-2}	0	5
cotton, plain-weave, 297 g m^{-2}	NI	0
cotton, flannel, 408 g m^{-2}	0	5
cotton, flannel, 422 g m^{-2}	0	0
polyester/cotton (65/35), plain-weave, 325 g m^{-2}	NI	0
polyester/viscose (52/48), plain-weave, 330 g m^{-2}	0	a
polyester/cotton (62/38), twill, 760 g m^{-2}	0	0
polyester/cotton (48/52), twill, 747 g m^{-2}	0	b
polyester, plain-weave, 185 g m^{-2}	NI	NI
polyester, plain-weave, 408 g m^{-2}	NI	NI
nylon 6,6, tricot, 320 g m^{-2}	NI	NI

NI – no ignitions
a – No ignitions for fabric touching burner; 1 out of 5 specimens ignited when 5 mm of fabric draped over burner.
b – No ignitions for fabric touching burner; 5 out of 5 specimens ignited when 5 mm of fabric draped over burner.
c – It is not clear if the temperatures were measured correctly, since a radiant source at 590ºC is not normally perceived as "bright red."

polybenzimidazole (PBI) parachute fabrics. Ignition of fabrics from nuclear weapons detonations has been studied by the Naval Applied Research Laboratory[1055].

Self-heating of (unoiled) fabrics is possible, although the temperatures and sizes involved preclude this from being a concern except at industrial processing establishments. Smedley and Wake[1056] reported on a study of a wool/nylon fabric which had led to a factory fire. Spontaneous combustion was found possible for a pile 0.85 × 0.6 × 0.49 m, if stacked at a hot-work temperature of 120ºC. Franke et al.[45] described a fire in a drum dryer used in the making of textiles from recycled fibers. This was found to be due to self-heating promoted by the use of 'unsuitable' spinning oils. They also documented fires repeatedly occurring in a vertical dryer used to dry nylon fibers at 165ºC. Glowing clusters of material would form, then drop down to ignite bulk material. They found out that if nylon fibers are rapidly heated, they melt upon reaching around 215ºC but do not show self-heating. But if heated slowly at 130 – 170ºC, the fibers char instead. Oven-basket tests of 100 mm cubes of the aged, charred material showed a critical temperature less than 170ºC; open flaming was not found, but glowing clusters did form.

ELEVATED OXYGEN CONDITIONS

In one case, an electrostatic spark from a workman who was wearing rubber-soled shoes ignited his trousers in oxygen-rich atmosphere[26]. In another case, the clothes of two workmen ignited with fatal consequences when they entered an environment where an oxygen-acetylene cutting torch had been used 2 days earlier and started up their torch[26]. For proper cutting, the torches release more oxygen than is actually reacted and the surplus oxygen can accumulate within a confined space. A confined environment is not necessary for ignitions of this type to occur. In one case, a workman died from ignition of his clothing when he was repairing a liquid oxygen tanker in the open air. There was a gaseous oxygen leak at the other end of the vehicle, but the exact cause why his clothing ignited was not established[26]. An insidious hazard of clothing fabrics when used by workers exposed to oxygen-enriched atmospheres (or to liquid oxygen) is that fabrics may retain a fairly high concentration of oxygen. It is reported that periods of up to ½ hour should be anticipated, and a number of industrial accidents have been documented when the oxygen-retention capability of fabrics was ignored[1057].

Voigtsberger[1058] studied the ignitability of a wide array of fabrics from electric spark discharges. He found that at 21% oxygen no fabric—clean or dirty—could be ignited, although some became locally singed or melted. Using a 100% oxygen atmosphere, however, nearly all clean specimens could be ignited with 193 J spark. Only silk, polyester, and nylon resisted ignition. Even at 0.45 mJ, 6 out of 17 specimens ignited. When dirty (oily), however, all of the fabrics ignited even from the 0.45 mJ spark. Repeating the tests with mechanical sparks produced from pressing a carbon-steel piece against a corundum grinding wheel, he found that no specimens ignited in 21% oxygen (although most were singed), but that all ignited in a 100% oxygen atmosphere, and it typically took only 1 s for ignition to be achieved. Fitt et al.[1059] undertook to reproduce Voigtsberger's experiments and discovered the crucial roles of two factors not treated by Voigtsberger: (1) the oxygen flow rate; and (2) spark duration. Increasing the flow through the experimental rig from stagnant to a high, but unspecified, velocity decreased the required energy for ignition by about a hundred-fold. Short-duration sparks were found incapable of igniting solid materials, simply because of inadequate time during which heat was being supplied. They only explored circuit parameters to a limited extent, but found that optimum spark duration was in excess of 100 ms. Plano[1060] conducted tests in a 100% oxygen atmosphere using 90 mJ sparks and determined a statistical probability of ignition for various fabrics: PVC 20%, wool 20%, tissue paper 10%, nylon 33%, PET/cotton 1%, cotton muslin 1%. Guest[1061] conducted tests in atmospheres of 52 – 64% oxygen and was unable to obtain any ignition of clean materials, but oily cotton could be ignited by 2.5 mJ sparks. Purser[1062] examined hyperbaric oxygen conditions and found that at 3 atm it was easier to ignite all materials than at 1 atm, but sufficient tests were not run to develop quantitative trends. A study[1063] has shown that for many fabrics, increasing the oxygen concentration beyond about 40% results in a very rapid increase in flame spread rate, which would presumably be reflected as increased injury potential.

EFFECTS OF TREATMENTS

Even small amounts of treatments can greatly affect the ignitability of fabrics. For instance, use of finishing agents, such as melamine resins or polysiloxanes, was found to make polyester fabrics ignitable that otherwise resisted ignition[1064].

Fire-retardant treatments are occasionally used for fabrics, although only in specialized applications, not for general wearing apparel. General principles of fire retardants for use with textiles has been reviewed by Gordon[1065]. Khattab et al.[1066] examined the effect on autoignition behavior of several water-soluble FR treatments for cotton fabrics, as tested in a crucible apparatus. A minimum loading of ca. 5 – 8% was found to be needed for useful improvement of ignition behavior. Smaller amounts of FR agents had no effect or even a deleterious effect. Reeves and Smitherman[1011] studied the effect of several different, non-soluble flame retardants added to cotton and cotton/polyester fabrics. For flame ignitions at both edge and surface, the effect on ignition time of the FR agent was negligible until some critical add-on percentage (typically 15 – 30%) was attained. For larger add-on values the effect was notable, but the authors only described these results as "ignition time > 3 s" rather than quantifying them. A handbook of fire-retardant formulations for fabrics was published by Reeves

et al.[1067] in 1974. While old, this collection describes in much detail the fire retardants available in that era.

Farm machinery

Striking of rocks with the cutter head of a combine can result in a field fire and some of these can be sufficiently rapid to destroy the combine itself. Other ignition modes include combustible debris on exhaust systems, leaking oils and hydraulic fluids, and electrical failures. Tracked equipment operated laterally on steep hillsides sustain large friction forces that may cause shearing off of hot metal particles.

Feedstuffs

A fire was reported due to spontaneous combustion of pallet-loads of stored bone meal, used as an animal feedstuff[1068]. Accompanying tests demonstrated the self-heating potential, but predictive constants were not evolved. See also: *Agricultural products*.

Felt

A 19th century treatise[1802] reports numerous fires that occurred due to self-heating of felt. Its use in today's economy is more limited and recent investigations do not exist.

Fertilizers

Most fertilizers are relatively resistant to ignition and applying a flame to a fertilizer will generally not result in combustion or other exothermic reactions. But some formulations, especially those containing ammonium nitrate, can undergo exothermic decomposition. The term 'compound fertilizer,' means that it contains ammonium nitrate and potash or a phosphate. If it contains all three, then the designation NPK is used (N = nitrogen, P = phosphorus, K = potassium).

Kiiski[1069] has summarized 11 major case histories involving decomposition of large quantities of fertilizers. The ignition source in these cases was typically a hot lamp or a welding spark. In most incidents involving decomposition, it was considered that a source of ignition was present, and that decomposition incidents were not solely due to self-heating. But when organic material is present in the mixture, then oxidation also becomes possible, not just thermal decomposition. At least one incident is reported of a true self-heating ignition for mixtures containing organic material[1073]. Médard[26] reviewed a number of fires associated with fertilizer production, storage, or shipping facilities. Self-heating was more of a problem in the 1960s and '70s, when the first compound fertilizers were introduced, than it is today. Improved understanding of the solid-state reactions, measures implemented to control the pH, and precautions in production facilities to prevent the transport of hot material (exceeding 50ºC) into storage all helped to reduce losses.

If a fertilizer mixture contains organic matter, not just nitrates, superphosphate and other inorganics, the potential exists for thermal runaway due to an exothermic oxidizing reaction between the nitrate and the organic matter. The tendency to self-heating is proportional to the acidity of the fertilizer—those with pH > 3.5 tend to have a reduced self-heating propensity, while for pH > 4.5 self-heating is unlikely[1075]. Adding sufficient ammonia to the mixture to neutralize it is an effective strategy, as is adding a material such as cyanamide which will liberate ammonia when heated. Lime or dolomite is sometimes added, but this is not the best strategy, since their reactivity is poor. Urea is commonly added to suppress self-heating. The hazard from ammonium nitrate is that it readily decomposes into ammonia and nitric acid, initially under the action of free phosphoric acid and, after some self-heating has occurred, due to thermal decomposition. Even though ammonia is being evolved in this process, with excessive free phosphoric acid present, the proportions are such that the resulting mixture's pH is excessively low. Nitric acid, a very powerful oxidizer, then acts on the organic matter, with the reactions being highly exothermic. For the latter process, there are various reaction variants possible, since the nitrogen may go into a variety of nitrogen-containing reaction products. Fertilizers containing more than 70% AN behave differently in that they normally melt; as the supporting matrix for decomposition is not present, the melting produces an endothermic effect and in most cases the decomposition stops. But if the melt flows to confinement (e.g. drains) and excessive heat is present, an explosion may occur. Raising the pH may not be feasible with some formulations, due to solubility problems of phosphates[1072].

Various organic substances have different potential towards contributing to thermal runaway. Unfortunately, most of the practical fertilizer components are of the problematic type. This includes activated sewage sludge, animal and garbage tankage, brown rotten wood, cane sugar, castor pomace, cocoa shell meal, cornstarch, cottonseed meal, dextrose, fishmeal, ground burlap, ground cork, ground Kraft paper, lignin, millet seed, oak heartwood, peanut-hull meal, peat, sawdust, soybean meal, and tobacco stems. Only dried blood, casein, ground filter paper, egg albumen, and lampblack were found to be less problematic. Fertilizers containing no carbon are not susceptible to self-heating[26], but practical source materials are rarely carbon-free.

The addition of ammonia during the compounding of a fertilizer in order to neutralize the mixture is itself an exothermic process. Thus, care must be taken that this be done under conditions such that the mixture has cooled down before being aggregated into large piles.

The modeling of the self-heating behavior of fertilizers has been attempted using the F-K theory of Chapter 9, but the efforts indicated that a much more complex model needs to be constructed in order to obtain realistic values[1075]. The problematic effects included multiple reactions, high variations in thermal conductivity, water transport, and melting. However, the modeling also indicated that while the F-K

theory cannot be applied correctly, results are empirically correlatable in the form of a graph where $1/T$ is plotted on the x-axis and $\ln(r_c)$ on the y-axis, where T is the temperature (K) and r_c is the critical radius (m). For example, Huygen and Perbal[1070] gave oven-basket self-heating data for a 12-13-6 fertilizer from which $E = 144$ kJ mol^{-1} and $P = 61.7$ may be derived. The problem with the application of such plots to real-life problems is that, lacking a theoretical justification, only modest extrapolations can prudently be made.

