Fires in haystacks due to self-heating was already a problem known by the Romans[266,1172], and hay is one of the earliest substances which was studied for its self-heating propensities. Chemical consideration of the problem was undertaken by Ranke in 1873[1173]. The role of microbial action was also appreciated surprisingly early—Medem[35] speaks of it in 1898—although this understanding was not quantitative. The problem of self-heating in hay was of such practical importance that as early as 1907 an entire book on the topic of self-heating of hay was published in Germany[1174]. The earliest explanations of the phenomena, however, that would be consistent with modern science did not take place until around 1930[266,1172, 1175].

Firth and Stuckey[1176] report that spontaneous combustion fires in haystacks most typically break out at 5 – 10 weeks from stacking, although times as short as 10 days or as long as 3 months are known. Drysdale[1177] states that the most common interval is 2 – 6 weeks after storage. According to Firth and Stuckey, if it takes more than 3 months for fire to break out after stacking, this is due to the hay having gotten wetted in the interim. The pivotal role of moisture in actual fire incidents of self-heating of hay was documented after a Vermont flood, when piles of hay started self-heating 2 – 3 days after being flooded, and in one case caught fire after 4 days[1178]. During self-heating prior to runaway conditions being reached, the odor is described as caramel-like[1179]. If visible wisps of 'steam' rise from haystacks, that is also a danger sign. The odor of spontaneously combusted haystacks is aromatic, resembling tobacco or tea leaves; it is different from the acrid smell of a haystack ignited externally[1176].

It is considered that the self-heating of hay generally progresses through three stages. In the first stage, the biological respiration of the plant material still continues and provides heat. In the second stage, fungi and bacteria can flourish, and these provide additional heating. Their action can be complicated since one of the effects of microbial decomposition of carbohydrates is the production of water, thus changing the moisture balance of the material. The final stage occurs after temperatures have risen enough to kill off microorganisms. This involves the chemical oxidation reaction of the hay itself.

Firth and Stuckey[1180] consider that there is significant similarity between the self-heating of haystacks and the production of silage. The latter is produced in silos where air flow is excluded. In the early stages, cell respiration provides self-heating. Cell activity stops when the air is exhausted or when a combination of cell respiration and microorganism action raises temperatures beyond about 40ºC. At that point, cells die and microorganisms start to multiply, deriving nourishment from the dead cells. Fungi are probably dominant at lower temperatures and bacteria at higher ones. The process results in breakdown of carbohydrates (and possibly proteins) and the production of CO_2, alcohol, organic acids, and unsaturated organic compounds. Oxidation does not play a significant role, due to low oxygen levels. In well-made haystacks, the process is basically similar, except air is not excluded and moisture levels are lower. Activity of the microorganisms ceases when the water supply becomes exhausted, and temperatures do not continue to rise. Runaway self-heating of a haystack occurs when moisture does *not* get exhausted, yet air is present. As the self-heating process develops, chemical heating starts becoming important at about 70 – 75ºC, and at around 76ºC bacterial activity stops, even of high-temperature tolerant, thermophilic bacteria. From that level up to about 170ºC, chemical decomposition reactions take place which are dependent on the presence of moisture. Some of the decompositions reactions become autocatalytic, which accelerates the process. Above about 170ºC, oxidation reactions predominate, and these continue to the point of thermal runaway. With oxygen continuing to be available, open flaming may eventually erupt.

Rothbaum[1181] discovered an important limit to the starting conditions of the hay, if thermal runaway is to occur. Bacteria metabolize strongly only at RH values over 95%. Thus, haystacks with RH > 95% would be the main ones vulnerable. There is an upper limit also. As RH approaches 100%, the thermal conductivity of porous materials begins to show a very rapid increase, and this increase gets progressively more so at higher temperatures. Since high thermal conductivity reduces self-heating, the humidity range where actual self-heating fires are expected to occur is confined to RH values of 95 – 97%. Expressed as moisture content of the hay, the critical range is about 39 – 49%. Rothbaum proved his hypothesis in laboratory testing. Hussain[1182] agreed that

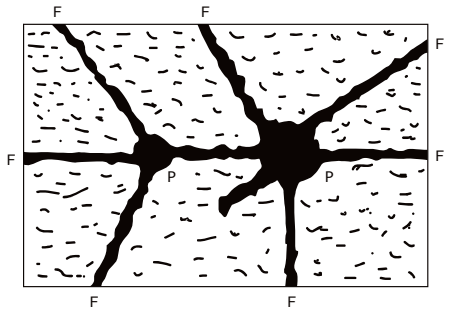

Figure 93 Pattern of flues (**F**) and pockets (**P**) formed in the interior of a haystack that self-heated to the point of charring

45% is the worst-case moisture content, but in his experiments runaway self-heating was possible for hay having moisture as low as 25%. Firth and Stuckey noted that MC = 25% is also the lower limit of moisture content found for actual case incidents, although Rothbaum considers the limit to be 33%. Rothbaum's basic findings were recently confirmed by Miao et al.[1183] They tested hay packed at a density of 50 kg m^{-3} in a temperature-controlled reactor and demonstrated that initial conditions of T = 110ºC, RH = 5% do not lead to detectable self-heating, nor does T = 50ºC and RH = 95%. But T = 70ºC and RH = 95% leads to runaway conditions (Figure 94). Thus, they showed the necessity of both (a) an RH value around 95% and an elevated temperature starting at around 70ºC. The latter, of course, validates the concept that biological heating (cell respiration + microorganisms) is needed to cause the initial stage of self-heating. They also elucidated that there is a contribution from the heat of sorption, since specimens which were initially at a higher moisture content showed less self-heating than did originally-drier specimens, when subjected to an environment of the same RH. In a follow-on study[1184], the authors concluded that the chemical self-heating of hay involves three separate groups of reactions: (1) decomposition; (2) oxidation; and (3) Maillard reactions. The latter involve condensation of carbohydrate decomposition products with protein or amino acids to form a dark-colored, insoluble polymer.

The theory that biological heating is an essential step of the process, while generally agreed to, has been questioned by one research group. In a series of oven tests at 104ºC, moistened bales of hay were found to ignite in 3 to 60 hours[1185]. The authors consider that the oven environment was ramped up so rapidly that any biological activity would have ceased very quickly and would not have contributed measurably under their conditions. On the basis of spontaneous combustion statistics, it has been argued that excessive *compression* of hay promotes self-heating[1186]. It was also observed that adequate ventilation is required in order to avoid self-heating problems[1187]. The role of ventilation in the self-heating process is a double one: (1) it provides a bulk flow cooling effect through the mass; this is normally ignored in simplified self-heating theory, but is non-

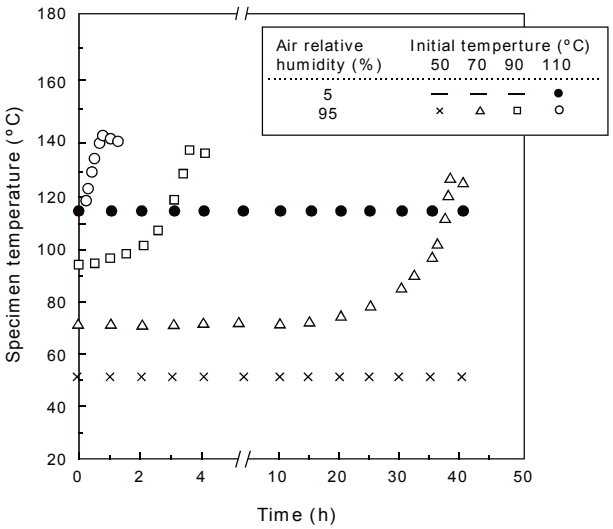

Figure 94 Effect of temperature and RH on self-heating of hay
(Copyright ASAE, reprinted by permission)

negligible at high enough ventilation rates; and (2) it suppresses the growth of thermophilic microorganisms.

Numerical calculations of the self-heating of hay have not produced adequately realistic results. This is due to the fact that the multiple exothermic processes which occur in an overlapping manner are difficult to accommodate in a theory simple enough to lead to solutions. Additional complications come from the need to model the flow of moisture and the need to represent accurately the thermal conductivity, which varies widely with moisture. In laboratory tests where small quantities of hay were initially exposed to a room-temperature environment, the time to thermal runaway was typically 15 – 40 days[1181,1182,1188]. Since this is similar to the range of spontaneous combustion times found for real haystacks, it is quite evident that time-to-runaway does not follow F-K theory (which would predict increasing times with increasing size).

As with any product susceptible to self-heating, the charring in a self-heating-caused fire is from the inside out, while if the haystack is ignited externally, charring is from the outside in. Firth and Stuckey also recommend that the investigator cut apart a suspect haystack (having a water hose ready to extinguish flaming, if flaming erupts during this process). Upon cutting through the center, if the haystack was self-heating to the point of charring, a gradation of damage should be seen, where going from the outside in, the color goes: greenish-brown → gold-brown → dark brown → chocolate → black hay still retaining structure → fine black powder. In addition, if a pattern of charred flues and pockets is found (Figure 93), this is indicative of charring due to self-heating. These flues will be surrounded by part-charred material; and should not be confused with crevices formed due to vigorous external burning. In the latter case, the crevices will only be charred to one side, and

not surrounded by charred material. Haystacks that have spontaneously combusted sometimes leave a glassy material as residue. These 'clinkers' are not a suspicious device, but rather are formed from the minerals contained in plants[1189].

Recommendations for optimum storage of hay are to keep it at 12 – 22% moisture content[1179,1190]; values over 25% may lead to spontaneous combustion (and to moldy conditions), while hay at very low moisture contents is nutritionally poor. It is reported that hay from clover or alfalfa is more prone to self-heating than from grasses[1191]. *Straw* is much less prone to self-heating, nonetheless recorded incidents do exist of spontaneous combustion of piles of straw bales[1192]. For sufficient self-heating to occur, fungal action is necessary, and the latter requires nitrogen-rich conditions.

When stored in *silos*, hay is optimally at 50 – 65% MC when put into a top-unloading silo and 45 – 55% for a bottom-unloading silo[1193]. Self-heating is most likely to occur for somewhat dry hay, at about 30%; this may occur due to air leaking in through cracks in walls or doors. Very dry hay at around 20% will not self-heat due to lack of conditions suitable to microbial heating. A fire is made more likely if the hay is improperly packed so that it is not tight against the silo walls—this condition makes it easier for air to reach the interior of the silage. Spontaneous combustion is less likely in silos constructed to be oxygen-limiting, compared to ones with more significant air leakage. Some practical aspects of fires in silos have been presented by Maloney[1194] and the US Fire Administration[1195].

Grasses of all kinds, even those not suitable for fodder, generally show similar behavior to hay. Rothbaum[1196] examined the self-heating propensity of Moroccan esparto grass. The crucial difference is that esparto grass takes up significantly less moisture for a given RH value, in comparison to hay. In the critical region of 95 – 97% RH, where chemical self-heating becomes important, the moisture content of esparto grass is 25 – 27%, compared to 66 – 71% for hay. In adiabatic calorimeter tests starting with an ambient temperature of 20ºC, self-heating of esparto grass was nil for specimens at less than 90% RH. Because of the smaller moisture take-up, esparto grass is considered to be less prone to self-heating than hay under otherwise similar circumstances.

A case incident is reported[1197] where a pile of spruce bark heaped up against a wood door self-heated and ignited the wood door even though the pile was only ca. 1 m in size. Eucalyptus leaves are quite prone to self-heating, much more than are chips of the eucalyptus wood itself. Jones and Raj[1198] reported results which produce the values E = 71 kJ mol^{-1} and P = 38.3 for leaves at a density of 140 kg m^{-3}. Jones et al.[1199] studied the self-heating of forest floor material. Their two data sets can, on the average be represented by E = 82 kJ mol^{-1}, P = 41; and E = 91 kJ mol^{-1}, P = 44. Jones[1200] also speculated that relatively minor concentrations of *inorganic materials* may play a role in the smolder-ignition propensity of vegetative materials, but did not present quantitative data. Earlier, Rudge[1201] claimed that spontaneous combustion in forest or vegetative matter is promoted by a chalk or limestone subsoil. In his view, moisture played a major role and the exothermicity of some calcium reactions could appreciably aid self-heating.

Fuel oil

Fuel oil consists of a wide variety of hydrocarbons; it does not show a unique boiling point, but rather a temperature range over which evaporation (fractional distillation) progressively occurs. Table 142 indicates some typical values[134]. The primary variable used to distinguish fuel oil grades is viscosity, with the higher-number grades being more viscous. Other properties tend to track with viscosity. In the US, characteristics of fuel oils are governed by ASTM D 396[1202]. The ignition temperature for small drops of heavy (residual) fuel oil follows the relation[1203]:

$$T_{ig} = \frac{76.6}{d} + 218$$

where T_{ig} = ignition temperature (ºC) and d = diameter (mm).

Table 142 Fractional distillation features of fuel oils

Fuel oil	Temperature (ºC) at which given % has evaporated		
	0%	50%	100%
No. 1	180	225	280
No. 2	190	265	330
No. 4	215	290	365

Furnaces and boilers

Boiler explosions[1204] are generally due to two causes: (1) a fuel gas/vapor explosion within the combustion space; or (2) a massive leak of steam into the combustion area from the rupture of a large tube or header. In the latter case, a physical explosion of the boiler takes place because steam enters the boiler so fast that the available openings are insufficient to stop the pressure rise.

Numerous fires occur when furnaces or boilers are placed improperly on the floor so that excessive temperatures can be developed on wood flooring materials. Schwalje[1205] documented a number of fires and near-misses due to this cause. In one near-miss case, he found a 25 mm layer of cement board under a boiler, underneath which was an OSB wood subfloor. A thermocouple reading at the interface between the cement board and the OSB subfloor indicated over 172ºC at the time of measurement, however, an identical installation in another building had resulted in fire. Further aspects of low-temperature, long-term ignition of wood materials are discussed under *Wood and related products*. Maintenance and troubleshooting of boiler low-water cut-off switches is described by Certuse[1206].

Arsonists have been known to rig furnaces to fail and thereby cause a fire. One method which has been described for a hot-air furnace involves disabling the mechanical operation of the fan, possibly by breaking the fan belt, then rigging the high-limit switch so that the wiring effectively bypasses the switch contacts[1207]. This form of incendiarism, of course, is not difficult to detect.

GAS-FIRED

Ostroot[1208] surveyed 116 explosions in industrial gas-fired furnaces and identified the causes (Table 143). Same as gas-fired water heaters, a gas-fired furnace or boiler needs adequate combustion air. If it is improperly installed so that combustion air is inadequate, flame 'rollout' can occur. This happens when air supply is too limited to allow proper inflow into the combustion chamber. A lazy flame can then leave the combustion chamber. Combustibles located nearby the furnace can get ignited in a 'rollout' event. Some recently-made furnaces have been equipped with thermal devices at the edge of the air opening which sense an abnormal temperature increase and cut off the fuel supply[1209]. Flame rollout can also occur due to flue blockage or blockage at the heat exchanger within the furnace.

Table 143 Causes for explosions of industrial gas-fired furnaces

Cause	Percent
gas leakage into furnace due to faulty shutoff valve	26
delayed ignition, miscellaneous reasons	28
inadequate air supply or unstable gas supply	16
inadequate purging, miscellaneous reasons	15
attempted lighting by hand or lance	9
repeated attempts to light pilot without intermediate purging	7

Nearby combustibles were ignited in a series of furnace failures involving a furnace improperly designed to reduce NOx emissions under California regulations[1210]. It was found that excessive temperatures were created within the combustion chamber which the metalwork could not withstand. Consequently, the heat exchanger would crack and rupture, and eventually flames would issue from exterior furnace openings due to action of the air blower, leading to ignition of external objects. Overfiring, and a possible fire, will occur if a furnace or boiler is converted from natural gas to propane service and a smaller-size orifice is not installed.

OIL-FIRED

Ostroot[1208] surveyed 98 explosions in industrial oil-fired furnaces and identified the causes (Table 144). Blum[1211] describes the following as being the main causes for fires originating from residential oil-fired furnaces:

- Clogged heat exchanger or flue pipe. A large number of faults can cause grossly poor combustion, leading to clogging.
- Puffback explosion. This happens if there is a substantial delay between introducing oil into the combustion chamber and igniting the mixture. The overpressure can crack lightweight furnace components or flue pipe parts, with the result that fire or hot gases can escape. Causes of delayed ignition include defective ignition transformer, worn or dirty electrodes, cracked electrode insulators, loose ignition wiring, low oil pressure, water in the oil, or a faulty nozzle.
- External oil leak which ignites.
- Firebox deterioration, leading to an opening being formed. This can be caused by flame impingement or by use of corrosive cleaning agents.

Table 144 Causes for explosions in industrial oil-fired furnaces

Cause	Percent
delayed ignition, miscellaneous reasons	51
defective ignition system	32
inadequate purge	12
improper fuel/air ratio	5

Sokalski[1212] reviewed fires originating at residential oil-fire furnaces and considers that common causes or contributing factors include:

- worn-out oil pump
- burner tip worn or clogged
- improperly adjusted burner
- failure of safety control circuits
- plugged flue, or defective or improperly installed barometric damper
- lack of an oil safety valve (OSV)
- clogged air filters
- miscellaneous electrical or mechanical failures.

One specific failure mode that can be a ready cause of fires is a failure of an elastomeric pump diaphragm in installations where (a) the fuel tanks are above the burner level and (b) an OSV is absent. In these cases, the static pressure of the oil in the tank will create an excessive supply of oil into the burner, which can lead to runaway combustion. An OSV is a form of check valve which can be placed in the fuel line from the tanks. The valve keeps the fuel line shut except when there is a negative pressure on its downstream side, created by the operation of the pump. When the pump stops, a negative pressure is no longer generated, and the check valve closes.

Another failure mode involves the cutoff valve. The pressure regulator typically contains a cutoff valve, the function of which is to close the flow of oil into the burner as soon as the pump is stopped. If this valve leaks, fuel will drip into the combustion chamber and an excess may build up, leading to an overfiring upon startup.

An unusual cause of over-firing an oil burner can be due to improper switching to a more viscous grade of fuel oil. If

the same regulator pressure is maintained, it is natural to presume that a lower flow would emerge from the nozzle when using a more viscous oil. However, the design of some nozzles is such that the flow rate is actually increased. This has been hypothesized to be related to the swirl-inducing characteristics, but details are not researched. The problem can also arise even without switching grades of oil if a much colder oil (which is more viscous) is introduced into a system set up to operate at a higher temperature. An additional effect of improperly introducing a more viscous grade of fuel oil is that it will have a higher heat of combustion. This means that, for a given air supply, longer flames will be generated.

NFPA 31 provides guidance on safe installation of oil-burning equipment[1213].

Furniture

Palmer et al.[1938] tested plastic furniture parts for ignitability with matches and found that for ABS, polypropylene, polystyrene, and polyurethane (rigid foam) specimens ignitions generally were possible only at an edge. Upholstered furniture is discussed under *Upholstered furniture and mattresses*.

Gas meters, regulators, and piping

A gas meter explosion has been described that occurred due to electrical causes[1214]. An electric power utility was repairing power lines after a storm and erroneously crossed over a hot line to feed the neutral. Above-ground-potential voltage now existed at the neutral of the service entrance of the building. The neutral-to-ground connection at the service entrance was defective, so electric current flowed through another connection that existed between the neutral and the gas piping. The gas meter was electrically insulated from the gas piping in the building by a thin washer (this is done in order that cathodic protection could be provided to the underground piping). The current arced across the dielectric, blew a hole in the gas piping and caused a gas/air explosion.

Fires caused by failures of gas lines due to ground faults have been documented[803]. The faults caused by excess flow of electric current resembled hacksaw marks in some cases, requiring careful efforts to avoid mis-identification. For flexible tubing, the failure is often near the connection (Color Plate 129), because the metal narrows down at that point. Another ground-fault ignition near gas meters is described under *Electric wires and cables: Stray current and ground faults*. A case has also been described[1215] where a building exploded due an accumulation of natural gas. The gas entered the building from a leaking gas pipe, and the leak in the gas pipe was caused by an electric fault which originated when a bird short-circuited a high-voltage power line.

Gas pipes can fail because of metal alloying. A case is reported where a small, round hole was found in a copper propane pipe[1216]. Investigation showed that aluminum had melted onto the pipe and created a low-melting-point alloy.

The forensic examination and testing of gas pressure regulators has been described by Cox[1217]. Regulators sometimes develop a small leak so that the valve does not mate in a gas-tight way against the seat. Under those conditions, if the regulator does not have a pressure relief vent, or if the vent becomes blocked (due to ice, paint, insects, flood waters, or other causes), the pressure on the outlet side can rise to the inlet pressure[1218]. Excessive pressure sent to the furnace or appliance control valves can then cause leakage or failure. In propane systems, failures have been observed where all the gas-using appliances were shut off, a leaky regulator led to excess pressures in the system, and this caused propane to re-liquefy in a cool portion of the piping[1219]. Upon turning on an appliance, the presence of liquid propane continues to sustain excessive pressures. Regulator failures can be hard to document, since often the cause of the valve not seating properly is a small piece of debris being caught there. When the gas supply is turned off in connection with the fire, the valve rises and the debris falls away.

Sanderson[1219] points out that house fires sometimes occur when a new owner first turns on a gas appliance, not realizing that the previous owner removed a gas appliance (e.g., dryer) and both failed to properly cap the outlet and had previously failed to install the mandatory separate shutoff for the dryer.

Gasoline

Gasoline is a blend of hydrocarbons of various types (primarily in the C_4 to C_{10} range), plus additives. On the order of 200 different chemical species may be found in gasoline. These different constituents have different vapor pressures. The technical specifications of gasoline in the US are governed by ASTM D 439[1220]. The vapor pressure of gasoline must stay within certain bounds, especially it must not be so high as to lead to vapor lock nor so low that it ceases to flow properly. Consequently, ASTM D 439 establishes five volatility classes, with Reid vapor pressure values ranging from 62 to 108 kPa. Vendors must then select the appropriate volatility class to sell, depending on the climate of the locale and the month of the year. However, the ASTM specification does not end up governing the gasoline that is sold, since stricter vapor pressure limits are generally set by the Environmental Protection Agency[1221]. When exposed to air, gasoline will 'weather,' which means that the constituents having higher vapor pressures will preferentially evaporate first. Thus, the fraction that remains will progressively show a lower vapor pressure and will comprise compounds of higher molar mass. Eaton[1222] has tabulated various other properties of gasoline. *White gasoline* (white gas) is an unleaded, uncracked gasoline which is sold as fuel in motorboats, stoves and lanterns. The additives contained in this fuel are primarily for anti-gumming.

The American Petroleum Institute[1223] considers that the flammable range for commercial gasoline is 1 – 7%; another source[1224] lists 1.4 – 7.6%. LFL values as low as 0.6% have been reported, but these are evidently erroneous. Frobese[1225] measured the flammability limits of gasoline vapors actually collected from the vapor space of a filling station tank and found a flammable range of 1.3 – 7.7%. The detonation limits[1226] are 1.1 – 3.3%. The minimum oxygen concentration[142] for a gasoline/air mixture is 11.6%, when dilution from 21% oxygen is by means of adding N_2, and is 14.4% when diluting with CO_2. The pressure limit[1227] of gasoline, at room temperature, is 4.0 kPa, that is, if a gasoline/air mixture has a total pressure below this value, flame propagation within the mixture is impossible, at least for ignition sources that are comparable in strength to what was used in testing. A complete gasoline/air/inert diagram for various diluents is shown in Figure 95.

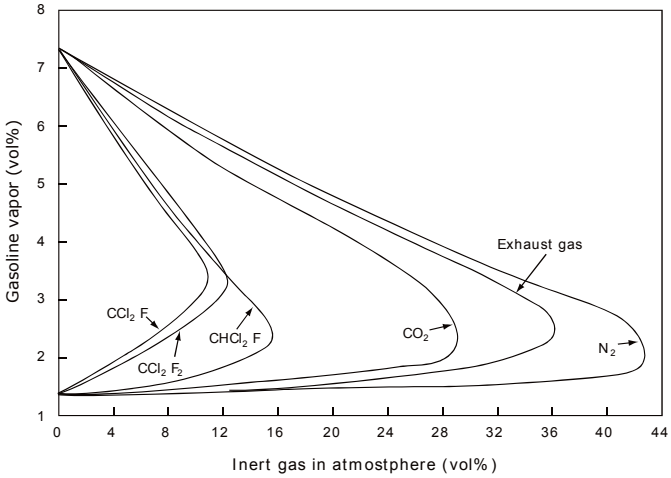

Figure 95 Inerting requirements for a gasoline/air mixture at 25ºC

The flash point of gasoline is typically around –45ºC. However, when stored for a long time in a closed container, an effective LTL of –65ºC has been found. This is because the flash point test apparatus does not represent the same heating and vaporizing conditions which occur under long-term storage conditions. The MIE of gasoline is 5 mJ at its flash point. In one study[1228], it was found that the MIE of gasoline sprays decreases for temperatures higher than the flash point, and reaches about 0.6 mJ at 10ºC.

The autoignition temperature of gasoline depends on the octane number. Ignition at a low temperature leads to 'knock' and consequently higher-grade gasolines are formulated to raise the AIT value. Using a 1 L flask test at NBS[1229], the AIT was found to be 248ºC for 65-octane gasoline, 258ºC for 73-octane, and 412ºC for 87 octane. The above values were determined at the concentration showing the lowest AIT, which was about 0.15 g L^{-1}. The temperatures take a jump upwards at higher octane numbers since the ignition mechanism changes. A red flame and a puff was seen at the lower octane values, but a blue flame (and much shorter ignition times) for the higher octane values. The dependence of ignition time on the temperature of the flask is shown in Figure 96. Modern-day, high-octane automotive gasoline typically has an AIT of 440 – 450ºC, although Hawksworth[1230] found values as low as 350ºC. The AIT of gasoline in oxygen at a pressure of 25 atm is less than 100ºC[1231].

Husa and Runes[1232] examined the possibility of igniting the vapors above large open pans of gasoline by an electrically heated pipe of 114 mm diameter and 1.2 m long. Temperatures in excess of 600ºC failed to ignite the vapors.

In fire incidents, gasoline vapors have been ignited by sparks from hammers, from boot nails on a concrete floor, and from metal tools dropped onto concrete[1233]. In laboratory tests, gasoline vapors have been marginally ignitable by sparks produced by grinding mild steel with an abrasive wheel, with much preheating of the steel being required; in many test conditions, negative results are reported[1234]. In actual fire incidents, grinding sparks have ignited ethylene, methanol, and oil vapor[1233]. These substances are of similar ignitability as gasoline, so grinding sparks should also be expected to ignite gasoline vapors in actual incidents. Steel tools cutting into quartz-bearing rocks readily ignite gasoline vapors, but this does not occur with other rocks[1235]. Bronze, brass, copper-beryllium, or aluminum tools are unlikely to ignite gasoline vapors.

The vapor pressure of gasoline is so high that, in most circumstances, the concentration in a vehicle's fuel tank and the appurtenant plumbing is above the UFL, and consequently, no ignition or explosion is possible. Frobese[1236] investigated experimentally the conditions under which this assumption might prove to be false. The problem was of special concern, since in 1993 European regulations were

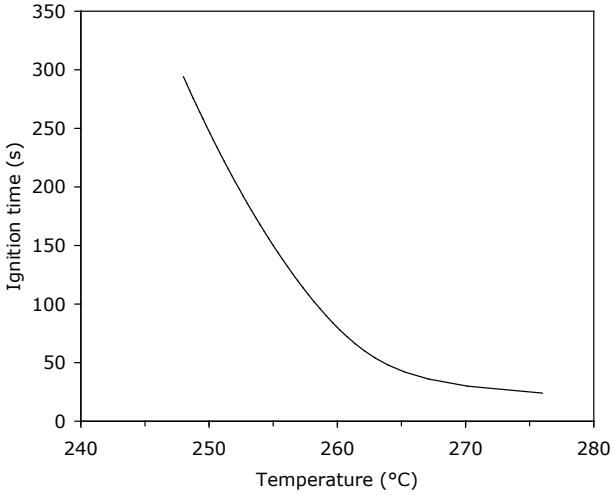

Figure 96 Ignition time of 65-octane gasoline, as determined by Setchkin in a 1 L heated-flask test

changed so the lower RVP limit of summer gasoline was dropped from 68 to 35 kPa, and of winter gasoline from 88 to 55 kPa. At a temperature of –20ºC, the 55 kPa RVP gasoline showed a fuel tank concentration of 6.0 vol%, which is within the flammable range; by contrast the 88 kPa RVP gasoline showed a concentration of 8.6 vol% at the same temperature. In the case of the 55 kPa RVP gasoline, for a flammable mixture to be attained (i.e., the UTL to be reached), required reducing the temperature to only –8ºC. In simulated vehicle-operation experiments, Frobese also found that the lower boiling-point fractions get preferentially decreased. This is primarily caused by temperature cycling of the vehicle, which produces a rise in pressure and a venting of the lighter fractions. Summer fuels, both new and old, showed negligible changes in RVP after the simulated vehicle-operation tests. But the old winter fuel decreased from 88 to 60 kPa, while the new one from 55 to 44 kPa. Frobese also conducted some ignition tests to determine the UFL for the fuels. A minimum-violence deflagration was found at concentrations as high as 8.4 vol%, although to achieve rapid and complete combustion required a concentration below about 6.7 vol%.

If the atmosphere within the gasoline tank is flammable, then it has been found that the spark energy from a breaking wire of an in-tank fuel pump is sufficient to cause ignition, but a break in the fuel tank gauge sender wiring is not[1237].

Gasoline is undoubtedly the most dangerous substance that is routinely handled by untrained individuals. Consequently, numerous accidents occur due to improper fueling, storage, or use. In many cases, individuals apparently forget that gasoline vapors are flammable and easily ignitable. Some details are discussed below and under *Water heaters: Gas-fired water heaters*. The issue of whether gasoline vapors can be ignited by cigarettes is discussed under *Cigarettes*.

GASOLINE SUBSTITUTES

In recent decades, concerns over air pollution and, to a lesser extent, over fuel availability have led to fuels being delivered at filling stations which are other than normal gasoline; these are sometimes referred to as *reformulated gasoline*. This is a generic term and it does not specify the chemical composition of the fuel. The Reid vapor pressure of reformulated gasoline is lower than for standard gasoline; one study reports values of only 46 – 48 kPa[1238]. The relative safety of vehicle gasoline tanks depends on the fact that, except at extreme winter temperatures, the atmosphere within the tank is non-flammable since the fuel concentration is above the UFL. A study by Vaivads et al.[1239] determined the UTL values for a variety of other fuels using a realistic tank geometry and a moderately large, 0.25 J ignition source. The results (Table 145) show that pure alcohols would be categorically hazardous. There is evidently no increased hazard with the reformulated gasolines under summer conditions, but reformulated winter fuels could be significantly more hazardous in cold climates. The small amount of tank fill was selected to represent worst-case conditions. For a half-full tank, the UTL values dropped by 2 – 10ºC. In related work, the authors[1240] provided flammability limits estimating rules for reformulated gasoline:

$$LFL = 0.58C_{st}$$

$$ULF = 2.8C_{st}$$

where C_{st} = stoichiometric concentration (g m^{-3}) and the units of LFL and UFL are g m^{-3}.

Table 145 Values of UTL determined in a fuel tank 1/30-filled with various fuels

Fuel type	Fuel is below UTL for temperatures under:
Winter fuels	
winter gasoline	–22
90 gasoline/10 ethanol	–26
85 gasoline/15 ethanol	–8
85 gasoline/15 methanol	–5
Summer fuels	
summer gasoline	–17
90 gasoline/10 ethanol	–14
85 gasoline/15 ethanol	0
85 gasoline/15 methanol	+1
Pure fuels	
ethanol	+38
methanol	+37

When ethanol is added to gasoline, the Reid vapor pressure rises until about 5 – 10 vol% is added, at which point a plateau is reached that is about 8% higher than for pure gasoline[1241]. Increasing the ethanol fraction further causes a monotonic decrease in RVP. For pure ethanol, RVP = 15.9 kPa. The peak occurs because it is easier for ethanol to evaporate from gasoline than from itself; this phenomenon is termed the 'hydrogen bonding dilution effect.'

FILLING OF PORTABLE GASOLINE CONTAINERS

Filling of portable gasoline containers ('jerry cans') at filling stations sometimes leads to an electrostatically-ignited fire. CPSC at one time waged an effort to reduce these incidents, which has resulted in signs being posted at the pumps that give warnings on this. Smoot[1242] studied the problem and concluded that the four main factors which increase the likelihood of a fire are:

- filling the container while it is sitting on a surface that is a good electrical insulator (the bed of a pickup truck having a polyethylene truck-bed liner, a carpet, etc.)
- use of a metal, rather than plastic, container
- failure of the user to make contact between the (grounded) nozzle and the container
- using a large fuel flow rate.

The atmosphere in the container will normally be above the UFL, but filling it with liquid causes vapors to be forced out; these can then accumulate on the truck bed. Ignition most commonly takes place when a spark passes between

the nozzle and the container. This will normally lead to only a small, non-violent fire, but victims sometimes panic and attempt to lift up the container, leading to a large spill and becoming injured in the process. Smoot concluded that the high-density polyethylene typically used to make truck bed liners is an unfortunate material choice, since it has an extremely high electrical resistivity and the layer of plastic reduced the effective container+truck capacitance from around 180 pF, which is measured on trucks without a liner, to around 70 pF. Metal containers are more hazardous since they are more likely to undergo a spark discharge between the nozzle and the container than are plastic ones. The charge accumulation from the streaming current associated with the gasoline flow depends only on the filling rate. Smoot measured streaming current values ca. 1.7×10^{-9} A for a filling rate of 19 L min^{-1} to ca. 6.8×10^{-9} A for 38 L min^{-1}. A lower capacitance leads to higher hazard, since a smaller charge suffices for a critical discharge voltage to be reached. Pratt[1243] presented a calculational example for the problem.

Experiments have been conducted to determine the minimum conditions needed for an incendive spark discharge between a metal gasoline can pouring spout and a container filled with gasoline[1244]. The necessary voltage V to ignite gasoline vapors was found to be:

$$V = 6.5\,C^{-0.3}$$

where V = volts (peak), and C = capacitance (F). Note that this equation does not represent a constant-energy relation. The equation given is a lower bound, and actual data points ranged up to a factor of 2 higher. Lowest values were obtained when slowly withdrawing the spout from a gasoline container in good contact with earth. If a typical capacitance of a person is taken as being 220×10^{-12} F, then 5100 V is needed to ignite gasoline and the ignition energy needed is 3 mJ. If discharge is not from a spout but from a needle point, the required voltage was found to be 65% of that given in the above equation. The lower-bound equation given above represents testing on a warm sunny day. For tests run at 9ºC, the needed voltage was about double that indicated.

A case history is reported of an individual who got burned due to the unexpected ignition when transferring gasoline outdoors from one plastic container (an approved, conductive-plastic type) to another in the absence of any overt ignition sources other than static created by the person's movements[1245]. The temperature was 25ºC and the humidity 65%.

Actual explosions of portable gasoline containers are rare, because this requires that the vapors inside be below the UFL. This can happen in extremely cold climates. It has been claimed that explosions can occur in temperate climates while emptying a container, due to entry of ambient air into the container. This is not supported by the published literature. There have been no case histories published where an event of this kind would have been documented. In addition, there have been no experiments that would support this suggestion; instead, experimental work has shown the opposite, that containers will not explode (J. D. DeHaan, Kirk's Fire Investigation, 6th ed., Pearson Education, 2006, pp. 70-71).

FUELING VEHICLES AT FILLING STATIONS

It has been reported that during the 1990s there was a large increase in static ignition accidents at gasoline filling stations in Europe[1246]. The frequency of incidents was related to times of low humidity. Studies and data reports indicated that a sizeable fraction of the cases have a common theme: at a self-service station the customer starts filling the tank and uses the 'latch-on' feature of the nozzle. She then sits down in the car seat and gets up when the filling is finished*. The sitting/rising action causes static charging which is discharged as she contacts the nozzle. PTB conducted laboratory studies[1247] on the problem and found that sparks could be created in several ways, most commonly for some car models at the location between the filler spout and conductive rubber membrane connected to the car body. Color Plate 130 shows a spark at this location that required only 3 kV. The study also showed that the charge that can be built up as a consequence of pumping the gasoline depends on the conductivity of the gasoline. But it was found that commercial gasolines show a huge range in conductivity of 8 to 760 pS m^{-1}. Since a car body represents a capacitance of around 1 nF, in the worst case 20 mJ energy could be stored, which is roughly 100× the minimum needed to ignite a gasoline/air mixture. The study identified the major factors leading to ignitions as being:

- Cars using plastic filler tubes without proper bonding straps between metal parts of the filler neck and the car body. Flow of only a few liters of fuel was sufficient to create a voltage over 4 kV in this type of design.
- Ground surfaces that are of excessively high electrical resistivity (often due to use of sealers).
- Use of new tire formulations that are vulcanized with SiO_2 and have very high resistivity.
- Inadequate grounding of the filling hose nozzle.
- Failure to use anti-static seats in cars, allowing high charge to be built up on people as they exit the car.

The first of these factors was found to be the most significant in actual field incidents. As an aftermath, some cars in Germany that had plastic filler tubes without necessary bonding straps were recalled. Claims have also been made that certain ignitions were due to personal electronics devices (e.g., pagers, cell phones), but these appear to be spurious and unsupported.

During 1999 similar problems started becoming of more concern in the US and the Petroleum Equipment Institute

* These incidents appear to be more common with women, because they are more likely to re-enter the vehicle during the course of the fueling.

issued an advisory report[1248]. It is currently estimated that there are about 150 – 200 such incidents per year in the US. Most of the incidents here too occurred in winter months because of the low humidity (absolute, not RH) prevalent in cold weather. A substantial number of the fires occurred while the person was in the process of removing the filler cap, prior to actual commencement of refueling. Also, a significant fraction reproduced the German scenario of the individual who re-enters and re-exits the vehicle during the refueling operation. A sizable fraction of US incidents involved certain Japanese car models from 1991 – 1996; the lack of significant representation of later-model cars suggests that manufacturers may have solved these design problems. The vintages involved of US-make cars were highly varied, with no clear trends. The study identified only a single incident involving a European-make vehicle (the car model in Germany that was subject to recall had not been exported to the US).

Since (with rare exceptions in very cold climates) the interior of the fuel tank is above the UFL and the outside atmosphere is below the LFL, somewhere between the tank interior and the outside world, concentrations must exist which are within the flammable range. Pidoll[1224] studied the effect of filler design and vapor recovery system details on this flammable zone. The vapor recovery mechanism of the gasoline pump can be set to recover a varying fraction of the fuel vapor. When set to recover at 150% (for reduced pollutant emission), he found that the flammable zone migrates down into the filler tube and this, under some circumstances, might increase the risk of explosion.

For environmental and other reasons, gasoline filling stations are nowadays likely to have plastic, rather than metal, piping installed for conveying the product. Hearn[1249] conducted full-scale tests on a nylon-lined polyethylene piping system intended to simulate an arrangement similar to what can be found underground at a filling station. A maximum potential of –8 kV was induced due to fuel flow in these experiments, which is significantly below the 20 – 25 kV needed for a brush discharge. Hearn concluded that, based on these results, there is not much danger of an electrostatic ignition in the piping system simply from the flow of liquid.

FILLING STATION TANKS

A localized flammable atmosphere may be created near vent pipes of underground storage tanks at a gasoline filling station due to pumping out of the liquid. German regulations had assumed that, so long as (a) the tank is covered by at least 0.8 m of earth, (b) the UTL of the gasoline is below –4ºC, (c) pumping is not continuous, and (d) the pumping rate is below 200 L min^{-1}, this condition cannot arise. However, Frobese[1225,1250] conducted tests using 10 and 20 m^3 tanks and discovered that these conditions do not prevent the possibility of a flammable atmosphere. Using a gasoline having a Reid vapor pressure of 75 – 85 kPa, he found that whether the upper portion of the vapor stayed above the UFL depended on both the pumping-out rate and the size of the vent pipe. Using a 40 mm diameter vent pipe, only at a 400 L min^{-1} rate did the top portion of the vapor space stay above the UFL; for rates of 200 L min^{-1} and lower, the tank stayed above the UFL only when it was nearly full. The vent pipe diameter is critical, because, for larger diameters, the velocity is slow enough so that the incoming air forms a layer on top of the gasoline vapors and does not adequately mix. At a low flow rate of 50 L min^{-1}, even using a very small 25 mm pipe did not suffice to maintain the tank above the UFL. Frobese concluded that no reasonable combination of pumping rate and vent pipe diameter can lead to an assurance that the tank's atmosphere will not be within the flammable range. However, he pointed out that the consequence of an underground tank explosion is likely to be minimal; in addition, ignition sources within the tank or at the vent pipe are uncommon. Yallop[180] has documented one fire that occurred when a vent pipe discharge was located too close to a source of ignition.

Ground fault circuit interrupters

GFCIs are intended to prevent electric shock (and, to a limited extent, certain types of fire ignitions) by removing power from circuits when a ground leakage current is detected. They also have the potential of being ignition sources themselves. Five cases have been documented[1251] where GFCIs located in public toilets suffered extensive corrosion due to water splashing from nearby plumbing fixtures. The corrosion was sufficient to create an overheating situation inside the GFCI but without activating the tripping function. Consequently, burning of plastic parts of the GFCIs occurred (Color Plate 131).

Gypsum wallboard

Janssens[1252] tested the ignitability of paper-faced gypsum wallboard in the LIFT test (Figure 97). His data give $\dot{q}''_{\min} =$ 26 kW m^{-2}, $\dot{q}''_{cr} =$ 9.3 kW m^{-2} and $B_{ig} =$ 311. As pointed out

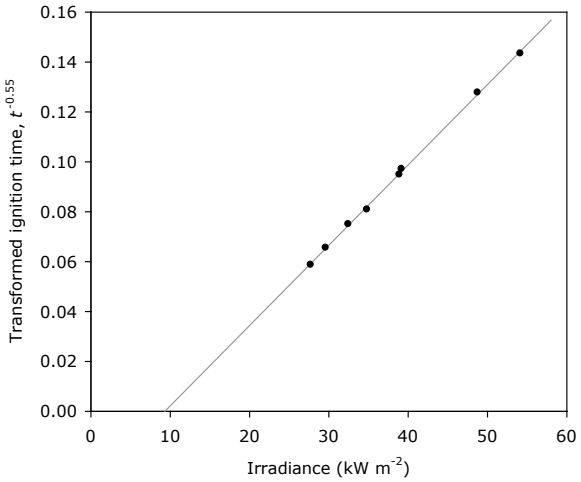

Figure 97 The radiant ignition of paper-faced gypsum wallboard, as measured in the LIFT apparatus

in Chapter 7, the product acts as a thermally-thick substance, despite the thinness of the combustible facing. The effect of the product density[1253] on the time to ignition was examined using Cone Calorimeter tests at an irradiance of 50 kW m^{-2}. Over the range $638 \leq \rho \leq 1173$ kg m^{-3}, the relation was:

$$t_{ig} = 0.1078\rho - 42.163$$

These results and others obtained on the ignition of gypsum wallboard must be taken not as precise, but only as broadly indicative. There is a significant variation in the thickness of the paper face among different manufacturers and even among different production plants of the same manufacturer.

Painting a gypsum wallboard surface generally has a negligible effect on ignitability unless blistering occurs. When many coats are present or when the wallboard is heated at a high heat flux, however, blistering may occur. In that case, the paint detaches locally from the substrate and acts as a thermally-thin material, giving much shorter ignition times. Mowrer[1254] obtained the Cone Calorimeter results shown in Table 146.

Table 146 Radiant ignitability of painted gypsum wallboard

Heat flux kW m^{-2}	Coats needed to blister	Ignition time (s)	
		Not blistered	Blistered
35	8	60 – 110	18 – 22
50	4	35 – 42	10 – 12
75	2	17 – 23	5 – 6

Hair

Peacock and Vaishnav[1106] developed a test method for examining the ignitability of substances by a small electric arc discharge. Surprisingly, they found that human hair ignited in 0.1 s, which was the same time as needed for black powder and smokeless powder. Most other consumer goods, including tissue paper, took about 0.5 to 1.0 s.

Hairdresser chemicals

A fire has been reported[1255] where rags soaked in thioglycolic acid (mercaptoacetic acid, $C_2H_4O_2S$) and sodium bromate ($NaBrO_3$) self-heated to ignition.

Heat guns

The peak temperature of the air coming out of a heat gun has been measured at about 580ºC at the nozzle[1256]. Clearly this can ignite numerous combustibles. Heat guns are commonly used to strip paint from wood, and an insidious form of ignition has been reported[1257] where smoldering was started inside a wall cavity while using the gun against exterior boards.

Heat tapes and heat cables

Heat tapes, heating tapes, heat cables are all terms for electric cables sold for do-it-yourself heating of pipes and surfaces. The term 'cable' is more commonly used when the device has an approximately round cross-section, while 'tape' often refers to devices having a shape of a flattened dumbbell, but the terms will be used interchangeably in this section (CPSC also considers these terms as interchangeable, although the manufacturers generally do not). The devices are commonly used to heat pipes subject to freezing (especially underneath mobile homes) and also to melt snow from the eaves of roofs in cold climates.

Heat tapes are generally rated at 16.4 – 23.0 W m^{-1} (5 – 7 W/foot) and normally plug into a 120 V outlet. The oldest variety, used in the 1930s, comprised a small-diameter heating wire, looped together and fitted with a plug; this variety is uncommon today. During the 1960s, a type became available which consists of two insulating filaments, separated by about 10 mm. Around each filament a fine gauge heating wire is wrapped helically, and the whole assembly is encapsulated in PVC. At one end, a length of unheated cord is supplied to be plugged into an outlet. The far end requires a termination to join the two runs of heating wire together. This termination must exclude moisture and some fires have occurred due to improper field termination. This type of heat tape is called a 'series resistance' design.

David C. Smith investigated thousands of heat tape failures[1258,1259] and reports that there are two different failure modes of series resistance heat tapes: (1) burnout, and (2) thermal decomposition. Burnout tends to occur due to aging of the PVC insulation or when a slightly excessive amount of thermal insulation has been applied. This raises temperatures higher than intended and the PVC (which is typically rated at only 75º, 90º or 105ºC) progressively loses its plasticizers, embrittles, and chars. Excessive temperatures then cause geometry changes of the heating wires and this causes further localized heating and charring. Smith reports that this failure mode occurs only when the heating wires are wound more finely than 1 turn per mm (24 turns per inch). Burnout causes failure of the heat tape and burns out a tiny section of heat tape, but normally does not cause fires. CPSC was able to create this type ignition in the laboratory by an accelerated aging program where a heat tape was operated at 150ºC for two weeks[1260]. This resulted in enough degradation to cause ignition.

Fires are much more likely to be caused by the thermal decomposition mode, even though, according to Smith, this failure mode accounts for only 5% of heat tape failures. This mode commonly occurs when a heat tape has been greatly overinsulated or has been doubled over itself, but such abuse is not a prerequisite. In this mode, significant arcing occurs, and the arcing can 'leapfrog' back to the power source. Flames of around 80 mm high are commonly seen and these can ignite nearby combustibles. The burning process is slow, and the heat tape is only consumed at about 150 mm per hour. Smith believes that ignition of fires has been facilitated by a change in the formulation of PVC

commonly used for the insulation around 1970, since heat tapes in the 1960s were not causing fires.

Once a failure has occurred at a certain point on the heat tape, it tends to propagate since the two polyester cords (around which the heating wire is wrapped) shrink when overheated[1261]. The shrinking is generally non-uniform, and this results in the heat tape twisting. Twisting promotes additional localized heating, and the fault thereby propagates towards the power supply. Twisting is reduced if the tape is equipped with a grounded copper braid.

Normal 15 or 20 A circuit breakers are not effective in preventing heat tape failure and possible ignitions, since a failed cable does not draw enough current to trip the breaker. What is effective, is using a GFCI in conjunction with an outer copper braid. Shorting of either conductor to the braid will then trip the GFCI. Many heat tapes are not supplied with thermostats, and tapes are often not turned off by the user in the summertime. The higher temperatures thus sustained serve to reduce the life of the heat tape.

A newer variety of heat tape is of a parallel-resistance design. In this type, two 12 AWG copper wires run down the length of the heat tape. Spirally wrapped around the bus wires is a thin Nichrome heating wire, which contacts the bus wires only every so often; for the rest of the length, the bus wires are insulated with a fluoropolymer insulation. The outer jacket is also made of a fluoropolymer. This type of product is generally marketed for industrial, not consumer, use.

The latest type of parallel-resistance heat cable was invented by Raychem, who developed a conductive polymer which has a negative temperature coefficient. In such cables, two long copper wires are used, and the polymer is used to bridge between the two wires. The heating is provided by the polymer, not by the two wires. Not only is no thermostat needed, but since the temperature is controlled locally, it is possible to double-up or loop the heat cable without causing an abnormal increase in temperature. These cables are called 'self-regulating.' The failure of such cables normally occurs due to ingress of moisture. This can occur due to improper end termination, burial in moist soil, or use in wet environments. The wet exposure causes arc tracking to progressively occur. Such arc tracking failure is termed 'wet fire' and resembles a series of firecrackers going off along the length of the cable. This occurs as the bus wires progressively short out along the length. Newer versions of this design have an improved jacket formulation intended to resist moisture ingress and improved end termination design. The latter is crucial, since if the end seal does not remain moisture-tight, failure can start there. A fuse built into the heat tape may not be effective against a wet fire, since it has been reported[1262] that "a full arcing fire could be sustained with currents as low as 40 mA."