Self-sustained decomposition of a fertilizer requires[1070] that three ions be present: NO_3^-, NH_4^+, and Cl^-. This is a commercial concern, since chlorine is a commonly incorporated in a fertilizer by adding potassium chloride. The primary decomposition reactions are:

$$NH_4NO_3 \rightarrow NH_3 = HNO_3$$

$$NH_4NO_3 \rightarrow N_2O + 2H_2O$$

$$5NH_3 + 3HNO_3 \xrightarrow{Cl^-} 4N_2 + 9H_2O$$

The chlorine acts as a catalyst and is not consumed in the primary decomposition reactions, although numerous secondary reactions then take place wherein chlorine is consumed. Cobalt or chromium can play a similar role as chlorine. The actual exothermic event that takes place depends on the physical nature of the fertilizer. Decomposition generally starts at about 230ºC and products which melt below that temperature undergo 'liquid fume-off.' This is a violent reaction but liquid fume-off requires that a large amount of product first be melted, typically by an external fire. If the product does not melt before the decomposition temperature is reached, then 'cigar burning' can take place, which is an exothermic zone propagation within the solid material[1071]. Cigar burning can be started by a small ignition source, resembles smoldering combustion, and is non-explosive in nature. The temperature of the reaction front[1069] is about 300 – 500ºC, but in the presence of organic materials, it can exceed 1000ºC. Small amounts of copper are synergists to the reaction. The main hazard is high toxicity of the combustion products. The fertilizer industry sometimes describes mixtures prone to 'cigar burning' as 'capable of undergoing self-sustained decomposition.' A chlorine amount as small as 0.003% has been found sufficient to catalyze the decomposition reaction[1072]. For various primary fertilizer ingredients (e.g., NH_4NO_3, $NH_4H_2PO_4$, KCl, etc.) stability diagrams have been prepared[1069,1070,1072] which show the relative proportions that may lead to liquid fume-off, cigar burning, or no sustained self-decomposition. These types of diagrams alone do not fully express the hazardous regimes since, in some cases adding an inert substance such as diatomaceous earth can cause a fertilizer which would otherwise be in a non-burning regime to enter into the cigar-burning regime[1070]. This appears to be a physical effect having to do with absorbing liquid reaction products.

International and national shipping regulations for ammonium nitrate/ammonium sulfate fertilizers have varied over the years, but it is typically recognized that mixtures with less than 45% ammonium nitrate are of lowest hazard (although these are not automatically to be considered safe!), mixtures of 45 – 70% ammonium nitrate are of similar hazard to AN itself, while mixtures containing over 70% AN are more hazardous than pure AN[26]. Experiments have shown[1073,1074] that ammonium nitrate is more hazardous than sodium nitrate or potassium nitrate. It is commonly considered[1075] that compound fertilizers will not exhibit criticality if the ammonium nitrate content is below 15%. Fertilizers without AN are considered not to present an explosion hazard. A specific UN test for fertilizers—Test S1, the trough test—is discussed in Chapter 9. Kiiski tested a variety of fertilizer formulations using a modified UN Test S1 (trough test) and found temperatures of 210 – 310ºC to be the minimum needed for ignition. Unfortunately, he did not specify the layer depth, so the results cannot be quantitatively compared to other studies. Additional information is given under *Ammonium nitrate and ANFO*.

Fibers

Various fibers of both animal and vegetable origin are susceptible to self-heating. These include cotton, flax, hemp, shoddy, silk, and wool. Systematic differences in propensity are observed between the two classes, however. Vegetable fibers are hollow and they consequently tend to absorb oxidizing foreign material. Once ignited, vegetable-origin fibers tend to burn more vigorously than ones of animal origin. Also see: *Cotton; Fabrics; Jute; Marijuana and hemp; Wool.*

Fibers covered with oil

For self-heating to occur due to oxidation (some substances undergo non-oxidative exothermic reactions), a ready supply of air is necessary. This is not possible, for instance, with a bucket of linseed oil, since oxygen is only accessible at the surface. A rag covered with linseed oil, however, presents a very large surface where there is contact between air and oil. While it may be very difficult to actually measure the exposed surface area of an oil-covered rag, nonetheless it is clear that the surface/volume ratio is orders of magnitude greater than that for the bucket. The minimum amount of oil or of cloth needed to lead to spontaneous combustion in a room temperature environment has not been precisely explored, but it is reported that 25 g of cloth may give marginal conditions and 75 g of cloth a higher probability[445]. The optimum mass of oil is about 100% of the mass of cloth. A very old study[2056] suggests that 5% of oil by weight may be sufficient, but there has not been a recent study exploring this point.

Self-heating propensity is generally proportional to the degree of unsaturation of the oil, since this increases the ease of oxidation. Mineral oils are normally significantly less prone to causing self-heating, since they are not readily oxidizable, however Monakhov[1076] points out that petroleum products such as mineral oil, bitumen, and asphalt can self-heat when applied onto fibers. Thompson also reported

spontaneous combustion in mineral-oil soaked cotton, but he had to start at 150ºC instead of 100ºC in a modified Mackey tester to elicit the behavior[1082].

The effect of the type of fibers may be expected to have some effect on self-heating potential, but this is a second-order effect and has been explored only to a limited extent. Early studies by Mackey[1077,1078] on the effect of fiber type provided contradictory results. Cotton fibers in contact with fatty oils are more susceptible to self-heating than fibers of animal origin. Fibers of mineral origin, e.g., rock wool, are the least conducive to self-heating. Spontaneous combustion of linseed-oil soaked steel wool has readily been created in the laboratory[1079]. If self-heating ignition is to occur, rags soaked in boiled linseed oil need to be loosely packed. Laboratory tests have demonstrated that tightly-packed linseed-oil soaked rags tend not to reach runaway conditions[1080].

In view of the difficulties in realistically recreating the packing conditions of oil-soaked cloths, it may not be surprising that not much data have been published giving example values. Gross and Robertson[109] determined self-heating data for various oils soaked into cotton gauze (Table 125). They used a weight of oil equal to 1/6 the weight of cotton, so the condition most conducive to self-heating (about a 1:1 ratio) was not captured. An old study cited by Ellern[1407] gives Q = 962 kJ kg^{-1} for linseed oil, but it is not clear if this is a reliable value.

The data of Gross and Robertson are of limited practical interest because of the very low loading of oil used. But if it is assumed that the most hazardous loading of oil is 100% of the mass of cloth, and if the estimation method is used whereby the heat of reaction, Q, is taken to be proportional to the fraction of oil, then the Q must be multiplied by (6+1)/(1+1) = 3.5 to estimate the worst-case condition. Making this adjustment, the new value of P estimated is 50.8. Note, however, that Gross and Robertson only tested raw linseed oil, but in most wood-finishing applications boiled, not raw, linseed oil is used. Horrocks et al.[1081] conducted oven cube tests on cotton fabric soaked in vegetable oils. They only applied small amounts of oil and conducted tests solely in 102 mm size cube baskets. For both cottonseed and rapeseed oil, at a 10% loading of oil, the critical temperature was ca. 100ºC, while for a 5% loading it was ca. 140ºC. Thermal runaway generally took 1 – 3 h. Thompson studied linseed oil soaked cotton in a modified Mackey test, where 30 g of oil was applied to 30 g of cloth[1082]. His research indicated that the reaction is auto-catalytic, rather than following a simple first-order Arrhenius form. More modern data on this question are given in the section on *Oils*.

On a practical note, Taradoire[1083] found 75 g of cotton rags soaked in the same weight of linseed oil typically went to flaming in 1 to 6 hours, and that there was a strong acrid odor shortly before eruption of flaming. Browne[1172] soaked 50 g of cotton in 50 g of raw linseed oil to which 5 g of cobalt oleate had been added, effectively simulating boiled linseed oil. The temperature rose to 400ºC in 1.5 h, at which time flaming occurred "when a gentle air blast was applied." In another test[1084], one cotton towel and 16 paper towels were coated with linseed oil and bundled up. A flaming fire erupted in 90 min. Zicherman[1085] studied linseed-oil soaked rags which were dropped into open-top cardboard boxes. He found that there was a great deal of data scatter—a number of tests using 24 rags failed to go to thermal runaway, while other tests using only 10 rags did. Thermal runaway took 4 – 10 h, in the cases where it occurred; it was always preceded by copious, highly acrid smoke. In most cases, thermal runaway was not followed by overt flaming, even though the aftermath was a pile of black-charred residue. DeHaan[1086] found that waste containers filled with linseed-oil soaked cotton rags developed smoke and acrid odors in about 1 h. Eruption into flaming then followed after another 4 – 14 h. In a test[1087] where 100 g of jute fiber was soaked with 25 mL of raw linseed oil and 3 mL of a drying agent (together, those two ingredients were used to simulate boiled linseed oil), ignition occurred in 2 h from a starting temperature of 27ºC. Cloths soaked in a linseed-oil based stain ignited in 4.25 h and flamed for about 0.5 h in another test[1594]. Another author[1088] reported that it typically takes 4 – 8 h for flaming to erupt, but also documents one test where it took 31 h for ignition to occur after a floor mop soaked in a linseed oil based preparation was wrung out, rinsed, and hand-washed. A fire incident where the time interval was 19 hours has been reported[1089]. In cases where there is doubt if a drying oil was involved, it is often possible to analyze the fire debris for fatty acid residues; this is discussed under *Dryers and washers*.

The propensity of linseed-oil soaked rags for causing spontaneous combustion is generally well-known by lay per-

Table 125 Self-heating properties for oil-soaked cotton, as determined by Gross and Robertson

Material	E (kJ mol^{-1})	AQ (W kg^{-1})	ρ (kg m^{-3})	λ (W m^{-1} K^{-1})	C (J kg^{-1} K^{-1})	P 1:6	P 1:1
castor oil	116	1.1×10^{16}	314	0.046	1400	55.3	56.6
cottonseed oil	101	3.0×10^{15}	338	0.046	1400	53.9	55.2
linseed oil, raw	88	4.7×10^{13}	309	0.046	1400	49.6	50.8
neatsfoot oil	103	5.1×10^{14}	316	0.046	1400	52.1	53.4
olive oil	78	3.3×10^{11}	308	0.046	1400	44.5	45.7
rapeseed oil	84	8.1×10^{12}	316	0.046	1400	47.8	49.0
sperm oil	84	2.1×10^{11}	313	0.046	1400	44.1	45.4

sons. Thus, some arsonists will try to exploit this phenomenon. Gray[1090] reports an interesting case where an arsonist tried to create the impression that his 'careless' use of oiled rags led to an accidental fire occurrence, whereas the fire was caused in an entirely different manner. Gray used self-heating tests and theory to analyze the case. He used twice the amount of rags claimed by the individual to be present (in order to take a conservative upper limit) and then explored the amount of oil needed to cause maximum self-heating tendency. Under such optimal conditions, he was able to show that a minimum ambient temperature of 68ºC would have been needed to cause thermal runaway. This temperature was way beyond any possible ambient temperature in a residence.

Hill[1091] investigated the self-heating tendency of waste from a process where cotton buffing wheels are used with a polishing compound. The latter was only described generically as containing alumina, fatty acids, and water. Using the FRS procedure, he found that critical conditions corresponded to a cube dimension of 1.0 m for a starting temperature of 40ºC, or 2.3 m dimension for a starting temperature of 20ºC. The real accident conditions are reported to have corresponded to a cube size of 0.92 m at a temperature somewhere between 20ºC and 40ºC. This would suggest a good validation, except for the fact that no details of the actual occurrence are available. Also, the experimental work was based on fitting a straight line through only 3 data points, which would not normally be considered a sufficient number of data points to make usable predictions.

Prudent disposal measures for linseed-soaked cloths can include: (1) burying underground; (2) burning outdoors in a safe place; (3) packing into empty metal paint cans, tightly hammering the lids shut, then placing in a non-combustible outdoor refuse bin; (4) dispersing cloths individually outdoors on non-combustible surfaces and leaving them there until the oxidative polymerization reactions are finished.

Turpentine is also subject to self-heating, when rags are soaked in it[1092]. Likewise, rags soaked in *polyurethane*-based wood-finishing preparations are known to self-heat[1093], although this has not been studied in detail. See also: *Oils*; *Paints*.

Fire hoses

MIT professor Gill[1094] documented a case history where a nominal 64 mm (2-½") fire hose ignited due to friction while it was connected to a pumper and pumping water. The hose was constructed of an outer cotton jacket, a rubber lining, and an inner cotton jacket. Vibrations of the pumper produced sufficient chafing of the hose to lead to ignition. Remarkably, laboratory tests were largely able to reproduce this situation, although it appears (details were not given) that the test hoses only charred and did not flame.

Fishmeal

Fishmeal is the dried and ground residue of fish that has been cooked and has had the oil extracted. It has a known propensity for self-heating and has been the cause of a number of ship fires. The self-heating is attributed to a combination of oxidation of the residual oil and action of micro-organisms[1095]. It has been reported[1096] that Chilean fishmeal is particularly susceptible to spontaneous combustion due to the high fat content in anchovy fishmeal. Conversely, it was found self-heating has not been a problem with fishmeal produced in Northern Hemisphere countries. Standard safety recommendations for transporting fishmeal on ships are:

- to dry the meal to between 6% and 12% moisture
- to store it at least 21 days prior to loading
- to not exceed 11% of fat content in the fishmeal
- to store bags of fishmeal is ship holds in such a way that air can circulate between bags.

Floor buffers

Case histories have been reported[1097] of three individuals burned due to ignition of solvent vapors from a floor buffer. The fires involved use of flammable solvents to clean a floor, buffing it with electric floor buffers. The mechanism of ignition was sparking from the motor, not static electricity.

Floor coverings

In the US, the Federal government enforces a standard whereby carpets and rugs must resist ignition from a methenamine pill. The test method used, ASTM D 2859, is described in Chapter 7. The test specimen may ignite and burn in the immediate vicinity of the pill, but flames must not travel more than 75 mm from the ignition source. This ignition source produces exceptionally small and localized flames. DeHaan[1098] reported that many polypropylene carpets currently on the market will pass this test, but when presented with a slightly larger flaming ignition source, will show unlimited flame propagation. Such carpets tend to show flames that are only 50 – 75 mm high and burn at a slow rate (ca. 1 m^2 per hour). The most common outcome when one of these carpets is ignited is that the entire carpet will be consumed, but furniture in the room will not be ignited. The floor coverings industry in the US describes flexible sheet and tile products as 'resilient floor coverings,' which is a confusing nomenclature since carpets and rugs are resilient substances, yet are understood to be excluded from that definition.

Palmer et al.[1938] examined the small-flame ignitability of carpets, carpet underlayments, and carpet tiles. They found that cigarettes and matches could not ignite any specimens. When ignited with a 200 × 300 mm piece of paper, folded up, 1 of 2 acrylic carpets and also latex foam and rubber underlayments suffered sustained ignition. Wool, rayon, and a number of blended-fiber carpets ignited but did not sustain burning. Polypropylene and nylon carpets, fiber felt underlayment and all carpet tiles did not ignite at all. When presented with a 15 g fiberboard crib or a larger wood crib, more ignitions were found. Acrylic, polypropylene and nylon specimens performed worst against crib ignitions, since at least some showed total destruction. A majority of carpets proved resistant to full burning, even when confronted with the largest source used, the wood crib; damaged areas were typically less than 0.5 m across. Settle[1099] tested carpets by using a 24 × 28 mm stainless steel plate electrically heated to a high temperature (Table 126).

The most extensive radiant ignition results on floor coverings were obtained by Van Hees, in the course of his doctoral research[1100]. Descriptions of the test specimens are given in Table 127, with results obtained from tests in the Cone Calorimeter given in Table 128. Van Hees also developed a model for correcting the data for heat conduction effects of the wire grid used to retain the specimens during testing and for differences in the substrate, compared to accompanying real-scale tests that he also conducted. For bench-scale testing, the wire grid was necessary because most floor coverings are only a few mm thick and show shrinking behavior, while some also show excessive swelling. Fiber cement boards were used in the real-scale tests, but these showed inconsistent data due to their water content and erratic spalling. In view of these factors, to obtain bench-scale data which would more reliably reflect the real-scale environment, Van Hees adopted the following procedure:

- Tests were conducted on floor coverings without backing board, but wrapped in aluminum foil. Beneath the foil only the ceramic wool specified in ISO 5660 was placed. The tests were conducted with grid and retainer frame.

- With a 1-dimensional heat transfer model, the corresponding temperature of the floor covering was determined at the time of ignition. The numerical heat transfer model used a Crank-Nicolson solver and included convection and radiation losses at the surface. The grid was simulated by a thin steel plate. As steel has a high heat conduction coefficient, heat conduction is only affected to a limited extent, but radiation losses at the surface, which were found to be important, are taken into account. The λ, ρ and C input values for the model were determined by obtaining a value of $\lambda\rho C$ using the Janssens method (see Chapter 7). Separate values for λ were determined by using C values from literature for the material. Knowing ρ for the material, the value of λ can be determined. Constant, non-temperature-dependent λ, ρ and C values were used.
- The above thermal properties include the contributing effect of the backing board. Thus, a new simulation was performed using the backing board and no grid (since the latter is not present in the real-scale). From this simulation new ignition times were obtained using the temperature of the floor covering, determined in the first simulation as trigger point for ignition. These ignition times were then used to determine the ignition temperature T_{ig} and effective $\lambda\rho C$ by the Janssens method.

Before this model was applied to all floor coverings in the study, the model was first validated by means of tests where different sample preparations were compared. The simulation method showed satisfactory results, despite the limitations of the method, being 1-dimensional and based on temperature-invariant material properties. The corrected values are shown in Table 130. Shown in Table 129 are

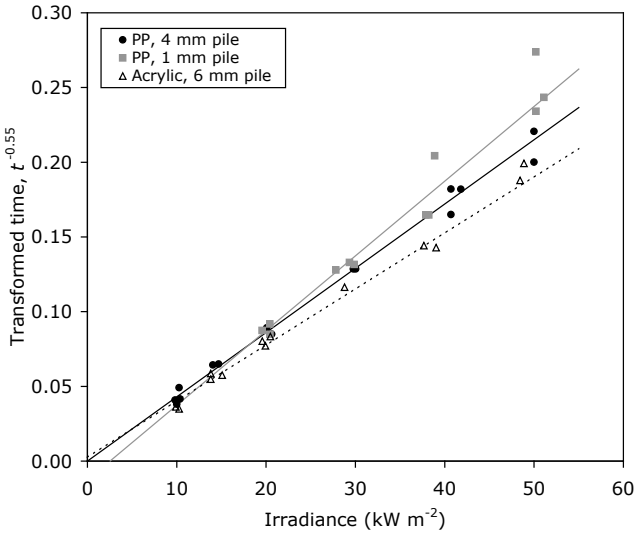

Figure 75 Carpet ignition (Yanai)

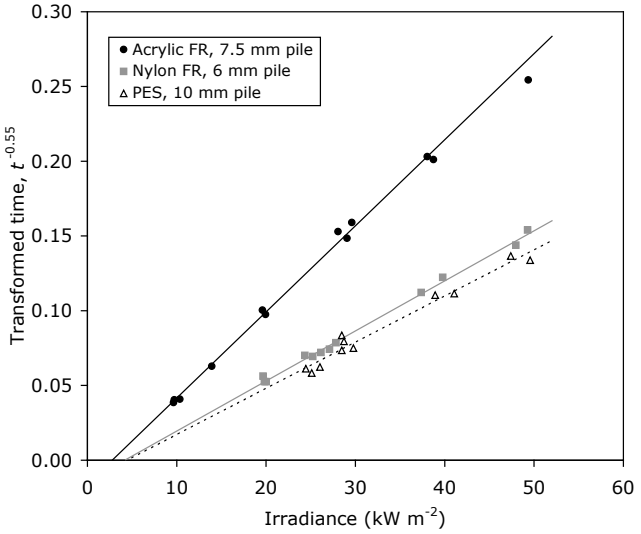

Figure 76 Carpet ignition (Yanai)

$\dot{q}''_{cr}$, the critical heat flux (kW m^{-2}); $\lambda\rho C$, the effective thermal inertia; and T_{ig}, the computed ignition temperature (ºC). As discussed in Chapter 7, ignition temperatures obtained by such calculational procedures are not always realistic, and values below about 300ºC must be viewed as artifacts.

The minimum flux[1102] for vertically oriented vinyl-asbestos tile of unspecified thickness was found to be 72 kW m^{-2} for autoignition and 38 kW m^{-2} for piloted ignition. Using specimens in the horizontal orientation, a minimum flux for radiant, piloted ignition of 14.5 kW m^{-2} was found[1101] for vinyl-asbestos tile. The tile was 2.4 mm thick, with a basis weight of 480 g m^2. Long[1102] measured the ignitability of carpets in a vertical orientation using a developmental NIST

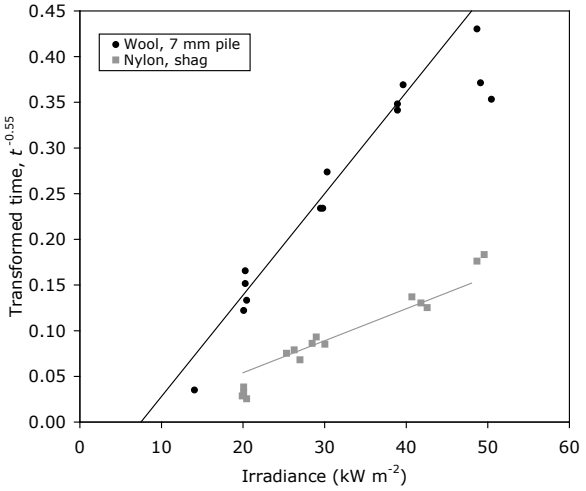

Figure 77 Carpet ignition—examples of specimens not conforming to thermally thick theory

heat release rate apparatus. His results are given in Table 132. Hirschler[1103] tested the ignitability of nylon carpet tile using the Cone Calorimeter in the horizontal orientation. All of the specimens ignited (piloted ignition) at the lowest fluxes used, 20 or 25 kW m^{-2}. Ignition times at 25 kW m^{-2} flux were 69 – 212 s. Hilado and Murphy[1903] tested the autoignition of carpets in the vertical orientation. They found no ignitions at a flux of 25 kW m^{-2}. Polyester, nylon, and acrylic samples did ignite at 58 kW m^{-2}, which was the next higher flux used. Wool did not ignite at 58 kW m^{-2}, but ignited at 81 kW m^{-2}. The test apparatus used was of poor quality, so the results should be viewed as only semi-quantitative. Tomann[1104] gave results on piloted ignition in the Cone Calorimeter for 4 different carpets tested at a flux of 35 kW m^{-2}.

The radiant, piloted ignitability of carpets was tested by Yanai[1105], who used the ISO 5657 test apparatus (Table 131). The specimens shown in Figure 75 and Figure 76 conform rather well to thermally-thick materials theory. The wool and the shag nylon data shown in Figure 77 do not. Carpet construction is highly non-uniform with respect to density—at the very top are some fluffy fibers, then more

solid yarns below, then finally a backing which has a different yet construction. Thus, it may be somewhat surprising that the data for the majority of carpets follows the thermally-thick relation. Apart from shag carpets, pile height evidently has almost no effect on ignitability, as seen by comparing the two PP results. The data indicate that PP carpets ignite at lower heat fluxes than do other types, although acrylics are close.

Foodstuffs

Peacock and Vaishnav[1106] tested a series of generically-described foodstuffs for ignitability. Using the CPSC test procedure, which involves applying a candle flame for 5 s to the surface, they did not find any foodstuffs that ignited. The tested foodstuffs that did not ignite were:

- flour
- fruit cereal
- instant chocolate drink
- instant coffee
- instant tea
- rice
- sugar.