Smith[1263] pointed out that, because of the thermal aging problem, most units have a field life of three years or less, but "none of the manufacturers state this fact on their instruction sheets." Apart from thermal aging, faulty installation, and physical damage, some mobile home heat tape fires are caused by animal damage. Smith also noted that some failures heat tape failures are due to creep, wherein the resistance wire migrates through the insulation due to prolonged mechanical stress. In cold climates, PVC insulation is apt to crack due to mechanical impact at installation or during its lifetime. In his 1974 paper, Smith also recommended that a grounding braid be used by manufacturers.

CPSC concluded that about 2/3 of the fires due to heat tapes could be attributed to improper installation[1264]. Improper installation was about twice as likely to be made with series-resistance tapes as with self-regulating designs. This is because doubling over the product, or over-insulating it, are not dangerous with the self-regulating type. Once failure occurs, it was found that in 42% of the cases, a wood material was the first item to ignite, and in 24% of the cases it was paper backing on fiberglass insulation. It was also found that about 60% of the heat tape fire incidents investigated with series-resistance tapes involved tapes less than 3 years old; by contrast, only 10% of the self-regulating tape incidents involved tapes less than 3 years old.

In 1988, prior to widespread adoption of UL standards by the industry, CPSC also found out[1265] that none of 12 commercial heat tapes they tested could meet the UL 94 V-0 test. In muffle furnace testing, it was determined that most heat tapes exhibited a thermoplastic behavior, softening at 107 – 113ºC and melting at 210 – 260ºC. One out of 11 specimens, however, did not melt but rather ignited at 400ºC; ignition temperatures for others were not determined. In tests with energized heat tapes improperly installed (adjacent turns abutted), it was found[1266] that temperatures in the range of 111 – 113ºC led to melting and charring, although tests were not run long enough to fail electrically. Since a worst-case mis-installation, such as might result from doubling of the recommended thermal insulation thickness, would result in heat tape temperatures of ca. 150ºC, CPSC engineers suggested that PVC material of 150ºC rating could significantly reduce ignition potential.

A test program on heat tapes was conducted by UL for CPSC[1267]. It found that an effectively grounded braid, in combination with a GFCI device, was the best protection. Other results were that longer runs of heat tape are more hazardous than short ones (because the probability of operating a fuse or circuit breaker is lower if the cable presents a higher resistance load), and that 'wet fire' failures are easily produced in the laboratory with older-generation self-regulating cables, but not with 1993 vintage specimens. It was also found that a 10 A fuse built into the heat tape was useful for self-regulating heat cables, but that a 30 A panel-

board fuse never opened. For series-resistance types, a 10 A fuse did not enhance protection.

Experience has shown that the grounding braid should be made of copper, and that aluminum braids are much less satisfactory. For this reason, aluminum braids, which earlier were used, are now generally obsolete. Even with a copper braid, however, there can be little assurance against ignition unless a GFCI is used.

According to CPSC, until 1991, some 90 – 95% of heat tapes sold were not tested nor Listed by any safety organization. Starting in 1991, virtually all products are labeled according to UL (UL 1462[1268] or UL 2049[1269]) or CSA (C 22.2 No. 130) requirements. Neither organization implements a scheme for ensuring that a minimum service life would be obtained, during which a cable would not self-ignite. However, even despite that omission there is reason to believe that newer heat tapes are generally less prone to ignitions than previous ones.

Long heating elements are also very common in the chemical manufacturing industries, however, in such applications they are generally termed 'heat tracing,' and can comprise steam tracing, not just electric resistance heating. Electric heat tracing products are tested and specified according to IEEE 515[1270].

Heat transfer liquids

Lee and Walton[1271] characterized a series of heat transfer liquids used for solar collectors, but which represent chemical families which may also find application in other heat-transfer applications. Their results are shown in Table 147.

Table 147 Flash points and fire points (ºC) for heat transfer liquids

Liquid	Flash point		Fire point
	Pensky-Martens	Cleveland open cup	
alkylated aromatic	57	63	71
diphenyl/diphenyl oxide	116	129	135
ethylene glycol	118	121	135
extracted naphthenic	138	163	177
hydrocarbon oil (light)	52	71	82
paraffinic base A	135	152	168
paraffinic base B	163	182	193
paraffinic base C	199	235	254
polyalkylene glycol	249	291	316
silicone oil	285	318	> 371

Heaters, catalytic

Catalytic heaters are ones which utilize flameless combustion on a platinum-coated porous panel. The panel incorporates an auxiliary electric heater, since catalytic combustion cannot start from room temperature. A pilot flame is used for initial ignition, but not for subsequent operation. The operating temperature of the panel is normally around 400 – 500ºC. The fuel gas can be butane or propane. Use of methane is, in principle, also feasible, but a much higher panel temperature would be required. The potential of catalytic heaters to cause unwanted ignitions was examined by Rogowski and Pitt[1272]. In their tests, the heaters were run at their maximum output setting, giving a 525ºC panel temperature. Diethyl ether, hexane, and petroleum ether (VM&P naphtha) readily ignited when squirted upon the panel, but 100-octane gasoline did not. Jets of hydrogen readily ignited when directed against the panel, ethylene only under limited conditions, and propane only on 1 of 3 test heaters. Hydrogen jets also ignited on the platinum surface when the panel was not heated at all and was simply at room temperature. The ignitability of thin solids was more variable. One heater ignited cotton fabric, newsprint, and paper tissue. But a second type of heater only caused glowing, not flaming, ignitions, while a third type showed no glowing or flaming ignitions, except for the cotton cloth. Cellulose acetate and nylon test fabrics melted and charred, but did not ignite.

Heaters, electric

BUILT-IN HEATERS

According to Fitz[1273], the main safety features that should be incorporated into a built-in heater in order to minimize the chance of fire are:

- Normal discharge temperature to be less than 120ºC.
- Under transient conditions (e.g., when the high-limit switch is being activated), discharge temperatures should not exceed 175ºC for 30 s.
- A high-limit switch that detects discharge (not intake) air temperature across the entire discharge area (e.g., a capillary tube device) and that is manually, not automatically, reset.
- Any portions of a high limit switch exposed to discharge air should robustly resist high temperatures and not be damaged by over-temperature conditions.
- Means must be provided to prevent lint buildup.

Ignitions of combustibles from heaters built into walls come from four main failure modes: (1) a failure of both the thermostat and the high-limit switch; (2) designs where the high-limit switch is ineffective against certain modes of overheating (e.g., failure of fan motor, a partial blockage of airflow); (3) excessive accumulations of dust within the unit; and (4) ignition due to combustibles placed too close to the heater or actually introduced into the heater. UL standard UL 2021[1274] (previously UL 1025[1275]) is normally relied upon by manufacturers. These standards examine a variety of overheating modes, but not all possible modes are examined. Specifically, the test sequences do not examine the effects of partial blockage due to dust buildup (although some UL testing apparently involves this mode), failure of wiring due to vibration or temperature, nor the effects of failure of fan motor (apart from open circuit conditions). The standards also permit self-resetting high-limit switches that only give a pilot-light warning. Thus, a user may con-

clude that a heater which, due to some fault, is 'running on the high-limit' is simply lighting the pilot light to indicate 'heat on' rather than 'malfunction.'

Most built-in heaters do not contain a built-in on-off switch since this is not required by UL or NEC. The only control mechanism readily accessible to the householder is usually the wall thermostat, but, with some models, the latter may only be decreased to a low temperature, not turned off. Thus, unexpected activation of heater can take place, and this can create a hazard if combustibles have been piled at the heater, on the assumption that the heater will not operate. Such a thermostat function is useful if it is necessary to prevent water pipes from freezing. However, not all thermostats having a 'Low' setting actually keep temperature above freezing; in some models the temperature setpoint at that marking is much lower, e.g., one model has been measured to be at about – 23ºC. In some cases, units have a 'High/Low' switch, and fires have been reported[1276] where the occupant believed the unit to be turned off, not realizing that the switch position provides 'Low' heat, not 'Off.'

Built-in heaters typically have heating elements of one of three styles:

(1) zigzag Nichrome wire wound on several closely-spaced insulator boards;
(2) long helices of Nichrome wire; or
(3) tubular heating elements that contain a heating wire, a grounded outer shell made of stainless steel or similar material, and magnesium oxide packing as the insulator in between the two.

The type with zigzag elements may involve an air path having close spacings between adjacent elements; in such a case, there can be a potential for clogging with dust. The tubular heating element type is generally robust, but it can have a failure mode similar to the failure of a heating element in an electric oven: a short between the center conductor and the outer shell leads to an 'arc cutting' mode, whereby the outer shell is progressively ripped open by electric arc action and metal pieces are simultaneously ejected.

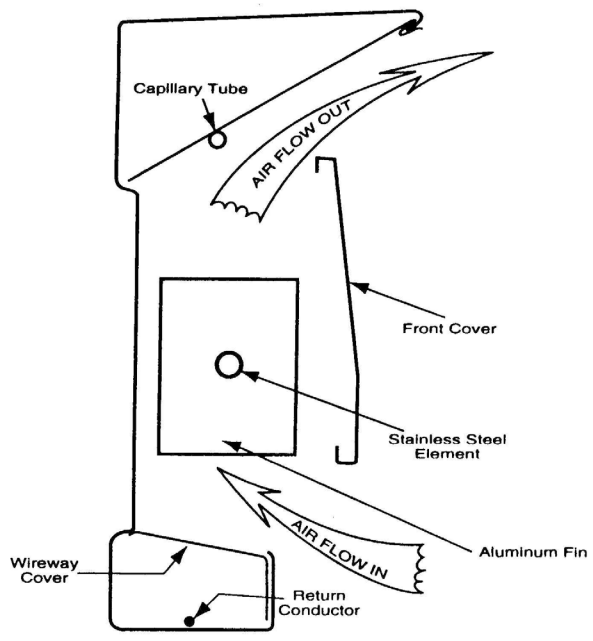

Figure 98 Baseboard heater cross-section
(Courtesy CAFI and Daniel B. Langlois)

Details of some failure modes were elucidated in the course of CPSC's investigation of a large US manufacturer of in-wall heaters[1277]. CPSC identified 134 instances where heaters smoked, sparked, caught fire, emitted flame or ejected burning particles. The remedial actions to be taken by the manufacturer included upgraded specifications of the high-limit switch; adoption of high-limit switches that provide an audible alarm or require manual resetting, rather than being self-resetting without audible alarm (note that CPSC does not consider visual alarms sufficient); improvement of blower wheels and wire crimping procedures; affixing of labels advising users of hazards of impeded airflow (due to lint or debris), of objects placed too close to heater, and of installation in insulated walls; and setting up of a quality assurance program.

Baseboard heaters are less prone to ignite combustibles because they are generally designed as convective rather than radiative devices, with lower heating element temperatures. A typical design uses cylindrical heating elements with convection-enhancing fins. In such a design, apart from the generally-lower temperatures, the fins tend to keep combustibles away from the hottest portion, which is the tubular element itself. Nonetheless, designs have been recalled from the marketplace where the thermostats themselves overheated and caused fires[1278]. A study on baseboard heaters[1279] concluded that both a failed high-limit switch and combustibles blocking air flow passages would normally be needed in order for an ignition potential to arise. A common type of baseboard heaters uses a heat element which is a resistance wire surrounded by magnesium oxide insulation, covered by an outer stainless steel sheath. These occasionally fail in a dramatic 'arc cutting' mode, as discussed above[1280]. Fires have occurred when individuals bypassed the high limit switch and subsequently created a blockage with combustibles[1281]. Fires have also occurred because a heater was installed upside down. Figure 98 shows that a typical heater has a thermostat sensing element (capillary tube) located near the top of the unit, so that it is properly positioned in the warm air outflow. If a heater is installed upside down, then the capillary tube senses the cold air coming into the bottom, instead. Laboratory testing showed that cheesecloth and bed sheets draped over its face are readily ignited by a properly functioning heater when it has been improperly installed upside down[1282].

Goodson et al.[1283] examined the fire-causing potential when electric wire (typically, Nichrome) heating elements fail. Because heating creates an elevated temperature of the met-

al, the rate of oxidation increases and eventually even a properly-installed element can fail. Failure can manifest itself either as sagging or as breaking open. In either case, contact by the sagged or broken location can be made to a grounded surface. For heating elements that are supplied from 240 VAC power, in the North American wiring scheme* neither leg is grounded. Thus, it suffices for either of the broken legs to contact a grounded surface for current flow through the element to resume. This current flow may be higher than intended, which can directly cause overheating, or result in a second failure of the element. Arcing associated with a failure can spatter hot metal, leading to ignition of combustibles that may be within the area. Goodson et al. further considered that a large fraction of failures is due to improper installation of replacement elements. Usually, the instructions do not make clear that coils of wire must be uniformly spaced throughout. Local bunching will lead to overheating and an earlier failure can be expected. In addition, if a failure occurs where the element breaks open, with one broken end then shorting to ground, any thermal protection device will be nullified if it is located in the leg that is open, rather than shorted. Consequently, a design is needed (and must not be circumvented by repair work) whereby each leg is protected by an over-temperature device.

PORTABLE HEATERS

Portable heaters come in two basic varieties, radiant and convection. Heaters with a visible glowing element are classed as radiant, the others as convection. In 1986 CPSC conducted an in-depth field investigation of fires originating at portable heaters[1284]. For radiant heaters, ignition of too-close combustibles was the predominant hazard pattern. But unless the heater sustains a failure, the peak temperatures at convection heaters will be below the ignition temperature of household solid combustibles. Thus, these fires (which were only about 1/5 as numerous as from radiant heaters) primarily involved malfunctions of heaters, typically of wiring or controls. Only one case was listed of a fire due to combustibles being too close and details were not supplied.

Radiant electric heaters commonly produce a heat flux around 10 kW m^{-2} at the face of the grille and the value drops rapidly with distance. Unless overt electrical failure occurs, it can be assumed that there is no source of pilot ignition. The question of interest then becomes what materials might autoignite at a heat flux of 10 kW m^{-2} or lower. Fabric and paper goods generally require substantially higher heat fluxes for autoignition. But cardboard can be ignited at fluxes below 10 kW m^{-2} (see *Paper products*). Of course, pushing any combustibles up to the face of a radiant heater is a misuse of the heater and, in that same vein, more abusive misuses are possible: stuffing material inside the grille or blocking the entire face of the heater. In the latter case, however, a properly designed thermal cutout should operate.

HOUSE FURNACES

Some fires have been caused due to ignition of the manufacturer's operating instructions, which were located inside the furnace.

Numerous fires have been reported due to the failure of electric heating elements dropping hot particles into combustible ducting located below the element.

Electric duct heaters can be ignition sources in the event the high limit switch and the airflow switch fail.

Heating equipment (general statistics)

NFPA statistics[1285] of home heating equipment fires are given in Table 148 and Table 149. FEMA statistics on the material first ignited[1286] in portable heater fires are given in Table 150. NFPA estimated the risk of fire (that is, the likelihood of having a fire, if a certain equipment is installed) for the various heating equipment types, as shown in Table 151. The NFPA report also contains details on the cause of fire and on the material first ignited; these are presented separately for each equipment category but not pooled. Kerosene heaters have a reputation for being high-risk devices, but the NFPA statistics indicate that wood stoves and fireplaces are vastly more risky. See also specific equipment: *Chimneys and flues*; *Furnaces and boilers*; *Heaters, catalytic*; *Heaters, electric*; *Wood-burning appliances*.

High-temperature accelerants

Accelerants for incendiary fires are commonly hydrocarbon liquids—gasoline, kerosene, paint thinners, solvents, and similar liquids. But occasionally incendiary fires[1287] have been observed where the ignition source shows unique characteristics:

- very high heat fluxes of 250 – 300 kW m^{-2}, and possibly up to 700 kW m^{-2};
- a huge heat release rate of about 10 MW m^{-2};
- enormous charring rates of wood, up to 10 mm per minute;
- very rapid or extensive destruction of concrete;
- melting or burning of iron and steel.

These traits are inconsistent with those of liquid accelerants. But a research program[1288] showed that a formulation similar to what could be used as rocket propellant (ammonium perchlorate, powdered aluminum, eutectic salts, and diesel fuel) produced in experiments similar outcomes to those seen in incendiary fires started with high-temperature accelerant (HTA) materials. Color Plate 132 shows scenes from a full-scale test burn where an empty retail store building was ignited at locations next to three columns.

A simpler form of HTA is thermite, and this has occasionally been used as an incendiary material. Color Plate 133

* In other parts of the world, 240 VAC power supplies are configured in an end-grounded, not center-grounded, topology.

Table 148 Home heating equipment fires for 1998, categorized according to function of equipment

Equipment	Percent
fixed space heater	23.5
central heating unit	17.0
chimney	16.8
water heater	15.4
indoor fireplace	12.6
portable space heater	6.9
chimney connector	4.8
heat transfer system	0.8
unclassified	2.1

Table 149 Home heating fires for 1998, categorized according to type of energy used

Type of energy	Percent
solid fuel	46.2
gas fuel	23.3
electricity	21.3
liquid fuel	9.2

Table 150 Material first ignited in portable heater fires

Material	Percent
fabric	35
wood or paper	22
combustible liquids	13
plastics	8

Table 151 Comparative risk of various domestic heating equipment, expressed as fires per 10,000 households

Type of equipment		Risk
central heating unit	gas fuel	1.06
	liquid fuel	3.68
	electricity	4.35
fireplace	solid fuel	15.38
fixed space heater	gas fuel	7.52
	solid fuel	33.45
	electricity	5.42
portable space heater	liquid fuel	3.00
	electricity	1.72
water heater	gas fuel	1.99
	electricity	0.49

shows the results of testing to recreate an incendiary fire where thermite was used to burn a kitchen range.

Hops

Baled hops are known for their self-heating potential. The severity of the problem depends on the variety, and 'super-high alpha' types are particularly susceptible. In addition to self-heating, it appears that sufficient vapors may be produced so that gas-phase explosions are possible; this was experienced in at least one fire[1289]. Hops are processed by being kiln-dried after harvesting, then packed into bales of about 0.6 × 0.6 × 1.2 m long, weighing about 90 – 100 kg. The self-heating potential is so high that hops must be stored in a refrigerated warehouse, with the normal storage temperature being –2ºC. Moisture is critical to self-heating of hops and hops at 8 – 10% MC show the least propensity for self-heating; bales that are much drier or much wetter than this are less stable[1290]. Some large-scale testing suggested that, if all other factors are optimum, bales can be warehoused at a temperature of 35ºC, while bales with improper moisture content, but otherwise properly processed, may be acceptably stored at 24ºC. But fires have been experienced even at the standard storage temperature of –2ºC, implying improper processing or plant material variations. The kiln drying conditions were also found to be important, especially the temperature of the material that is being baled, which should generally be below 40ºC. Additional data were reported by Jones and Raj[1291], but they did not have the opportunity to examine the varieties especially-prone to self-heating. A bale which was found to be self-heating and was set aside without being sent to the warehouse is shown in Color Plate 134. Smoldering bales pulled from a warehouse[1292] are shown in Color Plate 135. The stack height in this fire was 3.0 m high, although similar facilities stack the product up to 6.1 m high.

Humans

Few topics in fire investigation have inspired as much controversy or emotion as the issue of 'spontaneous human combustion' (SHC), there being fundamental doubt about the existence of such a phenomenon. The normal fire fatality who caught clothing on fire arrives at the hospital or morgue with skin destroyed, but very recognizably human. However, throughout history a number of fatalities have been recorded where the circumstances typically include near-total incineration of everything except the extremities. Near-total incineration might be expected from victims who were, for example, trapped in warehouse fire which burned for a day or so. However, deaths claimed to be caused by spontaneous human combustion involve very little burning in the vicinity of the victim. Such reported cases tend to share a number of characteristics (although not every incident possesses all of them)[1293-1295]:

- The victim is unrecognizable, with all of the body except the legs (sometimes also arms and head) being reduced to ash.
- The room where the incident occurred has suffered minimal fire damage; in some cases furniture, bedding, etc., within a very close proximity to the victim is unburned. Flashover (full room involvement) has not occurred.
- An oily residue is often found to cover the room surfaces, and the smell, if any, is described as "sweet," while it is claimed that in a normal-fire case the smell would be foul. The latter claim, however, is unsupported.
- No reasonable ignition source can be identified.
- The time scale varies, but in the more perplexing cases can be minutes rather than hours.

In addition, older writers commonly claimed that the victim is disproportionately likely to be female, elderly, or corpulent. However, Arnold[1294] compiled a large database which shows that there is no preference towards females in the cases of claimed SHC.

In essence, it is claimed that there are two puzzles concerning such victims:

(1) No source of ignition can be identified.
(2) The human body is a 'low-grade' fuel. Low-grade fuels (ones that are wet or have a low heat of combustion) burn only in environments where significant external heat can be supplied. Clothing items have little mass and can only burn for a short time. Even if a victim catches clothing on fire and can take no action (drunk, etc.), it has been difficult to envision starting and sustaining combustion of a human body with such a short-lasting source of heat.

There is also the subsidiary problem in that victims of 'normal' fires tend to have their extremities burned more, not less, than the other body parts. In 'normal' fires, this is due to heat transfer, in that the central portions of the body represent the maximum heat sink, with thinner portions being more readily raised in temperature, for a given incident heat flux.

When a solitary victim has been found fully cremated, it may be difficult to conclusively rule out external ignition sources. In a number of cases, however, the victim was known as a non-smoker, and evidence suggests the victim was not using candles or other forms of heat or flame, and was not close enough to any electrical equipment that might have been malfunctioning. The apparent lack of an ignition source, however, can simply be an indication of poor fire investigation or scene preservation. In some cases, no nearby ignition source exists because the victim moved some distance after catching fire before succumbing. Perhaps most perplexing have been the cases that do *not* lead to death, with the victim surviving his or her burns. But none of these reported cases appear to be comprehensively documented by credible individuals.

If one believes that the victims were not ignited from normal ignition sources, then it is necessary to posit one or more abnormal sources. This has been a point of considerable difficulty to the believers of SHC. It has been asserted that the cause may be related to ball lightning[1293,1294], but there are very few adequately-documented cases of any injuries from this source, much less cremation. Another phenomenon which is considered as a possibility is kundalini energy[1294]. This enters the realm of the metaphysical—an internal 'fire energy' is not the study matter of physics or chemistry. Arnold[1294] presents an extensive catalogue of other potential chemical, electrical, geological, atomic-particle, etc. causes. These do not find acceptance among orthodox scientists as potential ignition sources and all of them lack any documentation of causality.

Fire specialists have generally taken the view that SHC cannot occur. The debunkers of the 19th century often used to insist that the victims were all drunk and that this was sufficient to sustain combustion of a body which would normally not burn. This hypothesis was refuted in mid-19th century when experiments by the German chemist Justus von Liebeg showed that soaking flesh in alcohol is not sufficient to make it undergo sustained burning[1293]; other researchers also came up with the same conclusion[1294]. In the 20th century, UK Home Office forensic scientist J. B. Firth proposed the hypothesis that a 'wick effect' is responsible, and this was not too different from the conclusion reached by the French surgeon Guillaume Dupuytren in 1830. This was subsequently pursued by D. J. Gee[1296], who conducted small-scale experiments demonstrating that while human fat requires a temperature ≈ 250ºC to melt when heated directly, human fat made into a sausage with cloth casing acting as a wick can burn up completely in ambient air. Prof. D. D. Drysdale later illustrated this with a sausage-shaped piece of animal fat[1293]. These small demonstrations did not prove quantitatively an analogy to human bodies, however, since only roughly ¼ of the body mass is fat, the remainder being muscle, organs, blood, bone, etc. British researcher Stan Ames[1293] increased the realism of such studies by conducting an experiment burning in a fireplace an entire 70-kg pig chopped into pieces. Burning the chunks over a fire of British-type 'smokeless fuel' (coal with volatiles boiled out) during a 13 h period he succeeded in reducing the pig to ashes with just a few small bone and teeth fragments. His study was directed toward a particular criminal case where a victim was chopped up and burned. But success in obtaining complete combustion under those circumstances was not necessarily directly pertinent to SHC.

Ettling[1297] endeavored to recreate an automobile fire by use of large sheep. His first test was brief, but in the second test he used a 77-kg sheep, soaked in gasoline and placed on a car seat. At the end of the test, the remains of the sheep were only about 23 kg, and only the skull and the abdominal and pelvic regions were not fully burned. The burning process was one of fat rendering, with the body being supported on metal seat springs and dripping melted fat onto embers on the floor, where the fat would ignite and provide heat to render more fat out of the body. In his research, Ettling also discovered that Nazi extermination camps knew about this technique and suspended bodies on racks, with a fire underneath serving to render the fat.

DeHaan[1298] investigated a case where a sheriff's deputy discovered a woman burning in the woods, lying face-down on a layer of leaves. The deputy was able to photograph small flames about 0.35 m high licking above the body (Color Plate 136). Leaves directly next to the victim were charred, but there was no other fire damage. The body, however, had large portions of its middle section reduced to powder. Examination of the victim revealed stab wounds at the shoulder. The victim was burning for less than five

hours when discovered. The investigation developed that she was first murdered then set on fire. To reproduce such events in the laboratory, DeHaan conducted several experimental studies.

In the first study[1299], he conducted preliminary bench-scale testing with the Cone Calorimeter. For such samples, he established that at a 35 kW m^{-2} irradiance, bare pig* flesh can be ignited and feebly burned, but self-extinguished upon removal of the radiant source. When the experiment was repeated with the pig flesh covered with a cotton cloth, steady combustion was produced which continued to render fat and to burn the flesh. Next, he conducted a series of larger scale experiments, where he burned chunks of pork fat wrapped in fabric and measured the mass loss and the HRR. Finally, he placed small whole pig carcasses on a thermoplastic-fiber carpet, dressed in polyester/cotton garments, and ignited with 1 L of gasoline. These larger scale tests revealed that fat renders out relatively easily upon modest heating, but that it forms a pool of liquid with a high flash point which does not ignite and burn of its own. Sustained ignition becomes possible in the presence of a wick formed by the porous char of the fabric. The pig carcasses burned for around 1 to 2 hours, but did not fully burn up. DeHaan determined this to be because the mass (all less than 53 kg) was smaller than that for a typical human victim. Thus, in a follow-on study[1300] he used a pig carcass of 95 kg. This carcass burned at 55 – 65 kW for most of the 6.5 h test period. Flames of only 70 – 250 mm height were seen on and around the burning carcass. When the fire was extinguished, more than half of the carcass had been consumed; in the burned portion, bones burned also, since they become friable and fell apart upon applying slight pressure. The time scale seems consistent with Gee's credibly documented case[1296], where a woman's limbs burned up fully in 3 hours. DeHaan also noted that soot and unburned pyrolysates were produced in large amounts during the burning process which would be available for coating room surfaces. DeHaan also conducted additional Cone Calorimeter tests comparing pork fat and human fat. The two materials showed similar combustion and relatively similar HRR values. Finally, to rebut claims that self-sustained, wick-fed combustion could not take place without ignition from a flammable liquid, DeHaan conducted a small-scale demonstration[1301] where a cotton-wrapped piece of pork fat was ignited directly at the cloth without use of liquids. The outcome was also a self-sustained combustion.

Bohnert et al.[1302] observed the commercial cremation process for a number of bodies and reviewed similar earlier literature. Typically, after about 50 minutes, the major features of the body had been consumed and only larger bones remained. Christensen[1303] also reported on some studies related to combustion of humans. She first consulted with crematoria operators and learned that times needed to incinerate the human body vary widely, with elderly often being cremated in less than 1 h, while youthful individuals take up to 3.5 h. Her initial experiment involved burning of amputated human flesh. This gave a heat of combustion of 17 MJ kg^{-1} obtained by crudely estimating the HRR from flame heights. She then conducted cremation experiments on normal and osteoporotic tibia bones. She noted that most of the active burning took place between 625 and 790ºC and that the osteoporotic bones, which were originally about half the mass of normal bones, lost a somewhat higher fraction of their mass during the cremation. Thus, there would be a significantly smaller mass of bone left after a given thermal exposure from osteoporotic bones, as compared to normal bones. Her conclusion was that the propensity of elderly, corpulent females to become more fully burned in fires is physically explainable—they have a higher fat content and a lower bone mass due to osteoporosis.

Leitch[1304] did not conduct experiments, but he studied numerous fire fatalities and documented that the near-total burning up of the body is not unphysical. In the cases he studied, he concluded that physical causes of ignition were invariably present.

The conclusion to be drawn from these scientists' studies is that, starting with a normal ignition, human bodies can indeed be burned to a condition which resembles that of the victims identified as purported SHC victims. A means for sustained wicking is necessary for extensive combustion to take place. The wicking can be supplied by cotton clothes, charred leaves, or other appropriate adjacent objects. Combustion must be supported by such means until the flesh can shrink, split, and start the rendering process. Thus, quick-lived ignition sources such as flammable-liquid spills are neither necessary nor sufficient. The low *average* heat of combustion of the human body is not relevant, since combustion is initiated and sustained by the burning of bodily fats, which have an adequate heat of combustion. Concerning the availability of ignition sources, scientific studies can neither explain nor preclude metaphysical or supernatural causes, if these indeed sometimes play a role. However, recourse to such explanations would be needed only if there were cases which were thoroughly investigated by fire investigation *professionals*, who then concluded that there was no external ignition source. Such cases do not appear to exist.

HUMAN SKIN

Durfee[1305] conducted tests on human flesh, attempting to ignite it in a pure-oxygen atmosphere with an electric arc discharge from an electrode to the skin. Burn-off of hair could be achieved, but bulk ignition of skin did not take place. He points out that similar experiments conducted in the UK where ignition was reported to be possible were

* Pigs are often the preferred experimental animal for burn-injury studies because their skin is considered a reasonably close equivalent to human skin in regards to thermal injury. They also have a close resemblance to humans with regards to body size and fat distribution. Note however the results of Durfee which suggest that pig skin is easier to burn than human skin.

flawed due to direct exposure of fat to the ignition source. He also concluded that skin of suckling pigs, often used as a human-skin simulant in studies of burn injury, did not behave similarly to human skin with regards to ignitability: pig skin could be ignited in circumstances where human skin could not. An incident is reported[1306] where it is stated that a man's skin ignited during a fire in hypobaric oxygen chamber running at 0.34 atm pressure, but it is not clear how accurate the reported details may be.

HVAC equipment

All furnaces and other heat-producing equipment can be potential sources of ignition in certain cases, as can all manner of electrical motors, etc. used in non-heating air moving. There are cases however, of burning brand ignitions from such devices. Yereance[223] has reported on three types: (1) Evaporative coolers ('swamp coolers') are devices sometimes used in the desert areas of the US which provide cooling simply by adding moisture to air and then circulating it through a building. These are typically located on rooftops and have ducting discharging to various rooms. Water is applied onto pads and a blower then carries this wet air throughout the building. The pads are typically made of combustible material, which is not a problem unless the water supply pump fails to apply water. Cases are found where such pumps fail and start burning. This ignites the then-dry pads which burn and release firebrands into the air-moving system. The result is a number of spot fires that start simultaneously in different rooms. (2) While uncommon, there are residential furnaces so arranged that there is foam insulation inside the blower area. If this material is ignited and starts burning, a ready mechanism exists whereby firebrands are spread throughout the house and start spot fires in various rooms. (3) Occasional rooftop air conditioning units also have combustible thermal insulation inside the air path and have been documented to spread burning brands throughout a house.

Hydraulic fluids

Traditionally, the most common hydraulic fluid in aircraft applications was MIL-H-5606, which is a naphthenic, mineral oil that is usable over a wide range of operating temperatures, but which is also very easily ignitable. During the 1980s, this was largely replaced by MIL-H-83282, which is a synthetic hydrocarbon-based (hydrogenated poly-α-olefin oligomer) fluid with improved fire properties and usable as a direct replacement for MIL-H-5606. For new applications, designs have commonly used phosphate ester fluids, which are significantly less flammable. Snyder et al.[1307] compiled data on a number of aircraft hydraulic fuels (Table 152). The flash point values are from the Cleveland Open Cup test, the AIT values from ASTM D 2155, the hot surface ignition values from Federal Test Method Standard 791 (Method 6053), while the gunfire ignition test is from MIL-H-83282 specifications, which entails firing 50-caliber incendiary ammunition into part-filled aluminum canisters containing the test fluid; the results reported as the number of ignitions per 5 trials.

Table 152 Ignition characteristics of aircraft hydraulic fluids

Fluid	Flash point (ºC)	Fire point (ºC)	AIT (ºC)	Hot surf. ign. (ºC)	Ht. comb. (MJ kg^{-1})	Gunfire ignition
MIL-H-5606	102	113	232	388	42.3	5/5
phosphate ester	170	188	524	760	29.7	0/5
silicate ester	190	210	400	371	34.0	3/5
MIL-H-83282	230	254	354	322	41.0	1/5
silicone	276	343	409	477	22.6	0/5
chlorofluorocarbon	>500	>500	630	927	5.6	0/0
fluoroalkyl ether	>500	>500	669	927	4.1	0/0

Khan[1308] examined the pilot, radiant ignitability of various hydraulic fluids that are commonly used in mining industries. His study gives results at irradiance values over the range 30 – 60 kW m^{-2}; studies where low irradiances or $\dot{q}''_{\min}$ values would have been examined are not available. Khan also measured the fire points of a number of hydraulic fluids, using the ASTM D 92 method (Table 153). The mineral oil was for comparison purposes and would not ordinarily be used as a hydraulic fluid in mining machinery.

Table 153 Fire points of some hydraulic fluids

Type	Fire point (ºC)	
	Complete range	Typical values
organic/polyol esters	202 – 303	275 – 300
phosphate esters	163 – 320	310 – 320
mineral oil	252	252

Hydrazine

Hydrazine (N_2H_4) is a liquid which is widely used as a monopropellant and bipropellant fuel in rocketry and which also has uses as a boiler feed water additive, and as an intermediate in the plastics, pharmaceutical and agricultural chemical industries. Commercially, hydrazine is available as an aqueous solution (hydrazine monohydrate, hydrazine hydrate, $N_2H_4 \cdot H_2O$). The basic chemistry of hydrazine has been described by the Bureau of Mines[1309], along with a discussion of its hazards. The LFL of hydrazine in air is 4.7%, but the UFL is 100%, because hydrazine is able to decompose without the presence of an oxidizer. In nitrogen, the LFL of hydrazine is 38%. Decomposition occurs in two stages:

$$2N_2H_4 \rightarrow 2NH_3 + N_2 + H_2$$
$$2NH_3 \rightarrow N_2 + 3H_2$$

In practice, the second reaction is never complete, thus ammonia always remains among the products. Determining the ignition temperature of hydrazine is problematic, with erratic results commonly being observed[1309]. When tested in

pure glassware, an ignition temperature of 270ºC in air and 204ºC in oxygen was found. But when a platinum surface was introduced the ignition temperature in oxygen dropped to 30ºC. Upon introduction of ferric oxide, hydrazine ignited pyrophorically at room temperature. The combination was not pyrophoric at the dry ice temperature of –78.5ºC. Black iron and stainless steel were not pyrophoric and hydrazine showed ignition temperatures over 130ºC in these cases. Apart from iron rust, the decomposition of hydrazine can be catalyzed by chromium, copper, and iridium. Thus, hydrazine can spontaneously decompose if stored in a vessel which has such metallic impurities[142]. Hydrazine vapor is detonable at partial pressures down to 2.39 kPa; liquid hydrazine is not detonable at room temperature. Since hydrazine is a strong reducing agent, when used as a fuel in rocket propulsion, it is combined with an oxidizer such as dinitrogen tetroxide (N_2O_4) or hydrogen peroxide (H_2O_2) and it reacts hypergolically with strong oxidizers. Rags or paper tissues used to wipe up small anhydrous hydrazine spills will often autoignite in air if carelessly thrown into a wastebasket. Unnoticed and uncorrected accidental hydrazine leaks and spills will often result in autoignition by contact with contaminants on the floor. Even contact with vermiculite—a recommended packaging material in US Federal regulations (49CFR173.276)—will result in ignition. Anhydrous hydrazine must be stored under a nitrogen gas blanket. Accidental pressurization of hydrazine tanks with air or oxygen will result in explosions. There is an old monograph on hydrazine by Audrieth[1310], a monograph on hydrazine safety by Pedley et al.[1311], and a recently revised comprehensive study by Schmidt[1312].

Hydrocarbon gases

Certain simple hydrocarbon gases can, under pressure, decompose exothermically and thereby explode. These include not only acetylene, but also ethylene, propylene, cyclopentadiene, and cyclohexadiene, for all of which such accidents have been reported[1313]. The conditions leading to explosion have not been extensively documented, but in one case propylene was compressed to 955 atm at 327ºC, while ethylene has been observed to explode at 54 atm and 460ºC, and also at 254 atm at 331ºC.

Hydrogen

The AIT value for hydrogen has been controversial. In an early survey (1907) of studies of $H_2 - O_2$ mixtures (i.e., with no nitrogen), Falk[1314] found reported values to range from 518 to 845ºC, with most of the values being in the range 580 – 700ºC. Falk himself measured 523ºC at the optimum H_2/O_2 ratio of 50:50. In their 1952 compilation of flammability data[1315], the Bureau of Mines cites an AIT value of 585ºC for hydrogen in air. The value dropped to 400ºC in the 1965 compilation[4], while in their final (1985) compilation[127], the Bureau of Mines quoted a value of 520ºC. Unlike for much of their other data, none of the BM compilations provide a documentation as to the experimental basis of the hydrogen AIT values that were cited. Speaking specifically to the 400ºC value, Woinsky[1316] points out that "the Bureau of Mines has not been able to reproduce this temperature," and this value must be considered an error. According to the classic textbook of Lewis and von Elbe[1317], there is an effect of the diameter of the test vessel, with AIT = 596ºC for a 39 mm vessel and 558ºC for a 74 mm vessel. The standard German compilation of flammability data[1318] gives a value of 560ºC and this appears to be the value that is most consistent with the bulk of experimental results. A history of hydrogen accidents sustained by NASA has been published[1319].

The quenching distance for hydrogen in air is a minimum of 0.63 mm at the fuel concentration of 29.5%, and this value is quite close to the minimum for any concentration. In pure oxygen, a quenching distance of 0.19 mm has been reported at the stoichiometric concentration[1322].

The flammability limits of hydrogen are commonly quoted as 4 – 75%. The exact value of the LFL has been controversial. Using an 8 L test chamber, Hertzberg[1320] showed that the LFL ≈ 7% for a quiescent mixture, falling to ≈ 5% under turbulent conditions. The lowest reported values appear to be an artifact of a too-small size of test apparatus, since repeating the same experiments in a 12 L chamber (which is still much smaller than real-scale problems), he found LFL ≈ 8.1% for quiescent mixtures. Hydrogen is among the easier fuels to detonate. If mixed in suitable concentration (18 – 59%) in air, detonations within pipelines[1226] may take place if the length of pipe is 100× its diameter, or greater.

The ignition properties of hydrogen are exceptionally sensitive to the amount of turbulence, unlike most other gases, which do not show a major turbulence effect. Because of the low MIE value for hydrogen, a number of accidents have taken place in chemical manufacturing facilities where hydrogen accidentally ignited in a vent stack. Britton[1321] reviewed various theories, but concluded that good explanations were generally lacking.

Drell and Belles[1322] published a report that comprehensively covers flammability properties of hydrogen, although it is now quite old. Another extensive study was done by the Bureau of Mines[1323], where the work focused on spills and pool fires of liquid hydrogen. A more recent (though hardly current) review is by Hord[1226]. Even small spills were shown to create quite tall regions of flammable mixture. The maximum height at which a flammable mixture existed was found to be about twice as high for spills on gravel as on smooth macadam. For a 3 L spill on macadam in quiescent air, flammable mixtures were found at heights up to 4.1 m, which was about 50% greater than the height of the visible cloud. When ignited, the pools showed a momentary yellow flash and then burned with a non-luminous flame.

EXPLOSIONS DUE TO ADVENTITIOUS HYDROGEN PRESENCE

Hydrogen/air explosions sometimes occur not where hydrogen is deliberately used, but rather when hydrogen is accidentally created in an unwanted chemical reaction. Médard[26] reviewed a number of incidents of this kind and Schneider[1324] discussed one incident in detail. Baker and Willis[1325] investigated the possibility that sufficient hydrogen could be generated for an explosion by electrolysis when performing electrical arc welding on chemical plant equipment where aqueous solutions are in steel containers. They concluded that this is not possible for an all-metal system, but could conceivably be possible if welding current is passed through an insulating joint in metal piping. An interesting case has been reported where a workman was injured due to a dishwasher explosion[1326]. An inspection was being performed prior to placing into service a dishwasher at an apartment complex. When the knob was rotated to start the cycle, an explosion ensued shortly thereafter. Investigation revealed that the water heater was in service but water was not being used. The water heater contained a magnesium anode for corrosion control purposes, and this allowed a sizeable amount of hydrogen gas to accumulate and to disperse into the water piping. A similar case of a dishwasher explosion was documented by the US Navy[1327]. The explosion destroyed the dishwasher and caused structural damage in a vacant Naval housing unit. When a plumbing system is in regular use, the small amount of hydrogen generated is dissipated from faucets. But if an apartment in unoccupied, yet the heater continues to operate, hazardous levels of hydrogen may accumulate in the piping. Hydrogen hazards due to improper operation of sacrificial anodes are known in other contexts[1328].

Hydroxylamine

Hydroxylamine, $HO–NH_2$, is a highly unstable compound used in semiconductor manufacturing. In its anhydrous form, it is usually stored at 10ºC to minimize the decomposition hazard[3]. Small amounts of impurities, especially iron, can violently catalyze the decomposition reaction[1329]. In commercial applications, it is often used as a 50 mass% solution in water. Of the three hydroxylamine manufacturing facilities formerly in existence, Concept Sciences, Inc. was destroyed by explosion in 1999 and Nisshin Chemical in 2000, leaving solely BASF as the remaining maker[1330]. Studies of the decomposition kinetics were made by Cisneros et al.[1329] and by Iwata et al.[1331], but they did not explain the conditions leading to the accidents.

Incendiary timing, delay, and actuation devices

Arsonists often do not wish to be present while the fire they are setting starts. This can be either to give themselves an alibi or else to avoid personal injury, especially if flammable liquids or explosions are contemplated. This requires either a timing device or a remote-actuation device to ignite the fire. In case of flammable-liquid ignited fires, an arsonist may simply ignite a 'trailer,' which is commonly a roll of toilet paper, toweling, lengthwise-wadded newspaper, etc., leading from the safe point of ignition into the to-be-ignited interior.

A recent review of timing devices[1332] used suggests that the most common one is simply a cigarette which is lighted, then its unlit end is placed in a book of matches, between the match heads and the cover; kindling is placed around the match book. A delay of 10 – 20 minutes is obtained this way, but the start of a fire is not necessarily reliable. Electric timers of various sorts are often used, but they leave metal parts that are not destroyed by a fire. Attempts are sometimes made to not have the incongruity of a timing device noticed by utilizing a device which contains both a time-dependent function and a heating mechanism. One example is placing combustible fuels at a furnace, where they will be ignited when the main burner comes on, but not ignited from a pilot light. Another example is timed baking in an oven, where some readily ignitable substance is placed inside.

Remote-actuated devices are less commonly used, but may typically involve a radio receiver or an electronic circuit connected onto a telephone line. Swab[1333] published a book giving details of various incendiary devices.

Insecticides, pesticides, fungicides

These substances come from a wide variety of chemical families. Some exhibit self-heating. EPA investigated an explosion[1334] caused by moderate heating of an organophosphorus insecticide. A safe storage temperature of 26ºC was found for 'supersack' quantities of the material. Agricultural insecticides are often formulated as dusts or wettable powders in which the active ingredient is mixed in with a finely-ground clay. Such clay-diluted chlorinated insecticides can show self-heating when decomposing. The decomposition is promoted by acid sites on the clay[1335]. This problem is normally addressed by the use of clay deactivators such as urea or hexamethylenetetramine. A case history is reported[1336] where self-heating of Perthane powder [diethyl diphenyl dichloroethane; 1,1-dichloro-2,2-bis(4-ethylphenyl) ethane; $C_{18}H_{20}Cl_2$] caused a large warehouse fire. Because of the huge variety of chemicals used for these purposes, individual testing is necessary to determine actual self-heating properties.

Iron sulfides

Iron sulfides are a family of inorganic compounds which have long been known to be susceptible to pyrophoric action. These compounds are FeS, FeS_2, Fe_2S_3, and Fe_3S_4. When found as a mineral, iron disulfide (FeS_2) is termed *pyrite* (or somewhat redundantly as *iron pyrite*), the term directly implying its potential to cause fire. The most exothermically-reactive sulfur-bearing mineral is pyrrhotite[1337]. It has the empirical formula Fe_nS, where n = 0.8 to 1.0. Case histories on the spontaneous combustion in mines of iron-sulfide-containing minerals have been collected by

Ninteman[1338]; a more recent bibliography was published by Wu et al.[1339]

In petroleum processing equipment, crude oil, bitumen, etc., may contain sulfur. Either sulfur or H_2S that is formed may react with iron or iron rust (Fe_2O_3), to form FeS, FeS_2, or Fe_2S_3. Anaerobic conditions are required for these reactions to occur[1340]. But the iron sulfides which are formed inside pipes, vessels, etc., may then self-heat to ignition when piping is drained or air is introduced. The reaction of FeS_2 with atmospheric oxygen is:

$$FeS_2 + O_2 \rightarrow FeS + SO_2$$

Moisture promotes pyrophoric reactivity, and in the presence of moisture, another reaction can occur:

$$2FeS_2 + 7O_2 + 2H_2O \rightarrow 2FeSO_4 + 2H_2SO_4$$

In the case of mineral form pyrites, the ferrous sulfate that is formed then attacks the pyrite, causing its decomposition and accelerating the reaction. The FeS form can react with oxygen in two different ways:

$$4FeS + 3O_2 \rightarrow 2Fe_2O_3 + 4S$$

$$4FeS + 7O_2 \rightarrow 2Fe_2O_3 + 4SO_2$$

Finely-divided iron sulfides are more prone to react pyrophorically.

A special rust-related problem has been the cause of several explosions in crude oil tankers, where a pyrophoric reaction was determined to be the reason[1341]. A laboratory investigation determined that the chain of events begins with fine particles of hydrated α-ferric oxide, α-FeO(OH), sometimes known as goethite. The primary steps involved are sulfide formation:

$$FeO(OH) + H_2S \rightarrow Fe_2S_3 + H_2O$$

followed by oxidation:

$$Fe_2S_3 + O_2 \rightarrow Fe_2O_3 + S$$

The reaction was found to be pyrophoric at temperatures as low as 25ºC, although only under certain conditions. The sulfide formation proceeded actively only at low oxygen concentrations, while the pyrophoric oxidation required oxygen concentrations > 11%; lower oxygen concentrations led to slow heating only. The fact that one step of the reaction occurs only under high oxygen conditions and another under minimal oxygen, helps to explain why the problem is relatively rare in practice. The sulfur needed for the reaction comes from the crude oil itself, and it is common for tanker atmospheres to have H_2S concentrations up to 3.5%. An explosion occurs because the oxidation reaction can produce incandescent-hot particles. The authors speculated that similar reactions might also account for some boiler explosions that were never otherwise satisfactorily explained. Walker et al.[1342-1344] have further studied pyrophoric reactions with various iron sulfides.

Jute

Jute, if clean, has been found to have negligible self-heating. However, baled jute has been known to self-heat if contaminated with the fats or oils of agricultural products, especially if micro-organisms are present[1345]; a number of ship fires have been recorded due to this cause[347]. Following a series of unexplained fires of jute cargo in steam ships, NIST conducted tests on jute[1087]. Using the Mackey tester, no self-heating was indicated, except for samples which had been contaminated with drying oils. This was confirmed in some larger size bundles tested in ovens. No ignitions were obtained, although some self-heating was observed. It was concluded that either very large piles would be required or contamination with drying oils would be needed for spontaneous combustion to be a problem. In some simple ignition tests with cigarettes, bales of jute ignited in 2 of 12 trials, but "loosely piled" jute did not ignite in 20 trials, although the test arrangement was not clear.

A limited amount of self-heating occurs in connection with wetting. In an early study[1346], it was documented that wet bales of jute commonly show 'heart damage,' which apparently consisted of self-heating, but short of thermal runaway. For the damage to occur, moisture had to exceed 25%. A level this high requires soaking with liquid water, it is not achievable by an equilibrium process with moisture in the air.

Kerosene

Kerosene (also spelled 'kerosine') is a petroleum distillate product which represents the fraction between gasoline and gas oil (diesel oil). It originally came into use in the 1840s as a lamp oil, but later became common—in various grades—as a heater fuel and as a fuel for jet engines). Chemically, kerosene can contain all of the main petroleum distillate families: paraffins, naphthenes, and aromatics, although the aromatics are removed for certain applications and paraffins in general tend to predominate. The dominant constituents[1347] are in the C_8 to C_{11} range. The kerosene that is used for space heaters and similar applications is known as 1-K grade (or Ultrasene) and is desulfurized, with sulfur < 0.04 mass%. The specification for this grade is governed by ASTM D 3699[1348]. Visually, this grade cannot be distinguished from 2-K, which may not be used in unvented heaters. A Chinese study[470] determined the minimum flux for piloted ignition of kerosene to be 2.9 kW m^{-2}. Even though, by law, the flash point of kerosene in most countries is above room temperature, by applying a small flame to a 90 mm pan of kerosene held in open air for about 4 minutes it was found possible to achieve ignition[463]. This pre-warmed the fuel locally so that sufficient vapors were produced for ignition.