Manufactured foodstuffs, unlike raw agricultural products, are rarely associated with self-heating events, possibly because they are commonly not piled in substantial-size piles. But spontaneous combustion cases have been reported for noodles, potato chips, and deep-fat fried Indian foods. Gray[1090] described a case where pallets of shrink-wrapped '1-minute noodles' stored in a noodle factory underwent spontaneous combustion. The fire took place when production was sped up, so that the product was being packaged at 113ºC, instead of at 81ºC, as previously. Tests indicated that 1.24 m^3 pallet-loads had a critical hot-work temperature of 106ºC. Potato chip wastes have self-heated to ignition when stored in 1.5 × 1.5 × 2.0 m wire-mesh containers[1107]. The wastes were simply pieces that were broken or undersized in the production of potato chips. Subsequent oven testing in wire-mesh spheres was done to obtain the self-heating characteristics of the material. The following values were derived: E = 126 kJ mol^{-1}; ρ = 150 to 300 kg m^{-3} Q = 740 to 1220 kJ kg^{-1}; λ = 0.076 to 0.101 W m-1 K^{-1}, $A = 2.4\times10^{12}$ s^{-1}. The laboratory tests showed that at 40ºC the critical diameter is about 0.15 m, so the material can readily go into thermal runaway when in meter-size volumes. Coffee beans, powdered coffee, and powdered chicory exhibited strong self-heating tendencies in laboratory experiments[1108]. Dixon[1109] reported a case where a fire occurred about 8 h after an Indian food preparation made mostly from flour deep fried in rapeseed oil self-heated to ignition as it was draining in a large (size unspecified) colander after having been fried. Dixon determined the iodine value of the used oil, using an unburned oil sample, as 116. He then conducted a test where a bucket of the material was placed in an oven at 130ºC. Thermal runaway, but without flames, was observed in about 24 h. Self-heating was probably promoted in this case by the fact that a high surface/volume ratio—the foodstuff was described as being breadcrumb-like in appearance. Nelson conducted oven-basket tests to determine the self-heating properties of wheat flour[1597]. His results were: E = 129.2 kJ mol^{-1}, P = 58, λ = 0.060 to 0.177, and C = 1.49 to 3.14 kJ kg^{-1} K^{-1} ; the latter two variables being in the range over 50 – 140ºC. Takai[1110] reported studies on the self-heating of roast cocoa powder and soybean flour. The cause of some explosions in chocolate candies was found to be fermentation due to anaerobic bacteria[1111].

Forest materials, vegetation, and hay

The top causes of forest fires depend on the locale, but are commonly:

- lightning
- incendiarism
- careless use of heat or fire. The latter includes cigarettes and matches, campfires, machinery, uncontrolled agricultural burning, and badly executed prescribed burns.

Statistics[1112] for the US are given in Figure 78 and Figure 79. In most years, debris burning, arson, and lightning are typically the top three causes leading to the most fires, but the most destructive fires are from lightning, by far.

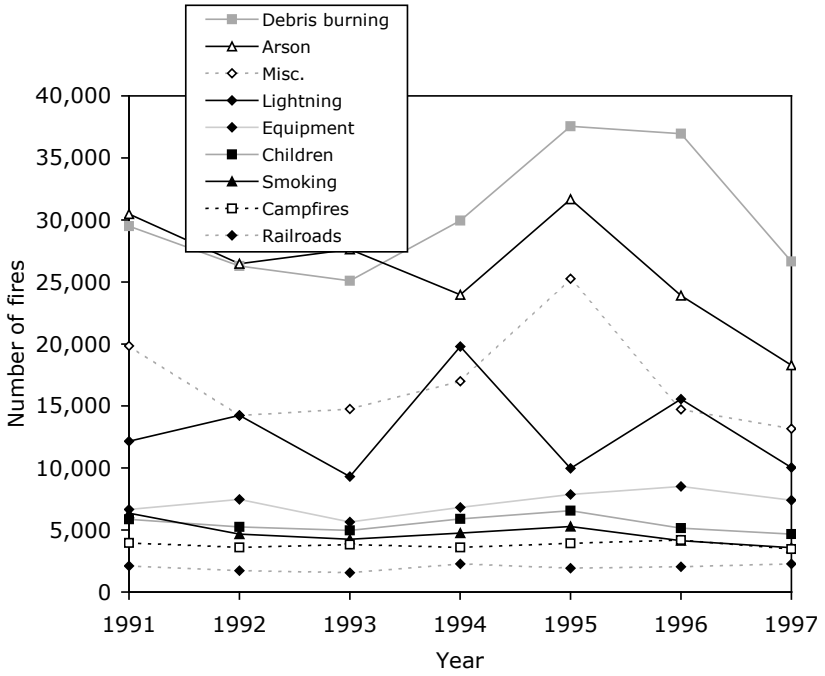

Figure 78 US wildland statistics for 1991 – 1997, based on number of fires

Table 133 Types of equipment leading to forest fire ignitions in California survey

Equipment type		Percent
Road vehicles		**68.1**
automobiles	30.4	
trucks	23.8	
motorcycles	4.8	
other	1.7	
unspecified	7.4	
Farm equipment		**16.8**
harvesters	6.3	
tractors	7.1	
other farm equipment	3.4	
Power tools		**7.4**
welding torches	4.3	
saws	1.1	
other	2.0	
Stationary engines		**3.1**
Highway maintenance or construction equipment		**2.3**
Other		**2.3**

Weber[1113] compiled data showing lightning was the top cause in some regions, but accounted for less that 5% in other regions. Apart from the above causes, the only other cause of some general prevalence is associated with high-voltage transmission lines and ancillary equipment, but this is inevitably a small percentage. In the US national statistics, it is simply grouped into 'Miscellaneous.' A category

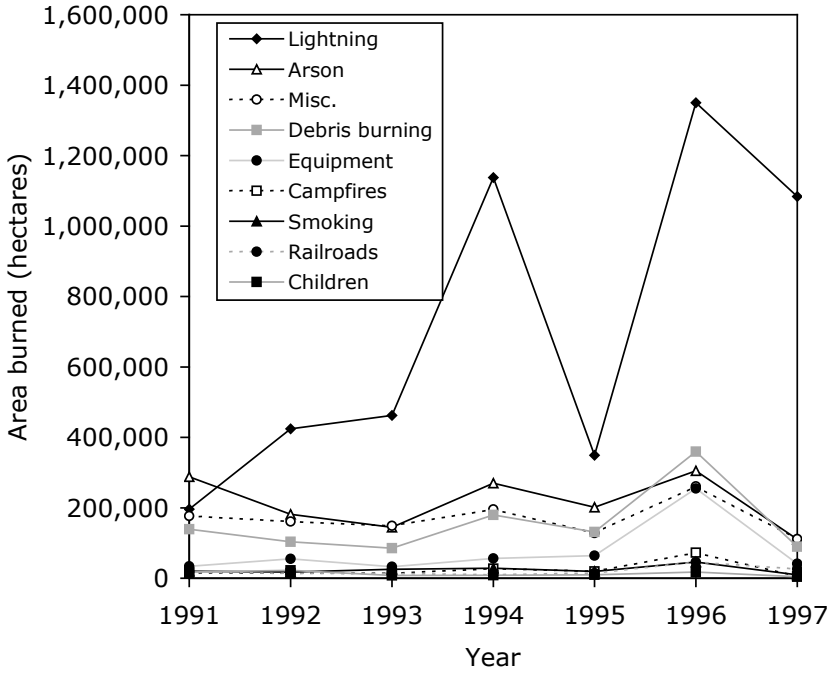

Figure 79 US wildland statistics for 1991 – 1997, based on hectares burned

not stated	2.3

of more readily preventable fires involves those due to use of equipment. 'Equipment use' is typically defined by forest fire specialists as any mechanical or electrical equipment except railroads or electric distribution systems. Some statistics on fires from equipment use in California have been published for 1962 – 1971, when it accounted for 28% of forest fire ignitions. Bernardi[1114] analyzed details of these fires, and the results are given in Table 133. The specific causes leading to ignition are identified in Table 134. During 1975 – 1979 California forest fires due to equipment use accounted for 39% of the land area burned[1115].

Prescribed burns that are improperly executed and then lead to major conflagrations of inhabited areas are another type of fire of special interest. The most notable such fire in recent years in the US was the Cerro Grande fire of May 2000 which grew into the largest wildfire in New Mexico's history and destroyed hundreds of homes and portions of the Los Alamos National Laboratory—several reports were written analyzing the failures involved[1116,1117].

Scientists commonly distinguish three types of forest (or wildland) fires[1118]:

(1) Ground fires. This type of fire burns in duff, organic soils, roots, rotten buried logs, etc.
(2) Surface fires. A surface fire burns fuels that are above the ground but below the canopy. The fuels comprise needles, leaves, grass, downed wood, shrubs, and short trees.
(3) Crown fires. A crown fire burns in the elevated canopy fuels. Apart from the rarely-seen 'independent' crown fire, crown fires are subdivided into active and passive. An active crown fire involves a solid wall of flame from near-ground level through the top of the canopy and encompasses many trees burning en masse. A passive crown fire involves only one or a small number of trees, with solid flame not consistently maintained in the canopy.

The ignition of vegetation is greatly influenced by its moisture content, *MC*. This is

measured on an oven-dry weight (ODW) basis and is defined as:

$MC = \frac{\text{mass of water}}{\text{mass of dry fuel}}$. For living vegetation, MC > 70% and for some species may reach 400%. The fiber saturation point corresponds to 30 – 35% MC, so dead vegetation that has not been flooded or recently rained upon will normally be below this value. In the absence of flood or rain, the MC of dead vegetation is established by atmospheric temperature and RH conditions.

The US Forest Service uses the concept of *moisture of extinction*, which is the maximum moisture that vegetation can have and still support a propagating fire. Its ue[1119-1121] depends on the type of vegetation, being typically 12 – 15% for light, airy fuels; 15 – 20% for dead grasses, 15 – 25% for logging slash; 20% for chaparral and brush, 25 – 30% for pine needles; 30% for forest litter, 40% for palmetto understory, and over 100% for many types of live timber stands. Matters are complicated by the fact, however, that wind speed must also be taken into account. Figure 80 shows the predicted combined effects of fuel moisture and wind speed on fire types, as developed by Scott and Reinhardt[1118]. Not surprisingly, the combination of dry fuel and high wind speed is seen to allow the most dangerous fire type—the active crown fire—to occur. Ground fires[1121], however, can propagate in some extremely wet materials, as much as 90% MC. All of the information on moisture contents needed to achieve a sustained ignition is unfortunately anecdotal and systematic research is absent. Thus, for example, Ford[1153] reports that 18 – 22% moisture content is needed to ensure that a fire will not propagate through fine fuels, which is substantially higher than the USFS values cited above. The moisture of extinction concept is based on the presence of sizable flames. When ignition is by flying brands, lower moisture contents are required. McArthur[1122] found that in eucalyptus litter at MC > 7% "only very large flaming brands will be effective in starting new fires," but at MC ≤ 4% "even the very smallest of burning embers have a high probability of starting a fresh fire." When using the concept of the moisture of extinction, it must be recognized that, for higher MC values, a fire may get ignited, but its HRR is likely to be so low that the hazard associated with such a fire will be small. Luke and McArthur[1141] consider fire hazard to be low if fine-fuel MC > 15%. They also consider that the probability of a fire starting becomes small for MC > 9% and very small for MC > 15%. Viegas[1123] categorized the hazard of surface or crown fires as:

- fine-fuel MC < 10%: extreme hazard exists
- fine-fuel MC > 20%: hazard is low (< 10 hectares can be expected to burn)
- fine-fuel MC > 40%: only trivial fires are possible.

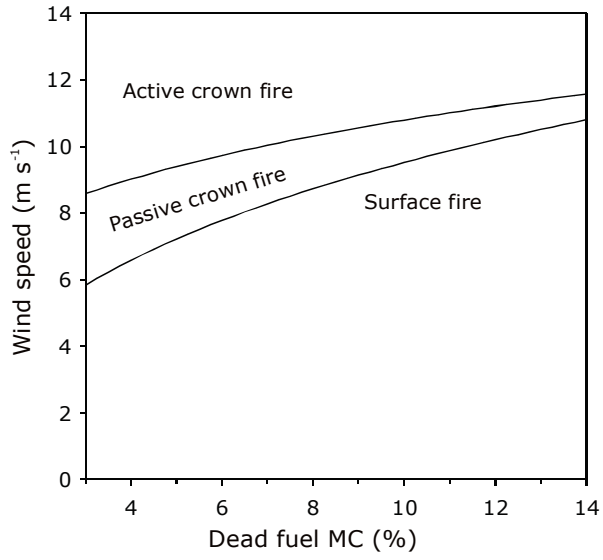

Figure 80 Effect of wind speed and fuel MC on the type of forest fire possible (this is an example calculation only; actual values are affected by the detailed fuel characteristics)

Another set of expressions[1124] has been derived empirically based on experience with grassland fires in Australia:
for $MC < 18.8\%$:

$$F = 3.35W \exp(-0.0897MC + 0.145V)$$

for $18.8\% \le MC < 30\%$:

$$F = 0.299W(30 - MC)\exp(-1.686 + 0.145V)$$

where W = fuel load (tonnes ha^{-1}), V = wind speed (m s^{-1}), and MC = fuel moisture content. F is a fire danger index which evaluates the probability that a fire can spread significantly from an initial ignition source. For moisture content over 30%, ignition and spread is held unlikely.