Kerosene heaters

Portable kerosene heaters are devices that typically have a heat output of 2.2 – 4.4 kW at maximum setting. Their design has changed over the last few decades, with safety features now being much more robust than previously. During the 1970s and '80s, CPSC encouraged the manufacturers to upgrade the safety of kerosene heaters. Consequently, kerosene heaters today have safety features which did not exist in earlier decades:

- improved guards or grilles that reduce the risk of accidental contact burns;
- a manual shut-off device which allows for a quick shut-off during an emergency situation;
- a wick-stop mechanism which prevents the wick from being retracted to a hazardously low setting;
- labels that stress the use of 1-K fuel and the importance to not mis-fuel with gasoline.

In the US, kerosene heaters are commonly manufactured to conform to UL 647[1349]. It is interesting, however, to consider a statistical breakdown of kerosene heater fires[1350] compiled in Great Britain in 1960-61 (Table 154), since they indicate a large component of human carelessness which better engineering may not necessarily prevent.

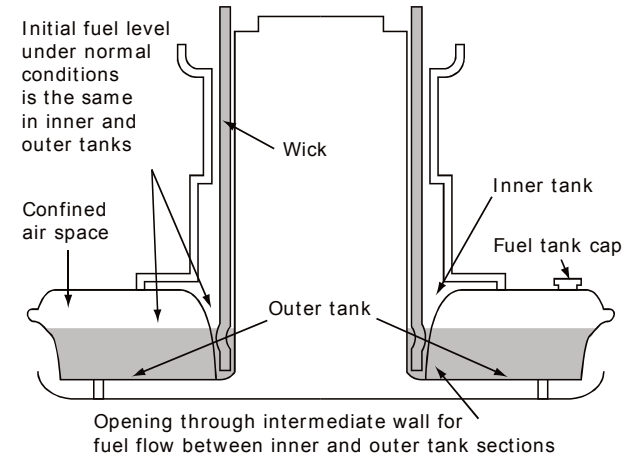

Figure 99 Failure mode for bottom-fed kerosene heater mis-fueled with high-vapor-pressure fuel
(Copyright Fire Findings, LLC, reprinted by permission)

Table 154 Breakdown of UK kerosene heater fires, 1960-61

Cause	Percent
overheated or flared up	24.8
turned too high	16.4
leakage or flooding	13.0
overfilled or spilled	12.2
too near combustibles	11.3
overturned or dropped	10.4
other or unknown	7.7
filling while alight	3.5
exploded	0.5

The two most common fuel-feed systems for kerosene heaters are the bottom feed and the cartridge-type fuel tank. The bottom-feed fuel system presumes that only the correct fuel, kerosene, will be introduced into the heater. Too often users erroneously introduce gasoline, or kerosene contaminated with a fuel having a high vapor pressure, such as mineral spirits or turpentine. The consequence[1351,1352] of this fueling error is likely to be a "heater enveloped in flames" (Figure 99). Cartridge-type heaters will overflow and show catastrophic flaming when fed with a fuel of the wrong vapor pressure. In addition, overflow can also result if the fuel cartridge develops a leak. A device has been described which can mitigate the effects of leaks in fuel cartridges and prevent flareups[1353].

Lambswool pads, imitation

A study[2087] found that some commercial imitation lambswool pads, such as are used to prevent bedsores or for automobile driver's comfort, were highly susceptible to self-heating. In one case, the pad was put into a sterilizer, and in another case it was put through a clothes dryer.

Lawn mowers

Exhaust system temperatures have been measured on one small, 3.5 horsepower lawn mower[1354]. A maximum temperature 350ºC of was found on the outside of the muffler, while the exhaust gases measured 370ºC at the discharge.

Lime

Unslaked lime ('quicklime,' CaO) reacts highly exothermically with moisture to form $Ca(OH)_2$. Rossotti[1355] relates that this was already known to ancient Greeks, who would smear quicklime with some readily combustible substance such as sulfur or crude oil on enemy buildings, then wait for rains to cause ignition. Fires due to accidental contact of moisture with quicklime have been reported[1453].

LNG and LPG

LNG is liquefied natural gas and comprises mostly methane. LPG is liquefied petroleum gas and comprises propane, butane, and small amounts of propylene, butylene, ethane, and other gases. In addition, an odorant is added to gas sold to consumers. The actual composition of LPG is highly dependent on the country in which it is produced. In the US, LPG is predominantly propane, while in some Eu-

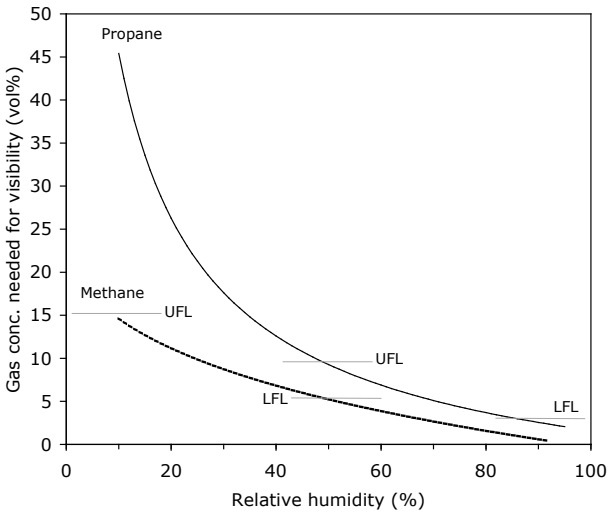

Figure 100 Relation of RH to visibility of liquefied gas plumes in air

ropean countries the major constituent is butane. LPG used for motor vehicle engines is produced to a specification known as HD5 which requires a propane content of at least 90% and a propylene content no more than 5%.

When LPG is sold in portable containers, the container is supposed to be filled only to 80% of capacity. Fires have been numerous when containers have been overfilled. When a container was filled in a cold environment and is then brought into a warm environment, if sufficient vapor space is not available in the container, expansion of the liquid will raise the vapor pressure sufficiently to expel the vapor from the safety relief, whereupon it can potentially ignite if ignition sources are present outside. The problem largely arises because liquid propane has an exceptionally high coefficient of thermal expansion, which is roughly 100× that of steel. Under some conditions (if the temperature change is extreme, or if the container is tilted), liquid—not only vapor—can be expelled. de Nevers has presented detailed calculations on the thermal expansion process[1356].

Modern, portable propane cylinders are likely to contain safety features which were historically not present. The background and features of quick-closing couplings[1357] (QCC) and overfill protection devices[1358] (OPD) have been documented. OPD valves have been used by US manufacturers of 1.8 – 18 kg (4 to 40 lb) cylinders since 1998 and have been required by NFPA 58[1359] since the 1998 edition of that document. These devices comprise a tank valve which has a special float which rises during refilling to block the filling process when the tank is 80% full. The valve handle on OPD-equipped cylinders is triangular shaped, as contrasted to round or star-shaped ones used previously. Propane cylinder BLEVEs are discussed in Chapter 13.

Liquefied natural gas occasionally autoignites when spilled on water. The Bureau of Mines[1360] documented several such instances in the course of laboratory testing, but did not produce a definitive explanation. It appeared that the explosions most probably were akin to steam explosions (physical, rather than chemical, explosions), possibly involving ice formation. For cryogenic temperatures, the effect of temperature on the LFL of methane[1361] has been determined to be:

$$LFL_T = 5 + 0.0052(298 - T)$$

where T = temperature (K). Large shipments of LNG and LPG are usually carried by refrigerating the gas below its boiling point, rather than by enclosing it in a pressure vessel. If a spill of refrigerated LNG or LPG cargo occurs, a visible plume will be seen in the atmosphere. The actual fuel gases are invisible at any temperature, but introducing a cold gas into the atmosphere causes local condensation of moisture. Blackmore et al.[1362] studied the relation between the relative humidity in the air and the fuel gas concentration in the spill plume at which the plume becomes visible. Figure 100 shows that propane plumes are difficult to see, and at 50% RH only that part of a plume which is over the UFL would be visible. For methane, on the other hand, a concentration essentially equal to the LFL can be seen in a 50% RH environment.

Marijuana and hemp

The marijuana (*Cannabis sativa*) plant contains from 25 to 40% hempseed oil and the latter is rich in fatty acids. The iodine number of hempseed oil is typically in the range of 145 to 167, which is only slightly lower than that of linseed oil. Consequently, the plant shows a pronounced self-heating tendency. Two cases have been reported where small quantities (one or several garbage bags) containing marijuana underwent thermal runaway in Canadian police stations[1363]. In one case, the self-heating progressed to a flaming fire. Thermal runaway is readily evident due to strong odor, even if flaming does not occur. The storage time in one case was only 1 – 2 days and was probably only somewhat longer in the other. More than 100 years ago, Moore[257] recorded that moist hemp has "been known to take fire spontaneously" but did not give details.

Matches and lighters

PROPERTIES OF MATCHES

In the history of technology, matches existed even in the times of the Romans, but prior to the 1800s, matches were either devices for propagation—rather than initiating—fire, or else were part of some wet-chemistry scheme, typically involving sulfuric acid[1364]. The current-day matches are pyrotechnic devices, with the material of the match head being a pyrotechnic mixture, where ignition and initial combustion is based on a solid-state reaction. Oxygen from the air is not involved except when the match stem ('splint') begins to burn. Apart from head and splint, a modern match has the top 15 mm or so of the splint dipped in paraffin wax

in order to make sure that the burning of the head ignites the wood splint. Conversely, the entire splint is also treated with a fire-retardant agent to suppress after-glow, once flaming is extinguished.

A match head composition originating from Vienna in 1820 comprised[1364]:

33% potassium nitrate
33% manganese oxide
10% phosphorus (P_4)
24% gum arabic.

Despite the early description, it is not clear when matches of this nature were actually commercialized. The first pyrotechnic-mixture based matches known to have been commercialized were those produced in 1826 by the apothecary John Walker[1365]. His match heads comprised potassium chlorate, antimony sulfide, gum, and starch. They were ignited by rubbing against sandpaper. The addition of sulfur to the composition by Isaac Holden in 1829 made ignition more efficient and practical. Early matches also had splints treated with sulfur, rather than wax. Safety matches were invented in 1844 by Swedish professor Gustaf Pasch, and were commercialized in the same year, although the initial product was not very satisfactory. The head contained mainly potassium chlorate and antimony sulfide, while the active ingredient in the friction strip was red phosphorus. Worldwide commercialization of safety matches is considered to have been started in 1855 by the brothers Johan and Carl Lundström, at the Jönköping Match Factory in Sweden. Consequently, during the 19th century safety matches were often called 'Swedish matches.'

Nineteenth century strike-anywhere matches were based on white phosphorus; its use presented toxicity problems and fire hazards in transportation and storage. This was solved by the development of phosphorus sesquisulfide. One formulation of a strike-anywhere match head involved:

28% potassium chlorate
13% phosphorus sesquisulfide (P_4S_3)
14% animal glue
15% ferric oxide
10% zinc oxide
20% ground glass.

The animal glue also serves as fuel, not just as binder. Physically, modern strike-anywhere matches use two different layers of pyrotechnic composition, one applied on top of the other; the tip has a high content of P_4S_3 for easy ignitability, while the base has more fuel in order to avoid premature extinguishment[1436].

The typical composition of a safety match head commonly includes red phosphorus, powdered glass, and glue, along with smaller quantities of other substances. The friction strip against which safety matches are lighted has typically about 50% amorphous red phosphorus, about 20% of an adhesive, and a smaller amount of abrasive, such as glass powder. Paper, i.e., 'book' matches, were invented in 1892 by Joshua Pusey and commercialized in 1894 by the Diamond Match Company.

Cooke and Ide[605] report that the ignition temperature of British safety matches is 180 – 200ºC and that of strike-anywhere matches is 120 – 150ºC; their book also contains much useful guidance for forensic investigations involving matches. An old study by Lucas[449] found an AIT of 40 – 85ºC for strike-anywhere matches and 120 – 175ºC for safety matches. His values for strike-anywhere matches are exceedingly low and apparently pertain to matches produced in Egypt in the 1920s. Phosphorus sesquisulfide itself has an AIT around 100ºC and this governs the rather low AIT value for strike-anywhere matches[1436]. The AIT of American strike-anywhere matches[443] was reported by NIST in 1947 as being 163ºC. Latham[1366] determined the ignition temperature of American and Australian strike-anywhere matches to be 215ºC, but with a very large standard deviation of ⌖50º. The temperatures at the head and at several places along the splint have been measured on burning book matches and wood (box) matches[1367]. The peak surface temperatures were found to be in the range of 800 – 900ºC, both at the head and also along the splint at up 10 mm away from the head. No significant differences in peak temperature were found between book and box matches. Actual flame temperatures have been reported[1368] to be in the range 1350 – 1930ºC, with most values being in the range of 1400 – 1500ºC. Since the peak temperatures in the similar flame of a candle are 1400ºC, the values at the high end of this range are probably in error, as is the low reported value[311] of 1130ºC.

The ignition process that occurs upon striking a match head upon a suitable surface and the subsequent combustion of match head and stem are complex and have not been studied in a quantitatively satisfactory way. Finch and Ramachandran[1365] consider that there are at least 8 steps involved in the combustion process.

CPSC has reported tests on matches[1369]. Their results are shown in Table 155. In some cases the matches went out before being consumed (for the dropped ones) or got too hot to hold (for the held ones). The drop distance was 457 mm and a significant number—but highly variable (12% to 58%)—of them self-extinguished during, or upon landing. These were not included in the burn time averages.

Table 155 Average burn times (s) for various matches

Orientation	**Book match** (35 mm long)	**Wood match** (40 mm long)	**Wood kitchen match** (55 mm long)
held horizontal	22.9	16.4	31.4
dropped on glass fiber board	42.6	41.5	40.2
dropped on cotton duck fabric	12.1	12.2	10.4
held vertical, head-up	31.0	28.3	28.8

The total burn time (non-hand-held) of American kitchen matches held head-up was determined to be 52 s, but Australian matches, which were slightly shorter (42 mm) burned up in 28 s[1366]. The difference appears to stem from the fact that they were also thinner and weighted 0.11 g, compared to 0.24 for the American ones. Burning time of matches held head-down were studied by Sale[1370], who found burn times of 13 s for a 49 mm wooden safety match, 16 s for a 63 mm kitchen match, and 18 s for a paper book match. The time taken to light a cigarette using a match is about 5 s, but about 10 s is needed to light a cigar or a pipe. For the latter articles, there was quite a wide spread found in the lighting times, with 95% of the data falling between 6 and 14 s.

After the head has burned off, a paper (book) match burns at a HRR of about 45 W, a wood kitchen match at about 100 W[1371]. Latham found that for kitchen matches placed vertically, head-up, an adjacent match has to be 8 – 9 mm away for it to autoignite by radiation[1366]. Matchbooks occasionally ignite when placed in airline luggage. Documented cases include match heads from one book rubbing against the striker of another book, and match heads rubbing against an emery board[1372]. In Latin American countries, *vesta* matches are sometimes encountered. These do not have a wood or cardboard stem, but rather resemble a miniature candle—there is cotton wick at the center, surrounded by paper rolled around it, with the latter being then impregnated in wax. In enriched-oxygen atmospheres, matches can burn up very quickly. Wharton[331] showed that a match burning downwards at 1.5 mm s^{-1} in a normal atmosphere burned at about 12 mm s^{-1} in 50% O_2.

IGNITION POTENTIAL OF BLOWN-OUT MATCHES

The problem of inadvertent ignitions from 'extinguished' matches dates to the very early days of match production. In 1868 S. Howse already received a British patent for impregnating chemicals to be used to reduce the afterglow tendency[1365]. In current manufacture, stems are treated with an after-glow suppressant such as a 1.5% solution of H_3PO_4. A consumer protection agency in Canada[1367] studied the temperatures of contemporary blown-out matches and found that some matches required more than 4 s to drop to a temperature of 400ºC and 5 – 6 s to drop down to 350ºC. Highest temperatures were reached at the midpoint of the head and for a 10 s pre-burn time. Shorter pre-burn times of other measuring locations showed lower values.

In Canada, FR agents used to suppress after-glow are often ammonium dibasic phosphate or ammonium polyphosphate. A study[1373] examined the effect of these agents on potential ignitions through afterglow. Of matches obtained in the Canadian marketplace, the afterglow at the head in some cases ranged to over 36 s, but was typically < 15 s. Afterglow at the splint was < 3 s in 91% of cases. For certain imported matches which did not have FR treated splints, 40% showed afterglow times of 15 – 35 s, while 60% showed times over 36 s. The authors then conducted target-item ignition tests. No ignitions of petroleum ether vapors were possible, nor were there any ignitions of lint or crumpled facial tissue, although in some tests up to 250 s of smoldering was observed, before smoldering self-terminated. As a worst case situation, ground-up facial tissue was used. Out of 23 tests with this target material, 20 trial resulted in self-terminating smoldering of less than 190 s duration. In one case, smoldering lasted for 10 min. In two other cases, smoldering transitioned to flaming when the specimens were covered with the target combustible and a mild draft applied. The times for transition to flaming were 12 and 15 min. The positive results were all obtained from afterglow of splints; no positive results were obtained from afterglow of heads.

In a further study, the same agency examined paper book matches[1374]. Untreated splints showed afterglow times of 22 – 60 s, while treated ones had times of 5 – 17 s. The matches that were not FR treated showed a strong tendency to re-light after being blown out, with only 16% of the matches tested not re-lighting. Of the untreated splints, no flaming ignitions occurred for: cotton lint; a cotton pad; paper towels; shredded newspaper; or petroleum ether vapors; smoldering times, if any, were short. When specimens were surrounded by ground-up facial tissue, flaming ignitions did not occur, but smoldering lasted up to 10 min. When specimens were placed within dried ground leaves, one out of 3 specimens initiated self-sustained smoldering that transitioned to flaming in 20 min. The most sensitive target fuel proved to be ground up newsprint. For one type of untreated splints, 100% went to flaming, which occurred in only 16 – 28 s. For another type, 20 out of 50 initiated self-sustained smoldering that transitioned to flaming in 15 – 35 s. For FR-treated splints, only 1 out of 50 samples initiated self-sustained smoldering; this specimen went to flaming after 36 s.

LIGHTERS

CPSC found that maximum burn times for disposable cigarette lighters ranged from 200 s to 960 s, depending on the size and design[1369]. For two out of four tested, the reported burn time was due to the lighter becoming too hot to hold, the others ran out of fuel. When ignited in an enriched-oxygen atmosphere, a butane lighter[331] will ignite with a 'pop' at 30% O_2 and a loud 'pop' at 45% O_2. ASTM F 400[1375] is the ASTM standard on lighters.

Metal alkyls

Metal alkyls are compounds of the general formula $M_x(C_nH_{2n+1})_y$, where 'M' stands for a metal. Examples include *n*-butyllithium, diethylzinc, triethylaluminum, and triethylborane. Many metal alkyls are either pyrophoric or require only moderately elevated temperatures for ignition. Marsel and Kramer[1376] studied the autoignition properties of several metal alkyls and Ellern[1407] summarized available information on others. When metal alkyls are diluted with

hydrocarbon solvents, they may still retain their pyrophoric properties, if present in a high enough concentration. Mudry et al.[1377] studied the behavior of such solutions. To characterize their relative pyrophoric hazards, they developed a simple test where a small amount of solution is dropped on a cellulose filter paper and a 'pyrophoric concentration' is declared to be the minimum concentration that causes the paper to be charred in 45 s.

Metal alloys

Certain metal alloys are pyrophoric or water-reactive. These include[3]:

- aluminum-lanthanum-nickel alloy ($AlLaNi_4$)
- a wide variety of cerium alloys, especially with mercury
- lead-zirconium alloys containing 10 – 70% zirconium (they pulverize and ignite on impact)
- silver-thorium alloy
- zinc-mercury amalgam.

Metal carbonyls

Many metals can form a compound of the general formula $M_x(CO)_y$, where 'M' stands for a metal and 'x' and 'y' vary according to the valence of the metal atom. More complex molecules incorporating several different metals in one molecule are also possible. The metal carbonyls where the metal is an alkali metal (lithium, sodium, potassium, rubidium, cesium) are generally pyrophoric, but carbonyls formed with other metals may also be. Examples include: iron pentacarbonyl ($Fe(OC)_5$), potassium carbonyl (KCO), sodium tetracarbonylferrate ($Na_2[Fe(CO)_4]$). Urben[3] provides extensive listings along with literature references.

Metal hydrides

Hydrides in general are divided into three categories, depending on the type of chemical bonds holding the hydrogen atom to its partner:

(1) Covalent hydrides contain covalent bonds, such as those in hydrocarbons and hydronitrogens.
(2) Saline or ionic hydrides contain hydrogen in the form of a negatively charged hydride ion H^-, such as in lithium hydride or sodium hydride.
(3) Metallic hydrides are formed by absorption of hydrogen into the electron cloud surrounding atoms in metals. The compounds are electrical conductors and are nonstoichiometric, allowing a wide variation of hydrogen contents. Many metals become embrittled as the result of inadvertent hydrogen absorption.

Many metallic hydrides are highly reactive. Examples with pyrophoric tendencies include aluminum hydride (AlH_3), barium hydride (BaH_2), lithium hydride (LiH), lithium aluminum hydride ($LiAlH_4$), magnesium hydride (MgH_2), potassium hydride (KH), sodium hydride (NaH), thorium dihydride (ThH_2), thorium hydride (ThH_4), uranium hydride (UH_3; UH_4). Urben[3] provides extensive listings along with literature references. Tests by the Bureau of Mines[1378] showed that 5 g quantities of powdered sodium hydride and lithium hydride ignite in air at 54ºC, but not at 32ºC. Moisture is necessary to elicit the pyrophoric behavior of some metal hydrides.

Metal oxides

Some metal oxides are oxygen-rich and can act as oxidizers, these include PbO_2, MnO_2, and CrO_3. Médard[26] reports that contact of oil with CrO_3 causes a near-instant ignition.

Metals

ALUMINUM

Because aluminum combustion has significant applications in the rocket propulsion field, its combustion has been studied in more depth than that of any other metal. The details of aluminum's ignition process have been described by Price[1379]. Ignition of aluminum does not require oxygen. Reaction can occur with halogenated hydrocarbons and some other compounds that are explosive in nature. NFPA has a standard, NFPA 651[1380], covering the safety precautions of working with aluminum powders. Werley et al.[1381] published an extensive review paper that discusses many specialized ignition modes, e.g., friction and impact.

BULK MATERIAL

Bulk aluminum is difficult to ignite. Grosse and Conway[1382] found that aluminum pools in pure oxygen at 1 atm in a high-temperature furnace did not ignite* at a temperature of 1000ºC. Brzustowski and Glassman[1383] ignited aluminum ribbons by resistance heating and found that the surface temperature at ignition was 1752ºC.

Zhu et al.[1384] explored the ignition of large specimens (10 mm diameter) of aluminum at the very low pressure of 8 kPa. As with any non-protected aluminum, the surface was originally oxidized, that is, converted to Al_2O_3. When approaching the ignition temperature, the oxide layer began to crack and separate. Ignition occurred in the *gas phase*, with initial flaming occurring at the cracked areas. At a constant heating rate of ca. 4ºC s^{-1} supplied by inductive heating, the ignition temperature of 1900ºC was nearly independent of oxygen concentration over the range of 20 – 100%. The measured ignition temperature was lower than the boiling point at 8 kPa (2035ºC) and also lower than the melting point of Al_2O_3, which is 2042ºC. When ignition occurred, a diffusion flame of Al vapor was formed about 2 – 4 mm above the specimen surface. After ignition, the temperature of the specimen continued to rise, and it eventually exploded due to trapped gases inside. In a related study[1385], the authors varied the heating rate. The ignition temperature was seen to be inversely dependent on the heating rate. For a heating rate < 2ºC s^{-1}, the ignition temperature approached the melting point temperature for Al_2O_3 of 2042ºC. At a heating rate of 2ºC s^{-1}, an ignition temperature around

* Their finding has been misreported in several surveys, where it is incorrectly given that 1000ºC is the ignition temperature.

1750ºC was found. The authors also studied the ignition of aluminum cylinders which did not have the natural coating of aluminum oxide. At 1 atmosphere pressure and an unspecified heating rate, the ignition temperature ranged from ca. 1550ºC (for near-zero air flow) to ca. 1670ºC (for air flow rates over 4 m s^{-1}). Such temperatures are, of course, well below both the boiling point of Al and the melting point of Al_2O_3. Zhu concluded that the *mechanism* of ignition of aluminum depends on the surface conditions. For an *unoxidized* surface, if the temperature is high enough, vaporization of Al proceeds at a sufficient rate that a gas phase flame can form. Conversely, if the temperature and vaporization rate are insufficient, O_2 diffuses easily to the metal surface and an oxide layer forms instead of ignition occurring. Ignition can occur subsequently at a higher temperature corresponding to oxidized-surface ignition. For an *oxidized* surface, the ignition temperature is lower than the melting point, because of reactivity. At elevated temperatures, surface heating occurs due to the reaction between the metal and the oxidizer. This is why the ignition temperature is progressively lower for higher heating rates. In cases where the oxide is forcibly stripped off the metal, e.g., by frictional rubbing, a vastly lower T_{ig} value is found. Benz and Stoltzfus[1386] found a value of 375 – 425ºC under these circumstances.