IGNITION BY HOT GASES AND HOT SURFACES

Ignition temperatures of vegetation have been measured by numerous researchers, as detailed below. However, the reported values are widely discordant. It is first necessary to ask whether there should be differences in ignition temperatures of vegetation of various types. Since the chemical composition varies somewhat, the answer must be Yes, but generally one would expect that most vegetation of a particular type (e.g., deciduous leaves, needles, grass, etc.) would show ignition temperature variations only within a modest range. Another variable that is important is the moisture content of the material since live vegetation can have MC values over 100%. However, MC should not have an effect if a thin specimen is heated for a long time at a heat flux close to its minimum ignition flux—in that case, all of the moisture should be evaporated before ignition takes place. A major complication is that many of the reported results have been obtained by foresters, botanists and other workers who may not be well-versed in physics or chemistry and have never conducted ignition experiments on any other substance. Thus, the equipment used has generally been uniquely-designed and not calibrated with any reference materials. A physical complication is that inadequate specimen size may have been used. Since practical

ignition usually involve a substantial bed of material, rather than an isolated needle, twig, etc., some reported T_{ig} values are undoubtedly too high to represent such realistic fuel beds. The best recommendation that can be offered at the present time is to consider that the ignition temperature of vegetation is essentially identical to that of whole wood, as described later in this Chapter under *Wood*. The results of Di Blasi, which are recent and obtained by a combustion specialist, are highly suggestive that this is a reasonable conclusion.

Di Blasi et al. tested the ignition of beds of straw in a convective-heating apparatus where both the air stream temperature and its velocity could be varied. Their results are considered in detail in Chapter 7, but the basic finding was that T_{ig} = 250ºC when the specimens were heated using the lowest temperature air stream. At higher heat fluxes, the values of T_{ig} rose. This phenomenon is identical to the one described for solid wood later in this Chapter.

The ignition temperature of pine duff was tested at the Forest Products Laboratory of Canada using an unspecified technique[1125]. They reported flashing ignition at 166ºC and sustained flaming at 177ºC. Bowes[1126] assessed the ignition temperature of dried (6% MC) grass to be 249ºC by using a crossing-point technique. Using a hot-air apparatus, Yamashita[1127] measured the autoignition temperatures for a variety of leaves and branches. Leaves typically showed an AIT of 375 – 400ºC, although some types required up to 600ºC for ignition. Small branches gave results as low as 350 – 375ºC and as high as 650 – 675ºC. Johnson et al.[1128] measured the autoignition temperatures for several botanic materials (Table 135). Their technique involved declaring ignition when a certain rate of temperature rise was exceeded, and visual observation of ignition was not made. Shu et al.[1129] reported ignition temperatures for leaves and twigs from 12 species of Chinese trees using a Chinese test apparatus. For leaves the range was 210 – 254ºC (average: 240ºC), while for twigs it was 228 – 244ºC (average: 236ºC); the moisture content of most of the specimens was ca. 50%.

Stockstad tested ponderosa pine needles in a horizontal tube furnace[1130]. A tiny amount of specimen was lashed onto a rod and held in the middle of the cavity; a maximum exposure time of 3 min was used. A minimum furnace temperature of 280ºC was found for piloted ignition, and a minimum of 365ºC for autoignition. The effect of moisture content was also explored, and the wettest specimens (MC = 33%) required a temperature of 350ºC for piloted ignition and 390ºC for autoignition. In his test procedure, he did not differentiate between glowing and flaming ignitions. Using the same technique, he also tested cheatgrass[1131]. A minimum furnace temperature of 380ºC was found for piloted ignition, and a minimum of 450ºC for autoignition. These values seem excessively high, but the reason for this is not clear.

Table 135 Ignition temperatures of several botanic materials measured by Johnson et al.

Substance	AIT (ºC)
corn 'beeswings'	302
fir sawdust	313
locust sawdust	291
tobacco	272
willow oak leaves	282

Table 136 Effect of species on ignitability at 400ºC

Probability of ignition at 400ºC	Percent of species tested

60%	0	2%
50%	2%	0
40%	2%	0
30%	0	0
20%	2%	0
10%	0	2%
0	2%	0

A number of workers examined ignition/non-ignition of specimens using only a single furnace temperature. Mutch[1132] examined the ignitability of ponderosa pine needles (MC 5 – 6%) and sphagnum moss (MC 19 – 20%) by dropping them into the Jentzsch tester, which is a heated crucible used in the early years of the 20th century for testing of liquids. Running tests only at 320ºC, he found that autoignition of pine needles took 36 – 39 s, while the moss ignited in 19 – 20 s. Liodakis et al.[1133] tested for the autoignition of pine (*pinus halepensis*) needles using 0.2 – 1.0 g samples placed into an oven. At an oven temperature of 500ºC, ignition time was 59 s; no ignition was found at lower oven temperatures.

Gill and Moore[1134] tested the leaves of 50 different Australian plants (which came from 19 botanical families) in a muffle furnace. Their tests all used spark ignition and most tests were conducted at 400ºC, although a small number of difficult-to-ignite specimens were re-tested at 500ºC. Using 10 replicates per plant type, they obtained ignition at 400ºC in 89.6% of the trials when using fresh leaves, and in 95.2% of the trials when using oven-dried leaves. Most species showed a 100% probability of ignition, but 17 species (for fresh leaves) and 9 species (oven-dried) showed probabilities of less than 100%. Species effects are summarized in Table 136. The authors repeated their tests at 500ºC using the five least ignitable species. At the higher temperature of 500ºC, still not all specimens ignited. Two species (*Myoporum acuminata* and *Geijera parviflora*) exhibited less than 100% ignitions when fresh, and one species (*Amyema*

cambagei) showed only 50% ignitions at 500ºC when oven-dried. The latter species was peculiar, in that at both temperatures a lower probability of ignition was found for oven-dried samples than for fresh ones. The authors also found that leaves with higher surface/volume ratios were more easily ignited, and, surprisingly, that ones with a higher mineral content were also more readily ignitable. Ignition times at 400ºC were typically 4× greater for fresh specimens than for oven-dried ones, although there was significant scatter from this trend. No specimen that did ignite required more than 57 s to ignite, with the minimum being 3.2 s.

Xanthopoulos and Wakimoto[1135] tested conifer needles for piloted ignition using a vertical tube furnace. They reported that almost no specimens ignited for furnace temperatures below 400ºC, while most ignited for temperatures of 440ºC and over. They did not specify their time of exposure nor the location of the pilot, leading to the possible conclusion that the surprisingly high temperatures reported might have been due to inadequate exposure time or due to poor location of the pilot. Montgomery and Cheo[1136] ignited leaves from plants of 32 different species in a furnace held at 750ºC and found that the ignition time would be represented as:

$$t_{ig} = 1.02 + 3.40d$$

where t_{ig} = ignition time (s) and d = thickness (mm). This linear increase with thickness indicates a thermally-thin behavior, which is consistent with the 0.05 – 0.58 mm range of thicknesses in their study.

A number of workers conducted tests where a sizable *hot surface* (ignition by brands is discussed separately later) was pressed into the vegetation and the temperature needed of the hot surface for ignition was determined. Results of this kind depend strongly on the size of the hot object, but most of the workers either did not specify the size or used irregular-shaped heaters. Wright[1125] dropped heated iron discs of about 6.5 cm^2 area and 45 g mass onto pine duff. No ignition was observed at 625ºC, but flaming ignition was found at 725ºC. Fairbank and Bainer[1137] conducted tests where simulated hot exhaust manifolds were used to test the ignitability of vegetation. The lowest temperature at which an ignition occurred was 448ºC for dry oats; a two-minute exposure was required. For temperatures over 600ºC, ignition was nearly instantaneous. Pine needles and dry, rotten wood (punk wood) required 760ºC, while dry grass ignited at 663ºC. Harrison pressed a rod-shaped electric heating element against forest fuels and determined their short-duration ignition temperatures[1138]. He first determined that a wind velocity of 0.9 m s^{-1} (2 mph) was optimum, then using this velocity found that 350ºC was needed to ignite dry pine needles and 400ºC to ignite dry grass for a 4 min exposure (Figure 81). Four minutes is a short exposure time, as indicated by the results obtained by Kaminski[1139], which showed lower temperatures. He conducted tests where a hot chain-saw muffler was pressed against various forest materials. Using an ambient temperature of 35.6ºC and a test time of 10 min, he found that punky (partly rotten) wood and bark underwent a glowing ignition at a surface temperature of 270ºC. With a temperature of 300ºC and a light wind, flaming ignition was observed. Cheat grass required 330ºC for a glowing ignition. Upon rerunning the tests with a pilot flame, cheat grass produced a flaming ignition at 270ºC, and sawdust at 260ºC. Rallis and Mangaya[1140] placed "fine, dry veld grass" on a hotplate and observed that glowing ignition required a hotplate temperature of 250 to 350ºC. For a hotplate temperature of 400ºC, it was possible to obtain a flaming fire by gently blowing on the specimen.

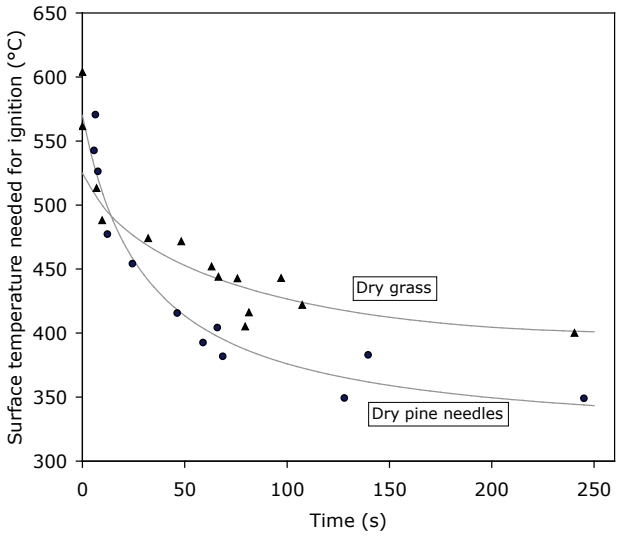

Figure 81 Hot surface temperatures needed for ignition of forest materials in Harrison's tests

IGNITION BY MATCHES AND SMALL FLAMES

Green grasses may have moisture contents as high as 350% and, for practical purposes, cannot be ignited. As a rule of thumb, moisture content must drop to the range of 20 – 25% for fine forest or grassland fuels to be ignitable[1141]. Sale[1370] conducted experiments on the ignition of dried grass by matches. The moisture content of the grass was ca. 5%. Matches were either dropped or thrown onto the grass. When dropped from a distance of 0.9 m, 80% of matches caused ignitions, but at a distance of 3 m the probability went down to 25%. Matches that were thrown, rather than dropped, showed a slightly smaller probability of ignition. Curiously, the ignition percentages from using larger wood matches were lower. An old US Forest Service report[1142] which has been widely cited advises that dropped matches will not ignite forest fires at wind speeds above 1.8 m s^{-1} (4 mph), but the author provides no experimental data and the conclusion is questionable.

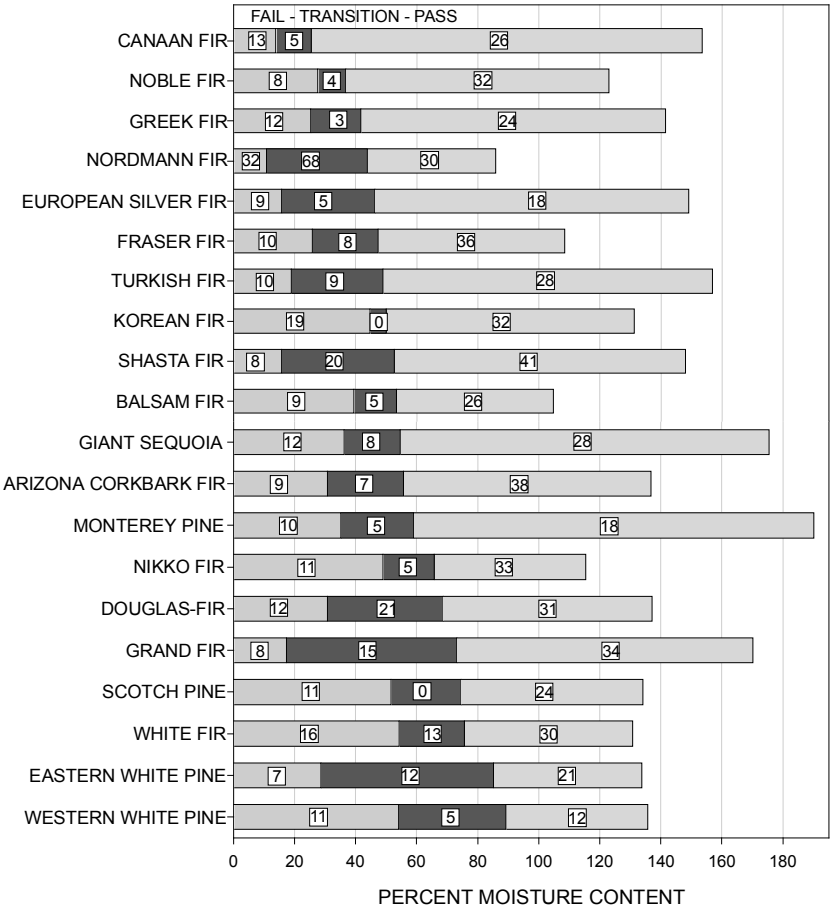

Figure 82 Effect of moisture content on ability of branches from 20 different species of Christmas trees to pass a modified California State Fire Marshal's flammability test. Bars show the moisture range where samples pass or fail the test as well as the size of the transition zone where some samples pass and some fail. Numbers in small boxes are the number of samples tested.
(Courtesy Gary Chastagner)

The effect of moisture on the ignitability of forest-floor pine-needle litter was studied by Blackmarr[1143]. He used three different wood match igniters: (1) a miniature match; (2) kitchen match; and (3) three kitchen matches tied together. The results focused on the role of moisture content for needles of *pinus elliottii* (slash pine), and it was found that there is a relatively narrow range of moisture contents over which the probability of ignition goes from near-zero to near-100%. For the miniature match, the 50% probability of ignition corresponded to 19.3% moisture content, for the kitchen match to 21.5%, and for the three-match set to 29.9%. The matches were used as ignition sources not because matches are a major form of forest material ignition, but simply as a surrogate for flaming brands of various sizes. Gill et al.[1144] conducted experiments where they ignited various specimens with 'large-headed' matches. Unfortunately, they did not record observed ignition but, rather, declared ignition to have occurred when 1 g of specimen mass was lost (their specimens were generally in the 10 – 40 g range). Their 'ignition time' results showed a modest influence of moisture for MC ≤ 11.1%, but nearly a doubling of ignition time when going from 11.1% to 16.6% MC.

The ignition behavior of *Christmas trees* is determined mostly by the moisture content. A fresh-cut Christmas tree will show moisture in the vicinity of 100 – 150%. The moisture loss is small while it is still baled and is stored in a cold place, and one study[1145] found that even after storage for 6.5 weeks in an unheated shelter (average temperature – 4ºC), the MC only dropped from 120% to 100%. But moisture levels can drop precipitously if a tree is brought into a heated room and not watered properly. Example data for Douglas fir[1146] are shown in Figure 83. Douglas fir is probably the worst Christmas tree from the viewpoint of 'keepability,' since under dry conditions Figure 83 indicates an MC loss of about 11% per day. Some other species[1145] show losses of only 4 – 6%.

For many years, the California State Fire Marshal had regulations requiring that Christmas trees used in certain occupancies be fire-retardant treated, with a small burner test

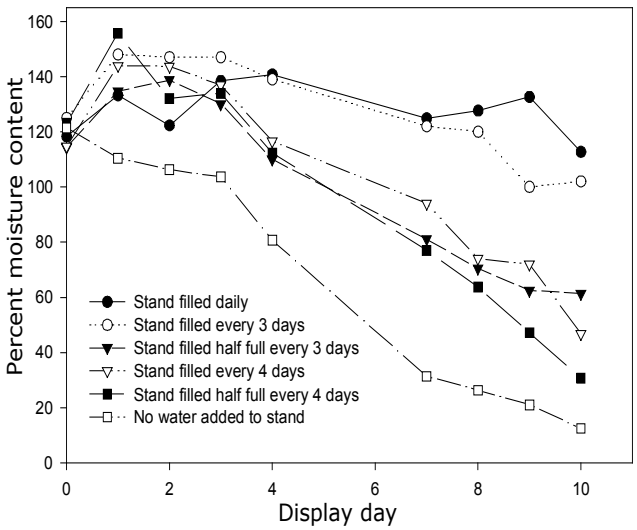

Figure 83 Effect of display care on changes in the moisture content of Douglas fir trees
(Courtesy Gary Chastagner)

being used to determine compliance[1147]. The test is to be performed 30 days after application of the FR agent. A diffusion flame from a Bunsen burner is applied to a branch for 12 s, with the flame adjusted to be 38 mm high. The specimen passes if fire does not spread and if afterflame time is ≤ 10 s. Using a similar small flame but applying it for 5 s, Chastagner[1148] examined the ignitability of non-FR Christmas trees of various species, as a function of the moisture content. His results, shown in Figure 82, indicate that there is a large species effect. Some conifers, e.g., Noble fire and Canaan fir, can more safely be used as Christmas trees since they are ignition-resistant down to much lower moisture contents. Chastagner[1146] also examined FR-treated trees and found that applications of the FR agent damaged the needles on many of the trees. Furthermore, the FR agents did not make the trees significantly more resistant to small-flame ignition, thus Chastagner concluded that trees must be diligently watered, but that applying FR treatments is counterproductive. A related study showed that resistance to small flames does not imply a Christmas tree cannot be ignited from a larger source[1149]. All test trees, even substantially wet ones, could be ignited and burned fairly completely if they were ignited with either flaming gift packages at the base of the tree or with a small burning toy. In those cases, there was a progressive involvement mechanism, whereby the initial ignition source preheats and dries out the tree locally, at which point the branches become able to burn; the drying/burning zone then proceeds to circle around the tree.

IGNITION BY CIGARETTES

Hoffheins et al.[314,1150] conducted experiments on the ignition of grass and forest duff and litter by cigarettes. For grass samples of 7 – 9% moisture content and 43 kg m^{-3} density, he found that ignition probability P depended on the wind velocity. At velocities ≤ 0.7 m s^{-1}, P = 0; at 1.4 m s^{-1}, P = 5%; at 2.0 m s^{-1}, P = 30%; and at 2.8 m s^{-1}, P = 50%. For velocities greater than 3 m s^{-1}, there was no further effect on ignition probability. Grass samples at greater packing density showed a higher probability of ignition. At 99 kg m^{-3} density, P ≈ 80% for the higher wind velocities. Ignition times, using 32 mm long cigarette butts, were about 5 – 11 min, with shorter times corresponding to higher wind velocities. Cigars were found to show roughly half the probability of ignition of cigarettes, under identical circumstances. For forest floor duff and litter, again wind velocity played a similar role, although, the exact nature of the vegetation was also of importance. The moisture content clearly plays an important role, but in these tests was controlled only indirectly, with solely the short-term RH being reported. In any case, probabilities approaching 100% were found for a variety of materials under wind conditions of around 3 m s^{-1}.

A later study on cheat grass and wild oats was conducted by Countryman[1151,1152]. In preliminary testing, he identified that grass is unlikely to ignite if a cigarette falls on stalks of grass that support the cigarette above the actual litter layer. Thus, he then focused on ignitions solely by applying cigarettes directly on the litter layer. His tests were all conducted at a temperature of 27ºC and with a wind of 1.3 m s^{-1} (3 mph), since limited testing indicated lower ignitability for smaller wind speeds. The cigarettes were pre-burned to a 50 mm length prior to placing on the bed. The ignition results were found to depend greatly on whether the fuel was coarse or fine. For fine fuel, ignition readily occurred for moisture contents up to 13%, with marginal ignitions up to about 14 – 15% and none beyond. Coarse fuel was not possible to ignite even for the lowest moisture tested, 1.9%. Medium fuel gave erratic results, but was less readily ignitable than fine fuel. Fine fuel is likely to occur in areas where foot or vehicular traffic repeatedly crushes the grass. In his main tests, no flaming ignitions occurred, the ignited fuels were solely consumed in smoldering combustion. Some further exploratory testing indicated that smoldering-to-flaming transitions occurred when a non-uniformity in the fuel bed was encountered by the smolder front. Countryman also found that the cigarette direction where the lit end faces into the wind is more likely to lead to ignition. Depth of the fuel bed had only a small effect on ignitability, with a 13 mm thickness showing slightly increased ignitability than a 6 mm thickness. From his study it can be concluded that there are two, related fuel effects:

(1) a minimum contact area must exist between the fuel and the cigarette; coarse fuel or geometries where the cigarette is supported at only a few spots prevents sufficient heat transfer for ignition to occur;
(2) the fuel array itself must not be so sparse or thin that initial points of ignition fail to propagate fire to the remaining mass of fuel.

Ford[1153] reported that, under some circumstances, vegetation with moisture contents of 18 – 22% is ignitable by cig-

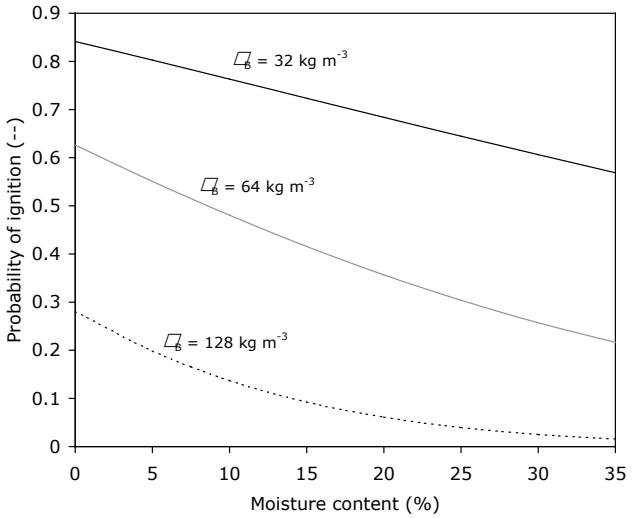

Figure 84 Effect of fuel moisture and density on the probability of ignition by lightning

arettes, but provided no details on vegetation type nor on wind conditions. He also concluded that the cigarette must contact fine vegetation for at least 1/3 of its perimeter for ignition to be possible. Markalas[1154] studied the potential of cigarettes to ignite foliage of various types. For materials dried to 4.5 – 6.5% MC, he found that: (a) no ignition could be achieved without wind; (b) with wind, ignition probability depended greatly on the species; (c) filter cigarettes were slightly less likely to cause ignition; and (d) thicker layers of vegetation were more readily ignited than thinner ones. Pine needles were least likely to ignite, while *Quercus coccifera L.* was most likely. Hardwood leaves only ignited when chopped into small pieces and compressed.