Liedtke and Rhein[1387] studied the ignition and combustion of aluminum/lithium alloys (typ. 90%+ Al; 2.5% Li; 1% Cu, 1-2% Mg) and found that the presence of lithium, in many cases, defeats the protective oxide layer of aluminum and enhances ignitability and combustion. Their study also showed strong reactivity of these alloys with certain salts. Notably, the extinguishing powder Met-L-X, used for extinguishing certain metal fires, was found to promote combustion of Al/Li alloys.

SINGLE PARTICLES

Friedman and Maček studied the ignition of single particles of aluminum by use of propane flat-flame burner[1388]. They found that even at zero oxygen concentration, ignition of 23 and 35 µm aluminum spheres was possible in the high-temperature combustion product stream of the propane burner (the particles spent a negligible time period in the flame itself). Furthermore, the ignition temperature hardly varied with O_2 concentration, being 2000ºC at 0% O_2 and 1940ºC at 36% O_2. These are temperatures that are very close to the melting point of Al_2O_3, 2030ºC. The induction period varied with particle diameter according to:

$$t_{ig} = 2.6 \times 10^{-3} d^2$$

where d = diameter (µm). When ignited, a flame temperature of ca. 2500 K was noted[1389]. Maček[1390] studied aluminum spheres of 35 – 45 µm diameter and found that a gas temperature of 2000ºC was needed at 1 atm and near-zero oxygen concentration. As the partial pressure of oxygen was raised to 1.7 atm, the temperature dropped to 1870ºC. The effect of total pressure appears to be larger, however. Kuehl[1391] studied 0.5 mm diameter aluminum wires and found, at 0.3 atm and higher, a constant value of 2050ºC. But for lower pressures, the temperature needed for ignition dropped significantly, reaching 1500ºC at 0.03 atm.

Frolov et al.[1392] summarized results from experimental studies conducted by several Russian research groups on the ignition of individual particles of aluminum. In experiments using very small particle sizes, for the smallest diameter tested, 7 µm, ignition was at 710ºC in air, rising to 930ºC for 10 µm and 1320ºC for 19 µm. But in another series, T_{ig} decreased with increasing particle size over the experimental of 80 – 250 µm. Frolov did not provide a consistent explanation for these trends.

Merzhanov and coworkers[1393] studied the ignition in pure O_2 of very fine electrically heated aluminum wires. The wire diameters ranged from 30 to 50 µm. The ignition temperature was found to depend on the heating rate. For high heating rates, a value around 1650ºC was found, while for the smallest heating rates a value around 1970ºC was seen, with a transition region joining these two temperature plateaus. By providing a gas velocity of 0.5 m s^{-1}, the ignition temperature dropped by 200 – 350ºC. Results for ignition in a CO_2 atmosphere were very similar. The authors provided an accompanying theoretical model, which includes both chemical kinetics and heat loss effects; this theory, however, does not seem to have seen further use by other researchers.

An explosion hazard can be created if powdered aluminum is mixed with a solvent that contains both halogen and hydrogen atoms[1644]. The reaction produces gaseous hydrogen and this may lead to a hydrogen explosion, in the presence of a suitable ignition source. Similarly, powdered aluminum moistened with alkaline water may release hydrogen and autoignite in air; this reaction is accelerated by traces of mercury.

DUST CLOUDS AND LAYERS

According to Hartmann et al.[1394], aluminum dust in air will autoignite at 645ºC. The temperature is size-dependent, and Maranda et al.[1395] found an AIT of 600ºC for particles of 11 µm mass-mean diameter, but over 1030ºC for 68 µm. Ignition temperatures of very small particles[1402] (< 0.1 µm) were reported to be 410 – 585ºC. The spark ignitability of aluminum dust is also highly dependent on particle size. At room temperature, an MIE of 20 mJ was found for particles of 11 µm mass-mean diameter, but rising to 246 mJ for 68 µm mass-mean diameter[1395]. Aluminum without an oxide coating is considered to be pyrophoric in sizes less than 0.03 µm[1459]; however, it must be noted that this is an exceedingly small particle size. *Flake aluminum* is more readily ignitable than atomized aluminum or other more compact particle shapes. This is due to the greater surface/volume ratio for flakes.

In a CO_2 atmosphere, aluminum powder (ultra fine, 0.03 μm size) was found to ignite at 360 – 420ºC[1396]. It appears that aluminum powder can ignite at 800 – 900ºC in a nitrogen atmosphere, although experimental results are highly inconsistent[1397]. If aluminum powder is moistened, it may ignite spontaneously in air[1398].

ALUMINUM IN PHYSICAL MIXTURES

Powdered aluminum is often used in propellants and in pyrotechnic mixtures. Ignition in such mixtures can be achieved at temperatures much below those needed for igniting pure aluminum. Nir[1399] studied the ignition of aluminum particles mixed with ammonium perchlorate oxidizer. He found that the aluminum ignites below 1000ºC, and he attributed this to a reaction between aluminum oxide and a gaseous combustion product of ammonium perchlorate.

ANTIMONY

Grosse and Conway[1382] found an ignition temperature of 650ºC for solid antimony burning in pure oxygen at 1 atm.

BARIUM

Grosse and Conway[1382] found an ignition temperature of 175ºC for solid barium burning in pure oxygen at 1 atm. Laurendeau and Glassman[1400] found an ignition temperature of 550ºC for solid barium burning in pure oxygen at 1 atm. Laurendeau and Glassman attribute this very large difference due to atmospheres used in the test work—the Gross and Conway experiments preheated the specimens under inert conditions, then applied an oxygen stream. The Laurendeau and Glassman procedure involved inductive heating of the specimen from room temperature in the pure-oxygen atmosphere. This results in a thick coat of oxide being built up on the surface. In addition, barium undergoes a great deal of self-heating before ignition, which was also considered to be a factor in explaining the difference. For applications where a protective oxide coating is not deliberately minimized, the Laurendeau and Glassman results would be more relevant. Finely-divided barium is spontaneously flammable in moist air[1398].

BERYLLIUM

Maček et al.[1401] found that single particles of beryllium (30 – 45 μm size) autoignite in an atmosphere of 21% oxygen at a temperature of about 2300ºC. There is a slight dependence on the oxygen partial pressure, and for an O_2 partial pressure of 5 atm the temperature drops to about 2100ºC. Beryllium powder (< 0.1 μm size) was found to spontaneously ignite at room temperature in air[1402] and in a CO_2 atmosphere[1396]; in a nitrogen atmosphere ignition temperatures of 504 – 527ºC were found[1403].

BISMUTH

Grosse and Conway[1382] found an ignition temperature of 775ºC for solid bismuth burning in pure oxygen at 1 atm. Laurendeau and Glassman[1400] found an ignition temperature of 735ºC for solid bismuth burning in pure oxygen at 1 atm.

BRASS

Brass powder can readily smolder. In hotplate tests on powder of unspecified particle diameter[1404], a hot-surface temperature needed for ignition was found to be 160ºC for 12.7 mm layer, 140ºC for 25.4 mm, and 135ºC for 38.1 mm. The authors pointed out that the stearic acid coating placed on brass powder to prevent rapid oxidation clearly affects the process, but uncoated powder would not be a stable item.

CADMIUM

Grosse and Conway[1382] found an ignition temperature of 760ºC for solid cadmium burning in pure oxygen at 1 atm.

CALCIUM

Grosse and Conway[1382] found an ignition temperature of 550ºC for solid calcium burning in pure oxygen at 1 atm. Laurendeau and Glassman[1400] found an ignition temperature of 790ºC for solid calcium burning in pure oxygen at 1 atm. Calcium powder (< 45 μm size) was found to ignite in air[1402] at 222 – 236ºC, and in a CO_2 atmosphere at 293ºC[1396]; in a nitrogen atmosphere, ignition temperatures of 327 – 671ºC were found[1403].

CERIUM, PYROPHOR, AND CIGARETTE-LIGHTER 'FLINTS'

According to one source[3], cerium ignites in air at 160ºC, but according to another[1405], a temperature of 400ºC is needed before cerium pellets ignite in air, and even then it is a mild glow type of ignition. Cerium has been the basis of 'pyrophoric alloys,' first described in 1903 by Carl Auer von Welsbach, and sometimes called *Auer metal*. These comprise about 70 – 80% *misch metal* and about 15 – 30% iron. Misch metal, in turn, contains mainly cerium and lanthanides; a typical composition[90] is Ce 49%, La 25.6%, Nd 16.0%, Pr 4.6%, Sm 2.0%, Tb 1.0%, Y 1.0%, and Fe 0.8%. The term 'pyrophoric' here is a misnomer. The material does not simply ignite upon exposure to air, instead, it functions as an igniter since it is very brittle and easily fractures; filing or scratching produces small readily burning particles. After Auer's invention, cigarette lighter 'flints' were usually produced of Auer metal; these are sometimes known as *pyrophor bars*. Rae[1406] dropped small particles of pyrophor bar onto a heated plate and found that the minimum temperature for ignition was 178 – 207ºC, with most results being around 180ºC. Amalgams of cerium and mercury are pyrophoric[1407].

Cerium powder (< 45 μm size) was found to ignite in air[1402] at 106 – 115ºC, in a CO_2 atmosphere at 172 – 190ºC[1396,1403] and in a nitrogen atmosphere at 216 – 230ºC [1403]. In a nitrogen atmosphere, fine cerium wires were found to ignite at 850ºC[1397].

CESIUM

Cesium is pyrophoric in air or oxygen and violently reactive with water[3].

CHROMIUM

In a CO_2 atmosphere, chromium powder (< 45 μm size) did not visibly ignite, but at 870ºC a slow glowing reaction was found to start[1396]. Fine chromium particles are pyrophoric[1407].

COBALT

Fine cobalt particles are pyrophoric[1407]. Cobalt finds use as a catalyst for polyester resins or drying oils such as linseed or tung oils.

COPPER

Jakowsky and Butzler[1408] ignited copper in an oxygen bomb and found an ignition temperature of 1050ºC at 1 atm, going down to 825ºC at 109 atm. Using a radiant heat source, Abbud-Madrid et al.[1409] ignited bulk copper in an O_2 atmosphere at 1 atm. The surface temperature at ignition was 1087ºC. Because of its very low heat of combustion, copper is difficult to ignite and burn, and most other investigators have reported 'no ignition.' Copper powder of very small diameters (0.01 – 0.03 μm) is pyrophoric[1410].

HAFNIUM

Hafnium dusts are prone to room temperature autoignition[1411].

IRON AND STEEL

Iron is one of the few metals which burns only heterogeneously (at the surface), showing no gas-phase flame. The main reaction takes place at the metal/oxide interface:

$$Fe + Fe_3O_4 \rightarrow 4FeO$$

Grosse and Conway[1382] found an ignition temperature of 930ºC for solid iron burning in pure O_2 at 1 atm. The identical ignition temperature was earlier reported by Jakowsky and Butzler[1408], who also found 600ºC at a pressure of 136 atm. Abbud-Madrid et al.[1409] ignited iron rods in a 1 atm O_2 atmosphere and found a surface temperature of 1197ºC at ignition. Sato et al.[1412] heated up iron rods in an inert atmosphere, then plunged them into a hyperbaric O_2 atmosphere. When plunged into an atmosphere at 5 MPa pressure, a minimum initial specimen temperature of 1280ºC was needed for ignition. Specimens at lower initial temperatures self-heated to an appreciable extent, but no ignition was observed except for tests where the specimen attained a surface temperature of 2930ºC or more. It is not clear why Sato needed higher temperatures for ignition when using hyperbaric oxygen, compared to 1 atm oxygen used by Grosse. Using a very different experiment of an electrically-heated wire, an identical ignition temperature was found by Jakowsky and Butzler[1413], who also documented a nearly linear drop with pressure, the value at 136 atm being 600ºC. Laurendeau and Glassman[1400] found an ignition temperature of 1315ºC for solid iron burning in pure oxygen at 1 atm. White and Ward reported that steel requires 1200 – 1300ºC for ignition in oxygen at ambient pressure[1445]; ignition in air was considered to occur at similar temperatures. Reynolds found that mild steel ignited at 1225 – 1275ºC in air[1414]. He also found that stainless steel ignited at 1350 – 1365ºC in oxygen, but melted without igniting in air. Schutt et al.[1415] found that, with heat generated by rotating stainless steel against stainless steel, an ignition temperature of 1232ºC was obtained in an oxygen atmosphere at 6.8 atm. Accidental ignitions of bulk steel members are rare, but one case has been described where carbon steel heat recovery unit tube fins started burning after long exposure to high temperatures[1416].

Grosse and Conway also measured an ignition temperature of 315ºC for iron powder. Commercial steel wool is ignitable with a match[1417]. Karim and Mehta[1418] tested the autoignition of steel wool in a wind tunnel at an air flow velocity of 4 m s^{-1}. The samples were solvent-cleansed of oil and contaminants before testing and packed to a density of 285 kg m^{-3} in wire baskets. For commercial grade 0 fibers (61 μm dia.) an ignition temperature of 417ºC was found, while for grade 0000 (20 μm dia.) the temperature was 377ºC, with intermediate temperatures for intermediate fiber diameters. Iron powder of very small diameters (0.01 – 0.03 μm) is pyrophoric[1410]. The ignition of small iron particles as function of their specific surface area (area per unit mass of particle) was studied by Evans et al.[1419], with their results given in Figure 101. Particles with a specific surface area higher than about 6 m^2 g^{-1} are pyrophoric, i.e., ignite at or below room temperature. The theory discussed in Chapter 8 indicates that this kind of result is also controlled by another dimension, the size of the pile being tested. Evans et al. describes their vessel only as being of 1 cm^3 volume. This is a very small volume, so much lower temperatures would be expected if a sizable pile were assembled. Stainless steel particles are also pyrophoric, when milled under exclusion of oxygen (i.e., covered with a hydrocarbon liq-

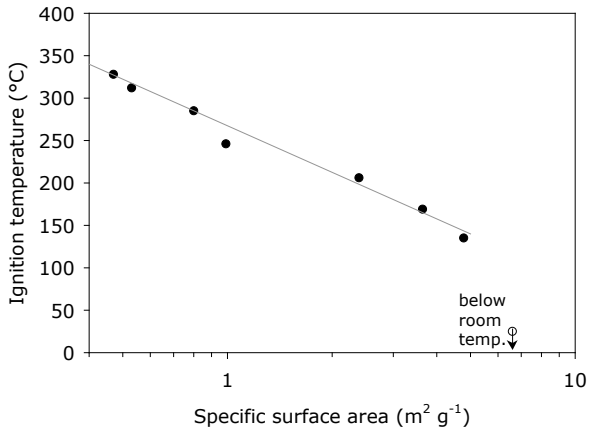

Figure 101 Ignition temperature of fine iron particles, as a function of the specific surface area

uid)[1407]. Ferrous oxide (FeO) is also pyrophoric in small sizes[1407], since it is only partially oxidized; ferrous hydroxide, $Fe(OH)_2$, is even more pyrophoric.

Sponge iron, also known as *direct-reduced iron*, generally produced in lump, pellet, or briquette form, has a notable propensity for self-heating. This is due to its physical form, which is porous and has a very high surface/volume ratio and low thermal conductivity. The density of sponge iron is about half that of pure, non-porous iron. The specific surface area is typically around 1 $m^2\ g^{-1}$. Because of this high surface area, ignition is possible when a pile is stored at ambient temperature[1420]; numerous fires in sea shipments have occurred[1421]. The lump form is somewhat more self-heating prone than the pellet form; the briquette form—especially if hot-molded rather than cold-molded—has the lowest specific surface area and is the least susceptible. Moisture plays a crucial role in self-heating of sponge iron. Alabi[1421] conducted an extensive study on the self-heating of sponge iron. The process involves a multiplicity of reactions and no simple expression for self-heating could be derived. Part of the complication stems from the fact that hydrogen is liberated in low-temperature reactions with moisture, and the hydrogen then reacts with the metal in dry zones, creating a highly activated iron which then leads to thermal runaway upon its oxidation. Additional kinetic studies were reported by Sraku-Lartey et al.[1422] Burning sponge iron does not produce a flame, but rather a red-hot glowing region[1423]. The propagation of reaction is very slow, much as for other smoldering-type reactions. Because of this slow burning rate, a fire can often be controlled simply by pulling out the burning material from the rest of the pile. The hazard of ignition can be reduced by using a similar strategy as in the production of charcoal—weathering the newly-made material in small layers until the surface is somewhat oxidized. Commercial coatings are also available to minimize the hazard. Sometimes ship cargoes are inerted with nitrogen as a safety measure.

Iron powder can ignite at temperatures below 400ºC when combined with a solid oxidizing chemical (e.g., BaO_2, $KMnO_4$, $K_2Cr_2O_7$, etc.) and pressed into pellets[1424]. A number of other elements react in a similar way to iron.

LEAD

Grosse and Conway[1382] found an ignition temperature of 870ºC for solid lead burning in pure oxygen at 1 atm. Laurendeau and Glassman[1400] found an ignition temperature of 850ºC for solid lead burning in pure O_2 at 1 atm. Fine lead particles are pyrophoric, as originally described by Michael Faraday[174].

LITHIUM

Lithium melts at 180ºC and ignites (apart from finely-divided powders) at a higher temperature than its melting point. What that temperature might be, has been an unsettled issue. Grosse and Conway[1382] found an ignition temperature of 190ºC for lithium burning in pure oxygen at 1 atm, but Rhein's survey[1425] found values in the very wide range of 180 – 640ºC. Moisture in air facilitates the ignition of lithium; at relative humidities above 90%, oxidation can be explosive[1425]. The combustion products are Li_2O, LiOH, $LiOH{\cdot}H_2O$, and Li_3N. In nitrogen, ignition temperatures from 170 to 600ºC have been reported. Molten lithium is extremely reactive and is very difficult to extinguish if ignited. Extinguishing agents containing water, foam, CO_2, halons, or the common types of dry powders accelerate combustion[3]. The primary useful extinguishants are those based on graphite powders[1425]. Lithium is a water-reactive substance, with the reaction being:

$$Li + H_2O \rightarrow LiOH + \tfrac{1}{2}H_2$$

but water does not necessarily cause an actual ignition. In one test, lithium at 248ºC was ignited by a water spray[1425]. Lithium reacts either vigorously or pyrophorically with most halogens and halogenated compounds at ambient temperature. Finely divided lithium is pyrophoric in air, water, and argon. In a CO_2 atmosphere, lithium powder (100 μm size) was found to ignite at 330ºC[1396].

MAGNESIUM

Grosse and Conway[1382] found an ignition temperature of 623ºC for solid magnesium and 520ºC for magnesium powder burning in pure oxygen at 1 atm. Laurendeau and Glassman[1400] found an ignition temperature of 635ºC for solid magnesium burning in pure oxygen at 1 atm. Magnesium alloys generally ignite at 500 – 600ºC[1445]. A survey[1426] of other results shows most data to lie between 591ºC and 645ºC, which is just slightly below the melting point of 650ºC. There does not appear to be any significant difference between the ignition temperature in air and that in oxygen. Abbud-Madrid et al.[1409] ignited magnesium rods by radiant heating in 1 atm O_2 atmosphere and found a surface temperature of 977ºC at ignition; this is much higher than obtained by other investigators and presumably was due to the heating technique used. Peloubet has described a study of flashing occurring upon machining magnesium stock[1427]; none of the experiments conducted led to any bulk ignition of material.

The ignition temperature of aluminum is much higher than of magnesium, but tests indicate that magnesium/aluminum alloys have ignition temperatures similar to pure magnesium if they contain about 10% or more of magnesium. For lower magnesium contents the ignition temperature climbs steeply up to the pure-aluminum value[1428]. Etching of magnesium/aluminum alloys in chromic acid has been found to produce a pyrophoric surface which can spark or explode on contact[1455]. This has been attributed to the creation of a powdery condition on the surface.

Ignition of magnesium particles in air was studied by Cassel and Liebman[1429]. For single particles burning in air, they found an inverse relation between particle size and ignition temperature. Particles of 15 μm size required 780ºC, while

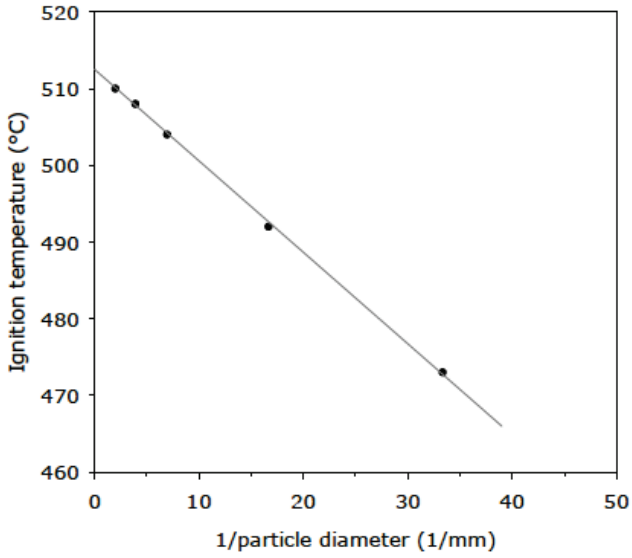

Figure 102 Effect of particle size on the ignition temperature of magnesium

55 µm particles ignited at 650ºC, with intermediate sizes igniting at intermediate temperatures. In dust clouds, lower temperatures suffice for ignition. A cloud of 7 µm particles at a concentration of 165 g m^{-3} ignited at only 525ºC. Magnesium dusts can burn in a CO_2 atmosphere, when ignited by an electric spark. Sparks from grinding operations have been shown to ignite a layer of magnesium dust which was at room temperature[1430].

The effect of particle size on the ignition temperature of magnesium was studied by NBS[191], as shown in Figure 102. Bulk material, described as small pieces of magnesium ribbon, showed an ignition temperature of 540ºC in the same tests. Actual test details, especially the size of pile tested, were not given.

Liebman et al.[1431] studied the ignition of single magnesium particles by laser radiation. They found that the heat flux necessary for ignition was directly proportional to the particle diameter, with

$$\dot{q}'' \approx 10^4 D$$

where $\dot{q}''$ = heat flux (kW m^{-2}) and D = particle diameter (µm). The experimental range covered by this relation was 28 – 130 µm. Laser ignition was different in nature from ignition by hot gases, since ignition did not occur until the particle reached the boiling point and started vaporizing; at that point, the vapors ignite.

In a CO_2 atmosphere, magnesium powder (< 45 µm size) was found to ignite at 749ºC[1396]. In a nitrogen atmosphere (oxygen content < 0.5%), magnesium powder (< 150 µm) was found to ignite at 530ºC[1397]. In another study (< 45 µm size), no ignition was found at temperatures up to 1071ºC[1403]. Magnesium powder is spontaneously flammable when combined with moist iron and chlorine and explodes if combined with chloroform or methyl chloride[1398]. Magnesium powder mixed with silver nitrate does not react, but bursts into flame if water is added to the mixture[1436]. Applying water onto finely-divided magnesium is likely to cause a fire or explosion, due to the exothermicity of the oxidation reaction $Mg + H_2O \rightarrow MgO + H_2$. The hydrogen gas liberated can then burn in a second stage of the reaction. This has led to exacerbation of fires in pyrotechnic manufacturing facilities that were not suitably fought. Magnesium however is not classified as water-reactive because the reaction only takes place in a pre-heated environment, not from ambient temperature. Applying CO_2 to burning magnesium promotes combustion, due to exothermicity of the reaction $2Mg + CO_2 \rightarrow 2MgO + C(s)$. NFPA 480[1432] contains guidance on the flammability of magnesium.

MANGANESE

Grosse and Conway[1382] found an ignition temperature of 450ºC for manganese powder burning in pure oxygen at 1 atm. Eckhoff[512] found that manganese dust in air has an MIE of only around 1 mJ, which means that it is extremely easily ignitable. Fine manganese and manganese nitride particles are pyrophoric[1407]. In a CO_2 atmosphere, manganese powder (< 45 µm size) was not able to ignite in a flaming mode, but at 696ºC it started glowing[1396].

MOLYBDENUM

Grosse and Conway[1382] found an ignition temperature of 750ºC for solid molybdenum burning in pure oxygen at 1 atm. Laurendeau and Glassman[1400] found an ignition temperature of 780ºC for solid molybdenum burning in pure oxygen at 1 atm. A value of 725ºC has also been reported[1426]. A dust layer ignition temperature of 360ºC has been found[1433]. Fine molybdenum particles are pyrophoric[1407].

NICKEL

Nickel powder of very small diameters (0.01 – 0.03 µm) is pyrophoric[1410]. 'Raney nickel' is sometimes described as a nickel/aluminum alloy, but this is only the starting material. In 1927 Murray Raney invented a process[1434] whereby a nickel/aluminum or nickel/aluminum/silicon alloy is pulverized, then leached in a strong sodium hydroxide solution. This dissolves out the aluminum, leaving a highly porous, pyrophoric nickel powder. The powder can be stored indefinitely in a hydrogen atmosphere, but Lee[1435] found that if liquid oxygen is admitted to a vessel that contains Raney nickel and hydrogen, then ignitions at cryogenic temperatures are possible. The lowest temperature at which he documented autoignition was 57 K (–216ºC), but this was limited by the apparatus design and ignition at lower yet temperatures may also be possible. A similar pyrophoric product can be made by alloying nickel, iron, or cobalt with zinc, then dissolving out the zinc[1436]. It has been claimed[1407] that Raney nickel is no longer pyrophoric if aluminum and hydrogen impurities are removed from it, but the validity of this claim is unclear.