IGNITION BY LIGHTNING

Latham and coworkers conducted extensive studies into the ignition of vegetation by lightning. Because of the nature of the variables involved, the formulation of their models was presented in probabilistic terms. In an early study[1155], they concluded that 20% of cloud-to-ground discharges comprise 'long continuing current' (LCC) discharges, and that only the latter are likely to be incendive. The probability of fuel ignition, given an LCC discharge, was modeled as:

$$P_{ig} = \left[1 + \left(\frac{\rho_B [0.17 + 0.0062MC]}{2822} \right)^{1.44} \right]^{-1402}$$

where P_{ig} = probability of ignition (--),ρ_B = fine fuel bulk density (kg m^{-3}), and MC = moisture content (%). Example plots are given in Figure 84, with density data being shown in Table 137. Other submodels were also created to estimate the ignitions expected per area of ground surface, given various characteristics of storms.

In a later study[1156], they concluded that positive and negative discharges have different probabilities. For either, the lighting discharge parameter governing the process is duration, not energy flux. The relative importance of fuel parameters varied with the type of forest floor material—for some moisture content was found to be the most important, for others depth of the layer or density of the material. For positive discharges, the optimal duration was found to be 50 ms, while for negative discharges it was 110 ms. At their respective optimal discharge durations, however, positive discharges were 3× more incendive than negative ones.

Table 137 Bulk densities of various fine forest fuels

Forest fuel type	Bulk density (kg m^{-3})
Alaskan black spruce	128
Eastern pine	64
pine-grass	64
sagebrush-grass	32
short-needle	128
tundra	32
Western annual grass	32
Western long-needled conifer	64

Actual data[1157] show the probability of starting a fire in North America, per flash (not per LCC flash), ranges from about 0.04% for grass to 5% for Douglas fir forests; most other fuel types show probabilities of 1.5 – 3% with an average of around 2.4%. These data reflect an overall statistic and are not differentiated with regards to fuel moisture. The main ignition mode in Douglas fir forests is when a lightning strike ignites the needles on the ground—actual ignition of a tree is rare and may not lead to a propagating fire. Furthermore, lightning strikes generally lead to ignitions which are smoldering first, and transition to flaming only later. Laboratory experiments led Latham to conclude that layers of Douglas fir duff need to be at least 28 mm thick before an ignition can take place.

A study of lightning-caused fires in Yosemite National Park[1158] showed that: (a) likelihood of ignition from a lightning strike greatly increases if larger-diameter dead and downed fuels have < 13% MC; (b) lightning is more likely to ignite fires in old-growth areas; and (c) for unexplained reasons, Douglas fir stands sustained an average incidence of lightning ignitions, but these led to fewer than expected crown fires.

IGNITION FROM CONTACT WITH POWER LINES

When trees or other vegetation contact electric power lines, there can be diverse outcomes with respect to the ignition potential. Stokes[1159] studied this situation in the laboratory and also summarized experiences learned by electrical utilities. His conclusions were that there is a minimal danger of ignition from live, growing vegetation contacting power lines. Under conditions where vegetation encroaches onto a power line, the contact is likely to be made by leaves or twigs. The consequence of this contact with an 11 kV power line is a current flow of typically 10 – 50 mA through the

vegetation. The flowing current through the vegetation heats it up and when the vegetation reaches around 70ºC it has been destroyed and will eventually die, even though it may appear for a while to still be 'green.' After some days, it then loses its 'green vitality' and shows a dull appearance. Then, after a further interval between many days to a month or so, the leaves finally turn brown and are blown off in strong winds. Stokes referred to the process as 'electrical pruning.' The process requires several thousand volts, and vegetation can be in indefinite contact with 415 V power lines without any visible effect. For a detectable fire hazard to exist, Stokes found that contact of relatively large (> 10 mm) branches was needed, as can happen when large branches or whole trees fall onto a power line. In such cases, the ignition sources that can be created include:

(1) Falling incandescent particles;
(2) Flames generated due to combustion of oily material, leading to falling flaming material;
(3) Carbonization of a branch and its smoldering ignition; the branch can then fall down and lead to ignition of ground-level material. This process takes place only within a narrow range of current values and Stokes found it necessary to 'fine-tune' the current to obtain the phenomenon in laboratory testing.

Whether or not a fire ensues will, of course, be strongly governed by the type and moisture content of the ground-level fuel. In many cases, when a branch falls down on a power line, none of the ignition sources will be generated, instead, the branch will be severed at the point of contact and fall down without leading to fire. The events in general depend both on the voltage of the power line and on the form of contact between the vegetation or branches and the power line—sustained or intermittent. If sustained contact is made with power lines carrying over 100 kV, a steam explosion can result. This is dramatic but does not, by itself, create a fire hazard. In addition, sustained contact may be accompanied by an electrical 'flashover' which of course entails extremely high temperatures. But Stokes found that the flashover events were not able to ignite combustible target solids, which he speculated was due to pressure effects associated with the breakdown process blowing out any incipient flame. However, if the sustained contact also creates ignition sources such as those listed above, then ignition of ground-level fuels can be possible. Ignition from particles ejected by conductor clashing is discussed below under *Brands and hot particles*. A related ignition hazard is from the operation of expulsion fuses that are used to protect HV power lines; this is discussed under *Electric circuit interruption devices*. The arc tracking process in trees is discussed under *Wood and related products*.

RADIANT IGNITION

Stokes[562] ignited beds of various forest-floor materials using the ISO 5657 test. The specimens were collected in the field under 'high fire danger' conditions but were not further dried in the laboratory. Table 138 shows the ignition time results. Except at the highest flux, all of the ignitions began as glowing ignitions, with transition to flaming occurring only later; at 50 kW m^{-2}, the ignition mode was not specified.

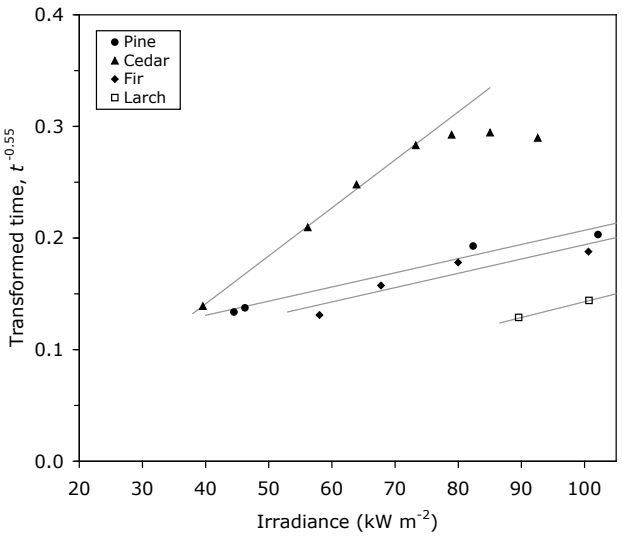

Figure 85 Radiant autoignition of conifer needles

Table 138 Ignition times (s) for the autoignition of various forest-floor materials

Substance	Heat flux (kW m^{-2})			
	10	15	30	50
hardwood litter	50, 600		14, 20, 36, 37	7
barley grass	47, 300	115	16	2, 6
pine needles				4

Filippov[1160] measured the radiant flux needed for autoignition of a variety of forest materials; his results are shown in Figure 85 through Figure 87. Moisture contents were not specified, but presumably were typical for the Russian climate. The lines fitted through the data give the parameters

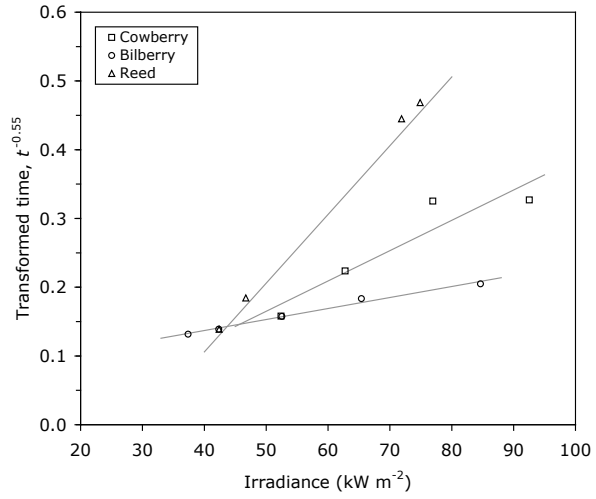

Figure 86 Radiant autoignition of shrubs

Table 139 Ignition properties of forest materials tested by Filippov

Material	Critical flux (kW m^{-2})	B_{ig}
aspen leaves	-0.21	161
birch leaves	1.9	177
pine needles	-63.0	787
cedar needles	7.2	233
fir needles	-51.6	781
larch needles	-5.2	735
reeds	29.4	100
cowberry	12.6	227
bilberry	-45.6	625
club moss	-14.0	398
sphagnum moss	53.0	175
Schrebers moss	14.3	172
alpine lichens	27.6	112

listed in Table 139.

White et al.[1161] conducted piloted Cone Calorimeter tests at a 25 kW m^{-2} irradiance on branches from various coniferous trees—balsam fir, blue spruce, Fraser pine, Norway pine, red pine, Scotch pine, white pine, and white spruce. Their results (Figure 88) show that increasing moisture delays ignition, but clearly other factors are also involved. Not enough samples were tested from any single species to enable botanical differences to be studied. Trabaud[1162] exposed a variety of vegetation types to a radiant heat flux of about 25 kW m^{-2} and measured the autoignition time as a function of moisture content. Typical ignition times at 0% MC were 10 – 20 s, increasing to 50 – 70 s at 20% and then rapidly increasing, so that MC=35% material typically took 300 – 400 s to ignite.

Dimitrakopoulos and Papaioannou[1163] tested the piloted ignitability of vegetation using the ISO 5657 test method, but using only a single irradiance value of approx. 45 kW m^{-2}. Their main objective was to determine the moisture content necessary so that no ignition would occur during a 300 s exposure period. For 24 species tested, this value turned out to be typically 60 – 140%. At the given irradiance, they found that the ignition time results could be represented by $t_{ig} = a + b\ MC$, where MC = moisture content (%), and a and b are constants. There was a wide disparity of results among the species, and some species took 4 – 5 times longer to ignite at a given moisture content than did others.

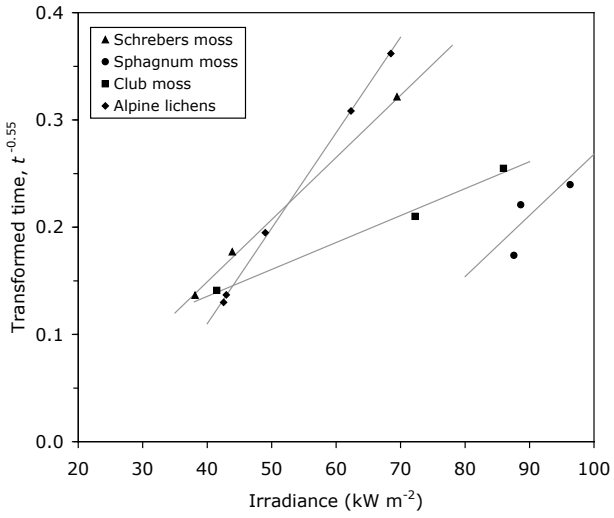

Figure 87 Radiant autoignition of mosses and lichens

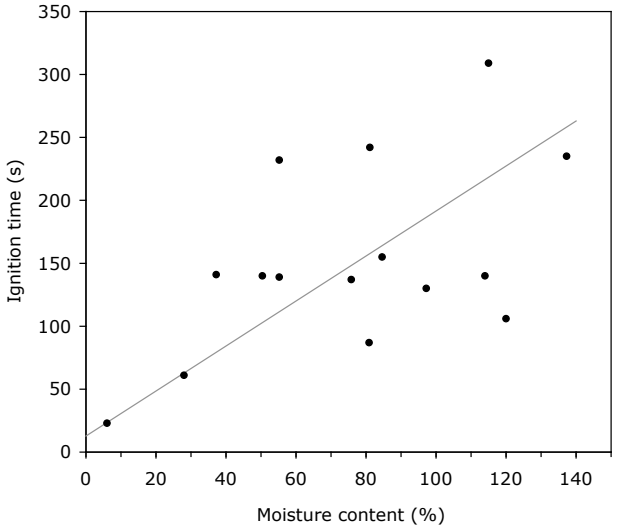

Figure 88 Piloted radiant ignition of conifer branches as a function of moisture

IGNITION BY BRANDS OR SMALL HOT PARTICLES

The experience of the US Forest Service is that a glowing brand only tens of milligrams in mass can start a smoldering fire in a highly susceptible target fuel[1164]. This is consistent with the laboratory results cited in the section on *Brands ejected from fireplace* in Chapter 11 which showed that burning coal particles of only 5 mg (about 2 mm diameter) inevitably cause ignition when dropped onto cotton wool. The investigators found that cotton wool was exceptionally easy to ignite, but other studies show that fine, dry vegetation material is not much more difficult to ignite, as discussed later in this Section.