PLUTONIUM

Plutonium is considered to be pyrophoric and, under some circumstances, mass plutonium has been known to ignite at room temperatures[1451].

POTASSIUM

Potassium is exothermically reactive with a wide variety of chemicals. It is not pyrophoric in completely dry air, but can pyrophorically ignite in moist air[3]. Grosse and Conway[1382] found an ignition temperature of 69ºC for solid potassium burning in pure oxygen at 1 atm. When exposed to air, the surface of potassium can become oxidized to potassium superoxide, and this compound is highly susceptible to explosion (see *Peroxides*). If dropped into water, potassium ignites and burns, undergoing an analogous reaction to sodium. Potassium is normally stored in kerosene, or a similar substance, to avoid reactions with air.

RARE EARTH ELEMENTS

Rare earth elements are 15 metallic elements with rather similar chemical properties: lanthanum (^{57}La), cerium (^{58}Ce), praseodymium (^{59}Pr), neodymium (^{60}Nd), promethium (^{61}Pm), samarium (^{62}Sm), europium (^{63}Eu), gadolinium (^{64}Gd), terbium (^{65}Tb), dysprosium (^{66}Dy), holmium (^{67}Ho), erbium (^{68}Er), thulium (^{69}Tm), ytterbium (^{70}Yb), and lutetium (^{71}Lu). These elements can show an explosive reaction with halogenated solvents. One study was prompted by an explosion in a grinding mill where the atmosphere consisted of nitrogen and Freon 113 ($C_2Cl_3F_3$). The study concluded that the exothermic halogenation reaction is autocatalytic, and this was seen to be the main reason for the violence of explosion[1437]. Dusts of some rare-metal alloys ($Sm_2Fe_{17}N_3$ in a 2 μm size and $Sm_2Co_{17}Fe_3Cu_4Ce_2$ in a 7 μm size) have been found to explode spontaneously upon dispersion into an explosion test vessel, without use of an ignition source[1438]. *Cerium* is discussed individually above.

RUBIDIUM

Rubidium is pyrophoric and explosively water-reactive; the latter reaction liberates hydrogen gas, which autoignites[3].

SODIUM

Sodium is highly reactive and may, under some circumstances, be pyrophoric; it has a low melting point of 98ºC. Grosse and Conway[1382] found an ignition temperature of 118ºC for sodium burning in pure oxygen at 1 atm. However, the Bureau of Mines[1378] tested 4 g quantities of sodium and found that it ignited in air at 54ºC, but not at 32ºC. Small droplets apparently require a higher ignition temperature, since Richard et al.[1439] found ignition to occur at 200ºC when testing 1 – 3 mm droplets. Yuasa[1440] measured ignition temperatures of sodium exposed to forced air flow in a stagnation-point geometry and found a strong effect of moisture. He reported an ignition temperature of 210ºC for a water vapor pressure of 133 Pa, rising to 290ºC for water vapor pressure of 1370 Pa. Neither the effects of air flow rate nor of specimen size were explored. Akita and Yamashika[1441] conducted experiments where they noted that a protective oxide layer is formed on the surface. When the oxide film was not disturbed, ignition temperatures for cube-shaped samples were found to be 300 – 400ºC, being above the melting point of the oxide (290ºC). However, when the oxide film was mechanically disrupted, ignition temperatures in the range 140 – 210ºC were obtained. Saito et al.[1442] measured the ignition temperature of sodium pools in moving air streams. Flow velocity raised the observed T_{ig} and the lowest value found in air was 115ºC at a flow rate of 5 L min^{-1}. They also produced a relation between the temperature and the oxygen concentration needed for extinction. For 115ºC, oxygen needed to be reduced to 6% for extinction. Below this concentration, there was an inverse linear relation between temperature and oxygen concentration—at 600ºC, the MOC was 2%. There were some anomalous results, however, and it proved possible to ignite the material at 450ºC and 0.5% O_2. They also found that reignition could occur even when the temperature was lowered to 50ºC in nitrogen.

If dropped into water, sodium ignites and burns violently. Three reactions are involved[1443]:

$$Na + H_2O \rightarrow NaOH + ½\ H_2 \quad \text{(evolution of hydrogen)}$$
$$2H_2 + O_2 \rightarrow H_2O \quad \text{(combustion of hydrogen)}$$
$$4Na + O_2 \rightarrow 2Na_2O \quad \text{(combustion of metallic Na)}$$

STRONTIUM

Laurendeau and Glassman[1400] found an ignition temperature of 1075ºC for solid strontium burning in pure oxygen at 1 atm. Finely-divided strontium ignites upon exposure to air[1398].

TANTALUM

According to Reynolds[1414], bulk tantalum ignites at 1240 – 1280ºC in air. Matsuda and Yamaguma[1444] studied the ignitability of fine tantalum powder (polydisperse, with a mass-mean diameter of 31 μm). Using an unspecified test method, they found a layer ignition temperature of 300ºC and a dust cloud ignition temperature of 610ºC. Using a test method somewhat similar to the Hartmann apparatus, but having a flat baseplate, they placed a conical heap of powder (1 – 2 g) upon the flat base and discharged a spark through the middle of the pile. Under those conditions, they found an MIE of less than 0.2 mJ, the latter being the lowest energy level that could be created with their discharge circuit. Repeating the MIE experiments on different types of tantalum dust samples, they obtained 1.3 mJ for one of 70 μm size and 30 mJ for flat particles of 25 μm diameter. In the MIE experiments, they found that the spark did not 'blow away' the dust particles, but explosion was not immediate. At first, a glow formed, and this propagated into a flash only after 1 – 2 s. They also conducted MIE experiments on dust clouds and found a value of 14 mJ for the original 31 μm material.

THORIUM

Grosse and Conway[1382] found an ignition temperature of 500ºC for solid thorium burning in pure oxygen at 1 atm. Under rare circumstances, mass thorium has been known to ignite at room temperatures[1451]. Thorium fires are likely to result in explosion[1451]. Some thorium/silver alloys are pyrophoric[1407]. In air[1402], ignition temperatures of 280 – 466ºC have been reported for particles sizes of 7.2 – 45 µm. In a CO_2 atmosphere, thorium powder (< 45 µm size) was found to ignite at 330ºC[1396]; in a nitrogen atmosphere, an ignition temperature of 620ºC was found[1403].

TIN

Grosse and Conway[1382] found an ignition temperature of 865ºC for solid tin burning in pure oxygen at 1 atm. Abbud-Madrid et al.[1409] ignited tin rods by radiant heating in 1 atm O_2 atmosphere and found a surface temperature of 883ºC at ignition. Laurendeau and Glassman[1400] found an ignition temperature of 940ºC for solid tin burning in pure oxygen at 1 atm. Finely-divided tin may be spontaneously flammable[1398].

TITANIUM

Titanium is one of the few metals where, as the temperature is raised, the metal oxide dissolves in the molten metal. In air, the AIT of bulk titanium is in the range 1200 – 1600ºC[1449,1447]. At ambient pressure, the ignition temperature in air and in oxygen is similar. The ignition temperature decreases with increasing oxygen pressure, going down to about 800ºC in pure oxygen at 20 atm. The ignition temperature is lowered if the material is thin and is being subjected to a very rapid heating rate. In a study on 0.1 mm thick strips (surface/volume ratio = 20 mm^{-1}), an empirical equation was proposed:

$$T_{ig} = 338 + 4.97 \times 10^5 \dot{T}^{-2}$$

where $\dot{T}$ = heating rate (ºC s^{-1}). The mechanism is suggested to be the formation of local hot spots under these conditions. Specimens with surface/volume ratio greater than about 5 to 10 mm^{-1} should be considered as 'thin' and therefore igniting at a lower temperature, but the size effect has been quantified neither for constant-temperature nor rapid-heating conditions. At the extremely small sizes comprising powders or dusts, reported ignition temperatures are very low. Bulk titanium sheets can be ignited at ambient oxygen conditions and room temperature and pressure by discharging a 1 – 10 J spark onto the surface[1445].

In pure oxygen atmospheres at high pressures, bulk titanium can ignite at room temperature or lower[1446], but these may be piloted forms of ignition, rather than autoignitions due to a uniform rise in temperature. It can be spark ignited at ambient pressure and temperature in an oxygen atmosphere. At room temperature, but in high-pressure gaseous oxygen, titanium can be ignited by projectiles or mechanical impact[1447].

The ignition temperature of fine titanium particles was characterized by Evans et al.[1419] as shown in Figure 103. The powder was tested in a tiny vessel of 1 cm^3 capacity, so much lower temperatures would be anticipated if a sizable pile were assembled.

Titanium sponge[1405] ignites (glowing ignition) at 580ºC. Grosse and Conway[1382] found an ignition temperature of 480ºC for titanium powder burning in pure oxygen at 1 atm. In air at ambient temperature, titanium dust can be ignited by an electric spark of 25 mJ[1433]. Strobridge et al. reported that fine titanium powder can ignite spontaneously in air at room temperature and pressure[1449], however according to a survey by Rhein and Baldwin[1447], most of the reported temperatures for ignition of the powder in air are in the range of 250 – 600ºC.

When used in systems which also contain iron, titanium may undergo a thermite reaction:

$$Fe_3O_4 + 2Ti \rightarrow 2TiO_2 + 3Fe$$

This has been the cause of some accidents where oxyacetylene cutting torches were used on equipment made of titanium and steel[1448]. The primary combustion product is TiO_2, although TiO and various other oxides are also found.

The combustion of titanium used in aircraft gas turbine engines has been studied by Strobridge et al.[1449] They point out that under normal operating conditions, titanium components will not ignite, since the service temperature to which titanium parts are designed is about 427ºC, which is significantly lower than the temperature at which titanium ignites in air. Nonetheless, during 1957 – 1979, at least 144 titanium engine combustion incidents were recorded. The incidents arise due to mechanical heating, such as rubbing, or due to stall conditions.

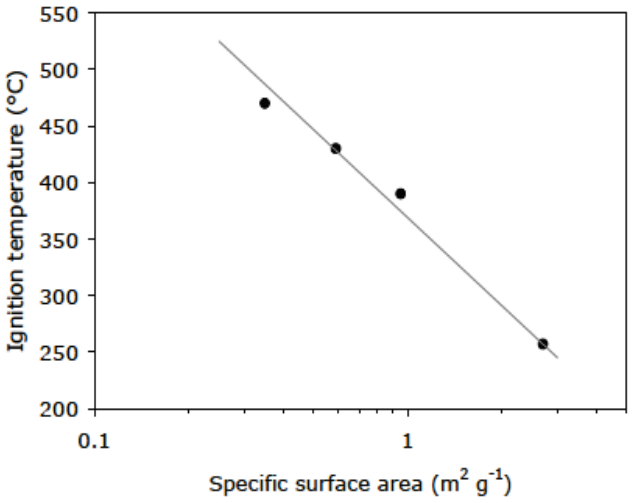

Figure 103 Effect of particle specific area on the ignition temperature of fine titanium particles

Titanium can also ignite in atmospheres of CO_2 or nitrogen. Titanium/aluminum alloys are generally more resistant to ignition than is pure titanium. In a CO_2 atmosphere, titanium powder (1 – 5 µm size) was found to ignite at 670ºC[1396]. In a nitrogen atmosphere, titanium powder was found to ignite at 760 - 800ºC[1397]. The ignition of titanium and its alloys under specialized conditions of impact, explosive loading, or liquid oxygen has been reviewed by White and Ward[1445].

Most conventional extinguishing agents cannot be used on titanium fires. Effective extinguishants[1447] include argon, trimethoxyboroxine, sodium chloride, graphitic powders, sodium or calcium carbonate, silica, and possibly TEC (20 mass% NaCl, 20% KCl, 51% $BaCl_2$).

TUNGSTEN

Reynolds[1414] found that tungsten ignited at 1240 – 1275ºC in air.

URANIUM

In one study, bulk uranium was reported[1414] to ignite at 320ºC in oxygen, and in another study[1450] at 500 – 600ºC in air or oxygen, but such elevated temperatures are normally not needed. In fact, uranium is so pyrophoric that it has been documented to ignite spontaneously at room temperature, while resting on dry ice, under vacuum, and even under water[1451]. On the other hand, experiments have been conducted where it has been heated to its melting point without igniting. In air[1402], ignition temperatures of 100 – 157ºC have been reported for powders in the range of 10.8 – 75 µm size. Tetenbaum et al.[1452] developed a theory for the ignition of uranium powder and this has been presented in Chapter 8. Self-heating theory indicates that, for a pile of material, an ignition temperature cannot be uniquely associated with a particle size, but, rather, also depends on the size of the bulk volume. When tested in a 9.5 mm diameter crucible, their smallest particles (specific surface area of 72 m^2 kg^{-1}) ignited at 245ºC. In a CO_2 atmosphere, depleted uranium powder (< 75 µm size, coated with 2% Viton) was found to ignite at 235ºC[1396]; in a nitrogen atmosphere, ignition temperatures of 354 – 360ºC were found[1403]. Carbides and nitrides of uranium are known to be pyrophoric, as are many intermetallic uranium compounds, including UBi, UBi_2, U_5Sn_4, U_3Sn_5, UPb and UPb_3.

ZINC

Grosse and Conway[1382] found an ignition temperature of 900ºC for solid zinc burning in pure oxygen at 1 atm. Abbud-Madrid et al.[1409] ignited zinc rods by radiant heating in 1 atm O_2 atmosphere and found a surface temperature of 787ºC at ignition. Laurendeau and Glassman[1400] found an ignition temperature of 905ºC for solid zinc burning in pure oxygen at 1 atm. Etching of zinc/aluminum castings in chromate solutions has been found to lead to pyrophoric ignition upon drying[1455]. This has been attributed to the creation of a residue of aluminum powder on the surface. Zinc powder can self-heat if exposed to moisture; fires due to this cause have been known since at least 1876[1453].

ZIRCONIUM

The melting point of its oxide is higher than that of the metal, and, as the temperature is raised, the melting oxide tends to dissolve in the molten metal. Abbud-Madrid et al.[1409] ignited zirconium rods by radiant heating in 1 atm O_2 atmosphere and found a surface temperature of 1282ºC at ignition. Beal et al.[1454] found that 854ºC is the ignition temperature for zirconium wires, both in air and in pure oxygen. They also found that molten drops of zirconium, dropped in either oxygen or air atmospheres, explode after they have fallen for a short distance. Explosions have also occurred in accidents where zirconium has caught fire[1451]. Grosse and Conway[1382] found that zirconium powder will ignite at room temperature in pure oxygen at 1 atm, although another study claims that an elevated pressure is needed[1446]. Testing in room air at 54 and 82ºC showed no reaction[1581], but there are some reports that ignition is possible in room temperature air in the presence of a spark[170]. Ignition temperatures in air have been reported as 210ºC (for < 45 µm particles) and 190 – 240ºC (for 3.0 – 3.3 µm particles)[1402]. Friction has been sufficient to ignite zirconium in air, at room temperature[1451]. Some of the zirconium accidents have been attributed to effects of moisture.

Zirconium sponge[1405] ignites (glowing ignition) at 870ºC. Finely divided zirconium can ignite at room temperature[1455]. The pyrophoricity of zirconium powder is highly dependent on particle size—powder of 3 µm is highly pyrophoric in air, while 12 µm size "does not catch fire at red heat"[1410]. To prevent unwanted ignitions, fine-size zirconium powder is stored under water. Zirconium powder is no longer pyrophoric and shows an ignition temperature of 300 – 400ºC, instead of 20ºC if it has[1456] (a) moisture content

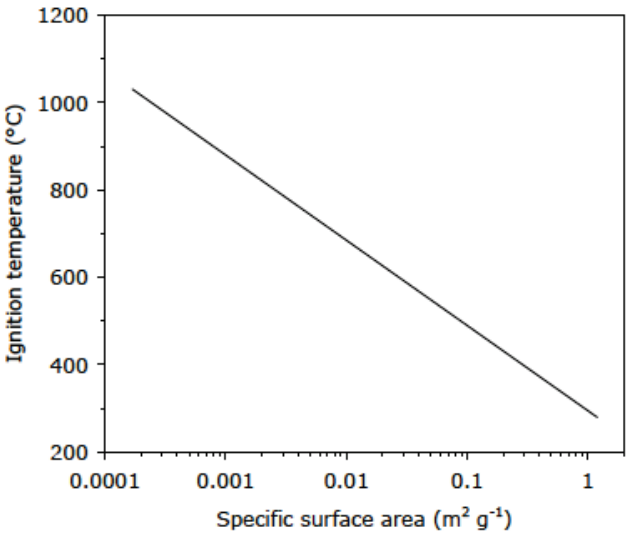

Figure 104 Effect of particle specific area on the ignition temperature of fine zirconium particles

greater than about 4%; or (b) ZrO_2 mass fraction greater than 45%; or (c) the oxygen content is reduced to about 10%. The effect of particle size, expressed as the specific area, on the AIT of zirconium powders is shown in Figure 104 from the work of Schnitzlein[1457], although his study did not extend down into the pyrophoric regime. Anderson and Belz[1458] also reported studies of this kind. The ignition temperature, using a 1 g quantity of material placed in a crucible, ranged from around 135 to 214ºC for material of 1 – 3 $m^2 g^{-1}$; the spread was due to differences in purity and preparation of the samples and did not correlate just to the specific surface area.

Zirconium powders and dusts may also ignite in atmospheres of CO_2 and of nitrogen. In a CO_2 atmosphere, zirconium powder (3 μm size) was found to ignite at 363 – 366ºC[1396]. In a nitrogen atmosphere, zirconium powder (< 45 μ) was found to ignite at 530ºC[1397]. Dust clouds of zirconium are considered especially hazardous, since static electricity generated in their dispersal may be sufficient to ignite them[1459]. Some alloys of zirconium with gold, silver, or copper can ignite upon rubbing[1407].

Methane and natural gas

For many years, incorrectly low values of the AIT have been published for methane in various compilations. Recent work indicates that the value is 600ºC or higher. Using a spherical vessel of 0.8 L, Robinson and Smith[1460] determined the value to be 601ºC for a boric-acid coated vessel and 612ºC for plain stainless steel. The minimum AIT was found at a methane concentration of 7% and ignition time was 17 – 20 s at the AIT. The effect of concentration was found to be very small, however, with mixtures of 2.7% and 10.0% both igniting at 616ºC in the stainless steel sphere. BM[1463] examined the effect of elevated pressure on the AIT of natural gas. At a pressure of 610 atm (the only pressure studied), the results were found to be strongly dependent on the gas concentration. At a 2.2% concentration, an AIT value of 319ºC was found, dropping to 242ºC for 14%.

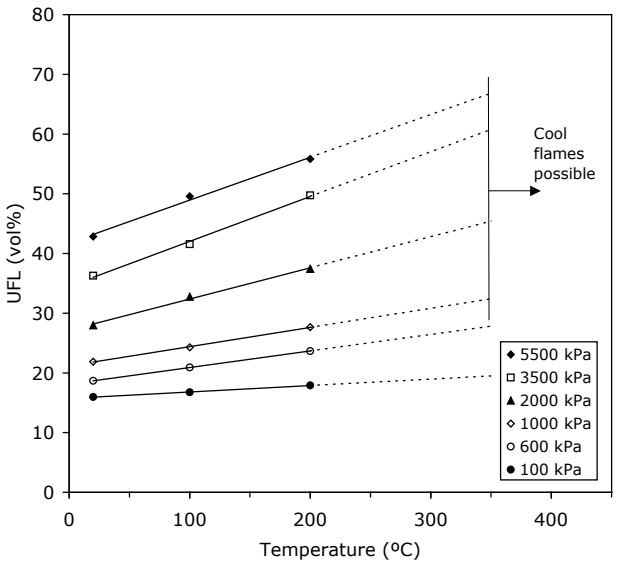

Figure 106 The effect of elevated pressure and temperature on the UFL of methane/air mixtures

Cashdollar et al.[1461] reported a recent series of measurements on the flammability limits of methane in air, and these confirm the traditionally-reported limits of 5% and 15%. The flammable and non-flammable zones of methane in air[1462] are shown in Figure 105.

Raising the pressure, temperature, or both will expand the

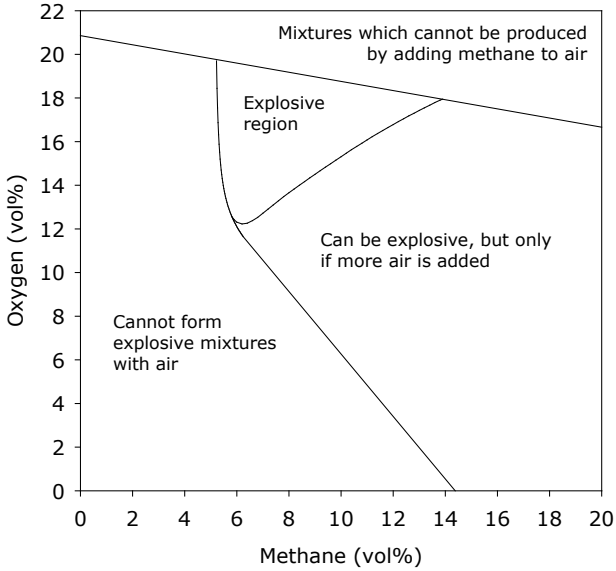

Figure 105 The limits of flammability of methane in air (nitrogen % = 100% – oxygen % – methane %)

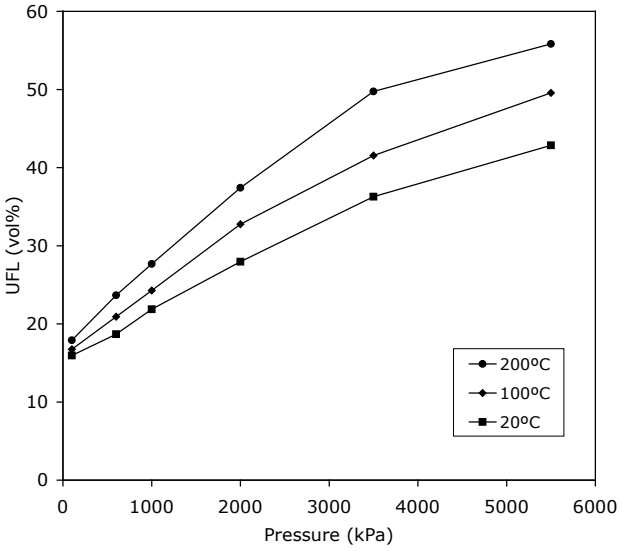

Figure 107 The dependence of the UFL of methane/air mixtures on pressure

flammable region. Data obtained by BM[1463] on natural gas show that for a pressure of 680 atm, the LFL drops to 2.3 vol%; for pressures between 1 atm and 680 atm, a linear dependence on pressure is seen. For the UFL, Vanderstraeten et al.[1464] obtained the results shown in Figure 106, which show a linear dependence on temperature. The same results plotted as a function of pressure (Figure 107) shows a dependence which is not linear. It can also be shown that these results can be linearly fitted by an ln(*P*) function at high pressures, but a logarithmic function would not represent well the lower-pressure regime. The pressure dependence of methane's UFL is *not* identical to that for natural gas, which shows values substantially higher at 20ºC, the only temperature for which data have been published (see Chapter 4).

Using the same apparatus, Caron et al.[1465] examined methane/air mixtures containing 30 – 85% methane at pressures of 500 – 2700 kPa. Even though their lowest concentration studied, 30%, is above the 1-atm UFL, they were able to get both normal flame and cool flame ignitions. At a vessel temperature of 410ºC, it was possible to obtain cool flame ignitions for fuel concentrations over 40 vol% and pressures over 500 kPa. At the same temperature, normal flame autoignitions were documented for system pressures over about 700 kPa. The optimum fuel concentration for normal flame ignition was 40%, with lower and higher concentrations requiring greater pressures. System temperatures above 410ºC did not change the outcome substantively, but for lower temperatures some very high pressures were required. For example, at 350ºC, about 3500 kPa was required for a cool-flame ignition. In general, their results suggested that above about 350ºC, cool-flame ignitions are possible at elevated pressures which are not extremely high, as indicated in Figure 106. For a fuel concentration of 60%, the authors provided two Semenov-type correlating equations:

$$\ln\left(\frac{p_i}{T_{cf}}\right) = \frac{14.53\times10^3}{T_{cf}} - 21.42$$

or

$$\ln(p_i) = \frac{13.88\times10^3}{T_{cf}} - 13.92$$

where p_i = initial pressure (kPa), and T_{cf} = sub-ignition temperature (minimum temperature for a cool flame ignition). Similar expressions were not provided for any other fuel concentration values. Melvin[1466] provided some limited data showing that at 10.4 MPa and 351ºC, even mixtures containing 90% methane are flammable.