Once a fuel bed starts smoldering, there is no definite time limit when—if at all—flaming may occur, since this depends on details of the fuel bed, its moisture, and the prevalent wind and temperature conditions. In extreme cases, when smoldering is initiated in combustible subsurface layers, punky portions of trees, etc., months may elapse (see *Ignitions from lightning* in Chapter 11). Pockets of smoldering material have also been undetected and stayed buried under a cover of snow during winter, only to turn into a flaming fire the following summer[1165].

Despite the importance of the firebrand mechanism in igniting or propagating forest fires, not much laboratory work is available on the subject. Several studies using engine exhaust particles were discussed in Chapter 11. More recently, Ellis[1166] tested the ignitability of pine needles using brands made of eucalyptus (*Eucalyptus obliqua*) bark cut into specimens of approximate size 50×15×5 mm and having a mass of 0.7 – 1.8 g. Both flaming and glowing brands were used. Under still air conditions and for rather-dry target conditions (MC ≤ 9%), when flaming brands were used, 100% of the targets ignited, all in a flaming mode. For glowing brands and no wind, it was impossible to achieve flaming ignition, but many tests resulted in a glowing ignition of the target fuel. When a wind of 1 m s^{-1} was applied, the probability of a flaming ignition from a glowing brand was found to be related to the fuel MC, as shown in Figure 89. It is of interest to note that these experiments were done under mild laboratory conditions—temperature was typically 22ºC and humidity 30% RH.

Wildland fires are occasionally ignited from high-voltage power lines when *conductor clashing* occurs (due to creep, ice storms, etc.) or some other arcing event that ejects molten aluminum or copper particles. Rowntree and Stokes[1167] published some data on the ignitability of oven-dried barley grass from molten *aluminum particles*. The study (Figure 90) grouped results into three groups—definite ignition, possible ignition, and no ignition. Two different theories have been proposed to predict this type of ignition: (1) minimum ignition energy; and (2) hot inert sphere ignition. The minimum ignition energy theory is less a theory than an arbitrary hypothesis, presumably formulated on the basis that if MIE is a useful predictor for the ignition of gases, it can also be applied to solids. The hot inert sphere ignition theory, on the other hand, is based on physics, as developed

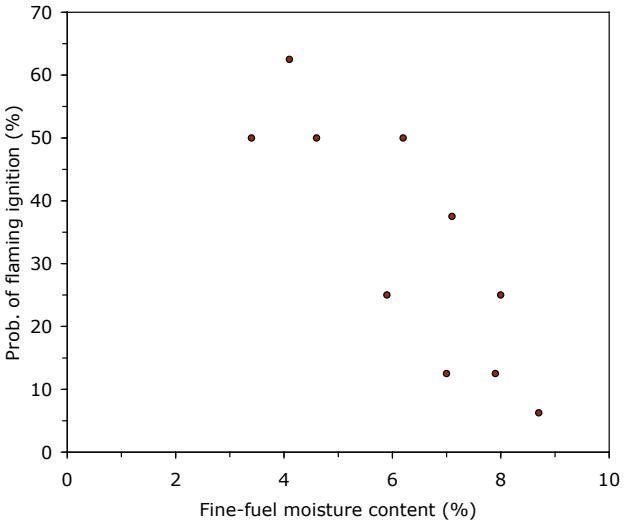

Figure 89 Effect of fine-fuel moisture content on the ignitability of pine needles from small glowing brands

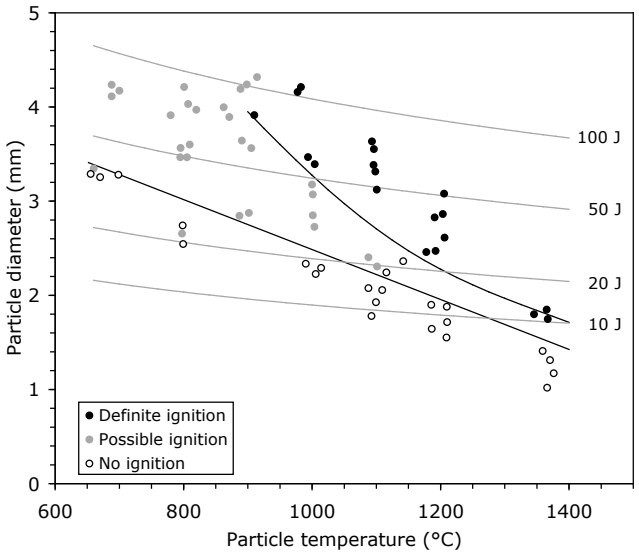

Figure 90 Experimental data on ignition of oven-dried barley grass from molten aluminum particles; also shown are data-envelope contours, fitted to the experimental results by eye (black lines) and contours of constant MIE (gray lines), indicating that MIE is not a viable criterion for ignition of beds of porous materials of this type.

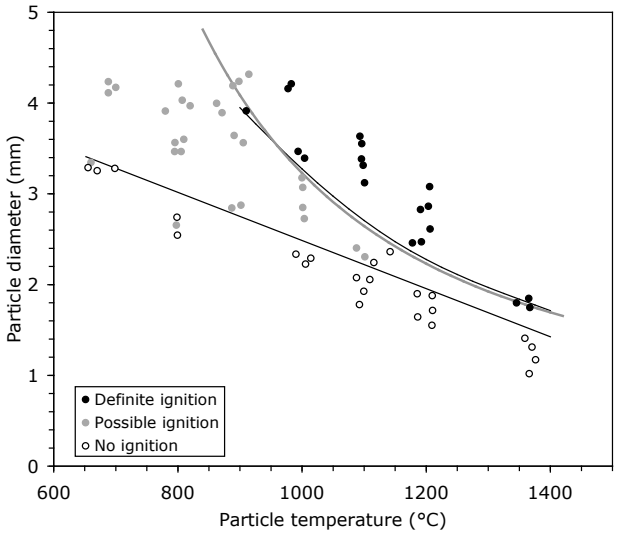

Figure 91 Comparison of Gol'dshleger's theory (thick gray line) to experimental results.

by Gol'dshleger (see Chapter 9). Since Rowntree and Stokes proposed that the experimental data can be adequately correlated by the MIE theory, Figure 90 shows the results of these calculations. The theory is based on computing the stored thermal energy in a sphere that can be delivered by cooling it down from its original temperature to the ignition temperature of the fuel. Since aluminum melts at 660ºC, the initial cooling from high temperatures will be for a liquid, followed by recovery of the heat of fusion at 660ºC, then cooling a solid material below this temperature.

The constant-energy lines in Figure 90 were computed by assuming that density = 2380 kg m^{-3}, heat capacity (which is similar for solid and liquid aluminum) = 1110 J kg^{-1} K^{-1}, and T_{ig} = 300ºC. It can also be shown that changing T_{ig} over a range of physically plausible values, say 250 to 600ºC, does not improve the correlation. The results from applying Gol'dshleger's theory are shown in Figure 91. Here, it was assumed that T_o = 293 K, ρ_h = 2380 kg m^{-3}, λ_h = 80 W m^{-1} K^{-1}, C_h = 1110 J kg^{-1} K^{-1}, ρ = 120 kg m^{-3}, λ = 0.043 W m^{-1} K^{-1}, and C = 2000 J kg^{-1} K^{-1}. Values of the chemical kinetics constants E and P are not known for barley grass, so a best-fit to the data was made, giving E = 70 kJ mol^{-1} and P = 36.2. In contrast to the MIE theory, the Gol'dshleger theory is able to predict slopes which are roughly similar to the experimental ones. These deduced values of E and P are quite close to measured values for some plant material studied by Jones (see *Self-heating* section below), suggesting that the chemistry of Gol'dshleger's theory may be reasonable. The 'possible ignition' regime may not be amenable to theoretical analysis, since the effects are likely to be created by local inhomogeneities of the fuel bed. Rountree and Stokes also presented some summary data indicating that other vegetation types—such as pine needles, and mixed forest floor litter (leaves, twigs, bark) from two different forest types—are less readily ignitable than is barley grass. Stokes[1168] also studied the ability of *copper particles* to ignite vegetation. The particles were created by an electric arc and fell only a short distance onto a fuel bed. The particle temperature was not measured but was presumed to be close to the melting point (1085ºC). Particles smaller than 1 mm showed essentially zero probability of igniting barley grass or forest litter from a hardwood forest, and only a small probability (< 1%) of igniting cotton wool. Particles with a maximum size of 2.5 mm showed about a 10% probability of igniting barley grass. The sizes refer to the maximum size within the shower of particles and most particles were much smaller than the maximum size.

Stokes also conducted some experiments[562] where steel and copper particles were emitted from an electric arc located 0.9 m above a bed of oven-dried fuel and were tested using two wind conditions: still air and a velocity of 2 m s^{-1}. Incandescent particle sizes were not measured in these experiments. Table 140 shows that steel particles were much more likely to cause flaming ignition than copper particles and, surprisingly, that a low-velocity wind decreased the probability. It is also interesting that cotton lint proved to be much more readily ignitable than did forest-floor materials. Stokes noted that some samples which did not yield flaming ignitions produced smoke, but did not assess the probability of smoldering ignitions.

In a second series of tests, Stokes characterized the particle size distribution of the incandescent particles, but the tests were conducted solely in still air. The particle sizes were typically 0.5 – 2.0 mm and the results from these tests are shown in Table 141. These results clearly established a rank order for incendivity as: steel (most), aluminum, copper, brass (least). The boiling points of the metals are all roughly similar, the volumetric heat capacity is similar for all except aluminum (which is about 100× lower), while the thermal inertia ranks, high-to-low: copper/brass, steel, aluminum. Thus, it is not clear what thermal properties actually are dominant in establishing the incendivity. Stokes also took photographs indicating that qualitatively the radiance of the spark showers was: aluminum (highest), copper, steel (least). Stokes also presented data on the effect of particle size on ignition, but these results cannot be readily interpreted since temperature was an uncontrolled variable—smaller particles are also cooler, but he was not able to control the temperatures. In addition, Stokes noted that particles have a varying propensity to break up upon hitting a fuel bed, but this trait depends on details of the fuel bed.

Table 140 Number of flaming ignitions in 10 trials for steel and copper incandescent particles falling onto various materials

Substance	Steel		Copper	
	No wind	2 m s^{-1}	No wind	2 m s^{-1}
cotton lint	10	10	10	10
barley grass	10	6	3	0
hardwood, sieved	8	7	3	0
hardwood, coarse	7	3	3	1
pine needles, fresh	10	2	0	0
pine needles, decomposed	10	9	3	0

Table 141 Probability (%) of flaming ignition in 50 – 100 trials for various incandescent particles falling onto ignitable materials

Substance	Alum.	Brass	Copper	Steel
cotton lint		0		
barley grass			48	
hardwood litter	58		8	90
pine needles, fresh	84		0	94
pine needles, decomposed	44		56	90

Two theories have been published[1169,1170] for predicting ground-fuel ignition distances from particles ejected due to conductor clashing. But these require making numerous assumptions of uncertain validity and experimental data are lacking to judge their realism.

SPOTTING FIRES

If a wildland fire carries brands which start new fires at distances remote from the ongoing fire, the ignition mechanism is called spotting. The propensity for spotting is determined largely by three factors: (1) fuel type; (2) wind speed; and (3) relative humidity. The first factor cannot be easily generalized and depends on local fuel characteristics. The effects of wind speed and RH, however, can be illustrated by trends observed in one geographic area[1171] (Figure 92).