The detonation limits of methane in air are approximately 6.3 – 13.5%. Pure methane[26] does not detonate in air, at 1 atm, unless the diameter of the pipe or vessel exceeds about 0.15 m. It should not be inferred from this that a similar limit pertains to natural gas; as discussed in Chapter 4, natural gas is easier to detonate than pure methane. Nitrogen dioxide (NO_2) has a strong effect in lowering the ignition temperature of methane[1467]. Adding 0.1% NO_2 to a methane/air mixture was found to lower the ignition temperature by roughly 120ºC.

See also: *LNG and LPG*.

Methyl bromide

Methyl bromide, CH_3Br, has sometimes been used as an extinguishing agent. In the standard Bureau of Mines 50 mm flame propagation tube it does not show any flammable range. Measured in a 2.5 L bell jar, an LFL of 13.5% and a UFL of 14.5% were reported[1468]. This would seem to imply very limited combustibility, but the idea was proven wrong by an explosion of a large storage tank containing methyl bromide and air under pressure[1469]. It turns out that at larger diameters the flammability limits are about 10 – 15% at 1 atm. But the flammability limits are strongly affected by pressure, and at 5 atm the range becomes 8 – 20%.

Methylene chloride

Methylene chloride, CH_2Cl_2, is a solvent commonly used as paint stripper. It is often described as "non-flammable," but this should not be taken literally. According to Coffee et al.[1470], violent explosions are possible at elevated temperatures or pressures. At a 1 atm pressure, the lowest temperature for flammability is 103ºC, at which the LFL and the UFL are identical at 15.1%. The flammability limits broaden at higher temperatures and at 258ºC the LFL is 13.1% while the UFL is 20.6%. Flammable behavior is also found at room temperature if the pressure is raised to 1.7 atm or higher. Methylene chloride is also flammable at 1 atm and 25ºC if it is present in a pure-oxygen atmosphere[1471]; in that case, the LFL is 13.5%. Many other chlorinated solvents that are "non-flammable" under ordinary circumstances are similarly flammable if temperature, pressure, or oxygen concentration are raised. Kuchta et al.[1471] give these details for a number of such solvents.

Microwave ovens

Miyazaki[1472] measured the time that it takes for small (40 – 80 g) portions of various foods to ignite when heated in a 500 W microwave oven. For the items that did ignite, ignition took 9 – 28 minutes. A correlation was found between ignition time and the water content of the food, with dry foods igniting quickest. It has been reported that broken carrots ignite particularly easily in microwave ovens and it has been speculated that this may be due to either their relatively high content of metals or else due to sharp edges distorting the electric field, but scientific studies are not available on this point. Sloan[1473] documented the ignition of a microwave oven in which the owner inadvertently set the timer for 40 min, instead of 4 min, in order to heat a small dish of food. The top of the cooling cavity had a thermoplastic liner and this ignited from the flaming food.

Mineral wool

This term is used somewhat differently in North America (and in this book) versus in Europe. In North America, it

means a product made from molten basalt or other minerals that has a softening point of 1000 – 1100ºC. In Europe, that particular product is known as *stone wool*, while mineral wool is a more general term that encompasses both stone wool (also called rock wool) and glass wool. The latter has a softening point of 700 – 800ºC and is made from glass (typically from silica, sodium carbonate, and calcium carbonate). Mineral wool insulation has a low organic content (ca. 5%) of a binder, commonly phenol formaldehyde. Even though the organic content is low, the thermal conductivity is also low, thus self-heating is possible and spontaneous combustion has occurred in stored stocks which have not been adequately cooled. The material can also smolder under some circumstances if subjected to external ignition sources. The exothermic mechanism is considered to be primarily a polycondensation of phenolic alcohols, although oxidation is also involved[1474]. Typical values are: $\lambda = 0.06$ W m^{-1} K^{-1}, $\rho = 175$ kg m^{-3}, $E = 56.54$ kJ mol^{-1}, $P = 35.4$, $QA = \beta \cdot 2.3\times10^{9}$ W kg^{-1}, β = organic fraction (--), and $C = 920$ J kg^{-1} K^{-1}.

Motor vehicles

The vast majority of motor vehicle fires[1475] involve passenger cars, as shown in Table 156.

Statistics[1476] for the cause and origin of automobile fires are shown in Table 157 and Table 158; 'Accidental, non-vehicular' typically means a structure fire that ended up burning a vehicle. Vehicle fires represent about 20% of all reported fires in the US and 24% in the UK. Unintentional automobile fires peak during the evening rush hour, while incendiary fires peak around midnight[1475]. Only about 0.1% of reported automobile collisions involve a fire, although the statistics on this point are fairly scattered[1477].

In more recent years, intentionally-set automobile fires have dramatically increased in the UK, with the 1998 statistics indicating that 67% of automobile fires are now deliberate[1478]. Of the accidental fires, smokers' materials account for about 10%.

In 1988 Cole collected statistics on the cause of over 200 automobile fires investigated by his firm that involved neither arson nor collision[1479]. The results are given in Table 159. A very substantial number of the fires was because of faulty or amateur repairs. Many were due to persons making repairs improperly reconnecting lines carrying ignitable fluids. Others were due to leaving wire bundles or combustible hoses close to heat-producing parts. One interesting fire was identified due to: "Shop left rag in engine compartment." Curiously, in his sample no fires were attributed to accidental ignitions by occupants of upholstery or other combustible interior finishes.

Cole also reports on the results of an insurance company survey in California in the mid-1980s[1480]. Of 1448 incidents examined, the cause could not be determined for 778; the results for the ones where the cause was successfully determined are given in Table 160. Note that arson, collision, and structure fires are not excluded from this tabulation. An official California state report[1481] for 1975 gave the breakdown shown in Table 161.

The above two studies do not identify any causes as being

due to backfiring of the engine. Statistics from the State of Florida listed 10% of vehicle ignitions as being due to backfire[1482], while national US statistics indicate 11.5%[1475]. A US Federal government survey[1483] identified that 0.18% of collisions result in a fire and that 20% of these fires involve a fuel leak. Most collision-induced fuel leaks do not lead to a fire, in fact, in the survey it was found that only 7.5% did. Within the US[1484], an average of 2.7% of motor vehicle fatalities involve fire, but there is a tremendous variation state-by-state, with the range being 0.1 to 5.3%.

The question is often raised whether vehicle age or model year have a significant effect on ignition of automobile fires. The last study[1485] on this topic is now fairly old, covering only pre-1985 vehicles. It was also limited solely to collision-caused fires. In that study, there was negligible effect of car age, but a strong effect of model year. 1969 year vehicles had 2.6 times the probability of fire, per collision, than did 1984 year vehicles, with intervening years showing intermediate results.

If an automotive fire occurs shortly after a vehicle is stopped, there is a good possibility that the cause is a fuel leak[924]. In numerous cases, if a fuel system leak occurs and the vehicle is moving, air flow may blow away the fuel. However, once motion stops, fuel may start to accumulate in locations where a hot surface can cause ignition. In actual automobile fire tests, it is found that gasoline or brake fluid leaking onto a hot manifold will not ignite without a flame or spark (e.g., errant spark plug wire), but that automatic transmission fluid and power steering fluid will[1480]. Engine oil can also be ignited in the same manner.

Fires ignited from electrical faults in the dash are likely to end up consuming most of the vehicle combustibles, but fires originating in engine-compartment faults are more likely to be confined solely to the engine compartment[1486]. In the case of more severe engine compartment fires, ignition of passenger cabin materials is more likely to occur if the windshield breaks out.

In field tests, it was shown[1506] that it is not difficult for an abusively stalled automatic transmission to set the engine compartment on fire. It was also claimed that it is not possible to create a sustained fire by overheating a rear wheel bearing, however, there is positive experience to the contrary, where an overheating bearing ignited a tire[1487].

Motor vehicles used in fighting wildland fires have been known to burn down due to embers being sucked in with the combustion air supply and igniting a paper or plastic air filter[1488]. Ember separators are required by NFPA 1901[1489], but are not always fitted.

An in-depth study of 21 collision-caused fires[1490] indicated that the most common location for the initial ignition is the engine compartment, but that passenger compartment combustibles are subsequently ignited very quickly, most commonly "immediately" to within 5 minutes.

While fuel tanks may contain a sizable amount of fuel, the fraction of automobile fires which originate in the fuel tank area is small, estimated[1491] to be 2.2% in the US. For automobile fires due solely to collisions, about 9% originate in the fuel tank area. Also, despite repeated portrayals in films, it is exceedingly rare that a gasoline tank will explode. Perhaps surprisingly, this also includes modern polypropylene tanks. Hollywood stunt technicians typically blow cars up by using a detonating cord to shatter a concealed firebomb (Molotov cocktail)[1492]. The primary reason is because the tank's air space will be above the UFL, except in extremely cold climates. This has been demonstrated by throwing lighted matches into the filler neck. The tank is also not built to withstand significant pressure, and if external

flames impinge upon it, venting will occur. This behavior has been demonstrated in a number of full-scale ies[1493-1495]. About the only simple way to explode a tank is to drain it of all the liquid. The vapor remaining will then likely be within the flammable region and could be exploded. This has also been demonstrated in numerous accidents where welding was attempted on an 'empty' tank. In a serious automobile fire, while the gasoline tank is unlikely to explode, the gasoline will likely become eventually involved. This occurs when the fuel pipe or the filler pipe fail, or when the tank itself begins to leak fuel. Crashes that destroy the integrity of automotive gasoline tanks are of two basic types: (1) compression of tank, resulting in a violent expulsion of contents (in this mode commonly the first release of fuel is through a popped-off sender unit); or (2) a simple puncture, resulting primarily in gravity drainage. Unfortunately, a NIST study[1496] indicated that ignition of the fuel is readily likely in both scenarios.

A vehicle may be fueled with relatively cold gasoline, then brought into a warmer environment. If the tank is overfilled, the liquid will expand and liquid or vapor will be expelled, depending on fuel system particulars. A case is reported where a car in this condition was parked in a garage where an extension cord was shorting out[1497]. Vapors coming out from the overfilled tank then ignited at the cord fault. An unusual incident occurred with a vehicle towing a boat up a long, steep hill when a broken muffler allowed exhaust gases to directly impinge on a metal fuel tank[1498]. The filler neck ruptured, allowing fuel to get ignited. The entire vehicle was engulfed in flames in a few seconds.

If an automobile is ignited and others are parked nearby, it is likely that radiation from the original fire will ignite the other automobiles, although the process generally progresses slowly. Joyeux[1499] conducted fire tests on a variety of European cars of 1980s – 90s vintage. The tires of a nearby car typically ignited in 10 – 20 minutes after the ignition of car #1, even though the fire spread in car #1 was rapid, since a window was left open and a seat cushion was ignited in a flaming mode. Tires were invariably the first portion of car #2 to ignite. Target tires were also exposed that were not affixed onto vehicles. These ignited at the maximum distance explored, 1.25 m. See also: *Tires and wheels*.

FLAMMABILITY OF INTERIOR COMBUSTIBLES

The flammability of passenger compartment materials used in automobiles is measured in the US by the MVSS 302 test discussed in Chapter 7. This is a remarkably lax test standard and materials passing the test may be exceptionally easily ignitable (and exhibit rapid flame spread and high HRR). Data to illustrate this point were collected by Hirschler[1500], as shown in Table 162. At both the higher irradiance (40 kW m^{-2}) and the lower (20 or 25 kW m^{-2}), the ignition times for the general-purpose plastics were much longer.

Table 162 Median piloted ignition times (s) for specimens tested in the Cone Calorimeter

Specimens	Heat flux	
	20–25 kW m^{-2}	40 kW m^{-2}
general-purpose plastics	479	85
automotive passenger compartment materials	59	26

AUTOMOBILE EXHAUST SYSTEMS

Exhaust systems of automobiles have the potential to ignite dry vegetation. Ignition can occur due to two different mechanisms: (a) contact of vegetation with heated automobile surfaces; or (b) ejection of hot material (e.g., broken pieces of catalytic converters) from the tailpipe. Automobile manufacturers normally consider the region up to 300 mm above ground the level as the zone where exhaust system temperatures should be restricted in order to minimize vegetation ignitions. Ignitability testing of forest fuels (see *Forest materials, vegetation, and hay*) showed that dry vegetation at 550ºC ignites within a few seconds, as would occur during driving. Conversely, when exposure times are of many minutes, temperatures of 350 – 400ºC suffice. Depending on the type of vegetation, some material can be loose and land on or be trapped on hot parts of the system (e.g., while driving over a cut field of hay or grain). With an extended residence time, this vegetation can be ignited, then drop down and ignite the field material.

In a typical exhaust system, temperatures gradually decrease down the length, although the catalytic converter may be a localized hot spot, since additional oxidation is being promoted there. Bends in the exhaust pipe also correspond to temperature deviations, thus often the highest temperature is found near the first bend of the exhaust pipe. Of course, actual temperatures vary widely with load, driving conditions, and engine conditions (e.g., malfunctions). In one study[1501], values from 174ºC to 457ºC were measured on exhaust systems, with the bulk of the temperatures being in the 200º – 400ºC range. In another study[1502], peak temperatures of 450 – 600ºC were recorded under difficult driving conditions. These US studies did not identify the heights at which different temperatures were observed. An Australian study[1503], however, did specifically examine temperatures at heights ≤ 300 mm from the ground. With the exception of one vehicle (an old, Wankel engine model) that showed a peak of 548ºC, the peak temperatures on other automobiles were found to be in the range 290 – 468ºC during strenuous uphill driving. The authors also conducted laboratory tests on exhaust systems that were brought to a certain temperature and then allowed to cool down naturally as vegetation was applied to the surface. The results were highly variable, but both glowing and ignitions were found when the metal starting temperature was 400ºC or higher. Glowing was usually reported as "immediate," but flaming always took at least 20 s to develop, even at a starting tem-

perature of 525ºC. There appeared to be no significant difference between the ignitability of grass at 0% and 11% moisture.

The conclusion from the above studies is that driving almost any automobile in vegetation of moderate (under 300 mm) height is unlikely to result in ignitions, but parking on dry vegetation could cause ignitions, as could driving in very high (> 300 mm) vegetation. Further conclusions from a California study were[1504]:

- under normal engine operating conditions, catalyst-equipped cars do not show higher exhaust system temperatures then older non-catalyst cars;
- under misfire conditions, catalyst cars develop higher exhaust temperatures than non-catalyst cars, but misfire is relatively rare in modern cars;
- the highest exhaust system temperature occur during misfire and not due to other problems (overly rich mixture, timing errors, excessive cranking);
- radiant heat from a catalytic converter is too low to ignite grasses, actual contact is needed;
- highest exhaust system temperatures occur with ignition misfires at high speed under high load; however, the motion of the vehicle under those conditions is fast enough that ignition will not occur.

The highest exhaust system temperature recorded during strenuous uphill driving in the California study was 604ºC under normal conditions and 688ºC under misfire conditions; these temperatures were within 300 mm of the ground. Claims that asphalt could be damaged by stopped catalytic-converter equipped cars were said to be disproved, since only an 8ºC rise was found under severe conditions. But the value appears to be very low and it may be that much greater temperatures occur under conditions somewhat different from those tested.

A modest temperature *rise* can occur in the peak catalytic converter temperature after the engine has been turned off; Hoffman et al.[1505] report measuring a rise in the vicinity of 40ºC. Field tests[1506] showed that, while an overheated catalytic converter may ignite dry grass, unless large amounts of vegetation are present, this fire will normally not propagate to ignite combustible parts of the vehicle.

Bertagna[1507] studied catalytic converter caused fires which originated from expulsion of hot material from the tailpipe and provided details on 39 fires investigated during 1985-1996. In a majority of the incidents, the vehicle caused more than one fire, with hot particles being repeatedly ejected as the vehicle traveled along a vegetated area. A typical failure of a converter is precipitated by an electronic ignition system malfunction; this leads to raw fuel being sent into the exhaust system. Temperature rise of the catalytic converter is proportional to the amount of material reacting within it, but the design of these devices only anticipates that minor amounts of unburned combustion products will enter into the converter, not sizable quantities of gasoline. Consequently, the unit overheats and melts down. The effect has been described as "fusees being thrown out of the vehicle" or "a steady stream of fire coming out of the exhaust system." Possible signs of a catalytic converter melt-down include:

- vehicle runs very rough
- backfiring
- vehicle seems to lose power.

The vehicle does not have to be old for this failure mode, with some failures being found on vehicles of less than 15,000 km. Identifying catalytic converter pieces can be difficult for the fire investigator, because the particles are non-magnetic and may resemble a light-grey pebble. The pieces range in size from very small up to 25 × 50 mm. Pieces have been found as much as 10 m away from the edge of the road, although most pieces are found within 1.5 m. Unlike fires caused by overheated metal-work, converter melt-down fires are not related to driving conditions such as pulling a heavy load or driving up a long hill. Apart from fires caused by expulsion of hot materials, Bertagna also documented that hot-surface ignitions of vegetation occur "instantaneously" once the vehicle comes to stop on dry grass. In several cases, occupants exited the vehicle as flames were already appearing underneath it because the vegetation was on fire.

A catalytic converter can also overheat due to an improperly functioning engine and ignite undercoating or carpeting inside the vehicle. A fire was documented originating from a converter that was missing a heat shield which allowed ignition of carpet at the front passenger seat location[1508]. Another case involved a car that was started in cold weather with a manual choke. The car was allowed to run for 30 minutes with the choke on. The converter overheated, melting carpeting and items in the car directly above it.

AUTOMOTIVE AIR BAGS

The first experimental airbags tested in the 1970s used compressed gas to rapidly inflate airbags in the steering wheel or in the dashboard to cushion the impact of drivers or passengers in the event of frontal collisions. Many compressed gas systems use a pyrotechnic charge to rupture the burst disc and also as a heat source to compensate for the adiabatic cooling during expansion of the compressed gas. These 'hybrid' units are still in use in some older automobiles. The first experimental all-pyrotechnic inflators used a double-base rocket propellant with a liquid fluorocarbon coolant, similar to slide inflators on the early models of Boeing 747 airplanes. The first all-solid propellant gas generators used sodium azide with iron(III) oxide or potassium nitrate as the oxidizer. The advantage of sodium azide-based gas generators is the clean nitrogen exhaust they produce, meeting all exhaust gas specifications issued by the automobile manufacturers. Sodium azide is very toxic and may form friction-sensitive metal azides when in contact with copper or lead. During the 1990s, sodium azide began to be gradually replaced by non-azide inflators in

new vehicles. Only after the automotive manufacturers relaxed their CO emission restrictions, was the inflator industry able to supply non-azide inflators, mostly based on high-nitrogen organic solids.

Currently used non-azide gas generators include:

a) 5-aminotetrazole with sodium nitrate or strontium nitrate as the oxidizer.
b) nitrocellulose/nitroglycerin extrudates.
c) copper hydroxide nitrate + cobalt(III) hexammino nitrate extrudates.
d) guanidinium nitrate/copper hydroxide nitrate/copper(II) oxide/sodium nitrate-ammonium perchlorate.
e) azodicarbonamide/alkali metal nitrates.
f) silicone/sodium nitrate-ammonium perchlorate.
g) stabilized ammonium nitrate/HMX/binder.

In addition, current-generation gas generators use typically boron/potassium nitrate as initiating material in the ignition train.

The pyrotechnic material inside an automotive air bag is heat sensitive, and it is normally expected that it will activate during a vehicle fire, since the critical temperature of 150 – 175ºC will be exceeded. What is not normally expected is a violent projectile, but at least one case has been documented in detail. In that incident[1509], the main steel portion of the inflator assembly created a large divot in the vehicle's roof, then was expelled some 4.5 m away from the vehicle. Meanwhile, two large rivets pierced the roof like bullets. ISO has produced a draft standard (ISO CD 12097-3[1510]) for airbags that entails an exposure-fire test; passing such a test would minimize the likelihood of dangerous projectiles.

FLAMMABLE REFRIGERANTS

In most countries, traditionally automotive refrigerant fluids were required to have low flammability. But after concerns were raised about ozone depletion, some regulations were relaxed and highly-flammable refrigerants are found in automobiles in certain countries*. These are typically mixtures of alkanes and can, in fact, be simply LP gas. Historically, most automotive air conditioning systems used R12 (CCl_2F_2). This has generally been replaced by ozone-friendly R134a ($C_2H_2F_4$), however, the latter is significantly more expensive than LP gas. R134a is 'practically non-flammable' in that it has no flammability limits in air at normal pressure and has an exceptionally high AIT of 743ºC. By contrast, alkanes are flammable over a wide range of concentrations, as shown in Chapter 15. Elias[1511] conducted a theoretical modeling study and concluded that a turbulent jet fire resulting from a break in the piping system is impossible and flames would either blow off due to excessive velocity or else a fire would be unsustained, if a large hole emptied the system rapidly. Elias did no experiments, however, and accidents indicate that the actual situation is not as benign as Elias hypothesized. Sloan[1512] reported that some used automobiles have been imported into New Zealand from Japan which had their air conditioning systems charged with LP gas. He describes one collision where rapid and extremely destructive combustion took place once the escaping gas was ignited by an electric spark. In that collision, the refrigerant's combustion did not cause passenger injuries, but refrigerant piping must necessarily extend into the dashboard area and introducing a flammable substance at high pressure into the passenger compartment creates a new and worrisome hazard. Maclaine-cross and Leonardi[1513] conducted a study which claimed that LP gas released within a passenger compartment cannot be ignited by electrical sources and argued that, expressed on a risk basis, the new hazard should be completely negligible, but they did not study actual accidents. Several manufacturers of LP-gas type refrigerants have also published papers claiming risks are minuscule.

* They are also found in some countries in domestic refrigerators.

Neon lighting

The high voltage for neon lighting comes from a transformer with a loose-coupled secondary. This means that the secondary voltage under normal load conditions is about half of the open-secondary voltage. It also means that the transformer is relatively invulnerable to thermal problems from shorts or other faults in the HV circuit. Instead, problems are generally found to lie in the installation of the HV cabling and associated connections[1514]. Fires are common when neon signs are improperly installed next to wooden members and arc tracking results[2089]. Tracking damage and ignition of a wood board from a 9 kV neon transformer circuit[570] is shown in Color Plate 137.

Nitrates

Deposits of sodium nitrate and wood dust have been known to ignite solely from heating of the sun[26]. If mixed with cellulosic materials, magnesium nitrate also promotes combustion. A molten mixture of $NaNO_3$ and KNO_3, along with a small amount of $NaNO_2$, is used as a heat-treatment bath for certain metals. Médard[26] reports that "it is not unusual for the operation to give rise to an explosion." Explosions can be steam explosions, or arise due to introduction of an organic contaminant, or due to overheating of the bath.

Nitric acid and nitrogen oxides

Nitric acid is considered to be the foremost chemical involved in reactive chemicals incidents[3]. Apart from its reactivity with a gigantic list of chemical laboratory substances, it can readily cause ignition of wood, sawdust, hay, and other cellulosic substances. Concentrated acid (greater than 43.6%[1515]) is necessary, however. *White fuming nitric acid* is a term describing acid that is at least 97.5% pure, although concentrations as low as 70% fume in air. Nitric acid decomposes into NO_2, H_2O and oxygen. A concentrated solution containing 82 – 85% HNO_3 and the remainder mostly NO_2 is termed *red fuming nitric acid*; the reddish color comes from the NO_2 dimer, N_2O_4, which is also pre-

sent. The red variety is even more reactive than the white and has seen use in rocket propulsion. In earlier years, nitric acid used to be shipped in glass carboys wrapped with straw, and ignition incidents were common if the container broke or spilled. Arsonists with some chemistry knowledge have on occasion been discovered using nitric acid for fire-setting. Nitric acid can also react explosively with rubber, due to the presence of sulfur compounds[3]. Explosions involving nitric acid oxidizing some other substance are often detonations, not just deflagrations[1516].

All nitrogen oxides (N_2O, NO, N_2O_3, NO_2, and N_2O_4) are oxidizers and can be involved in ignitions or explosions under some circumstances. Nitrogen dioxide (NO_2) is a stronger oxidizing agent than oxygen. Some nitrogen oxides, e.g., nitrous oxide (N_2O), are also mild explosives on their own right, since they can decompose exothermically. Médard[26] has reviewed a number of ignition/explosion accidents involving nitrogen oxides.

Nitrides

Nitrides comprise a wide-ranging chemical family, with some, but not all, of the members showing pyrophoric tendencies. Examples include: calcium nitride (Ca_3N_2), disulfur dinitride (S_2N_2), lithium nitride (Li_3N), potassium nitride (K_3N), silver nitride (Ag_3N), and uranium nitride (UN). Disulfur dinitride may detonate spontaneously at ambient temperature. Urben[3] provides extensive listings along with literature references.

Nitrogen, liquid

Liquid nitrogen (LN_2) is readily appreciated as being potentially hazardous if allowed to contact the skin, since a freezing injury will result. It is much more rarely that its use would lead to ignition of fire. Yet, Cooke and Ide[605] report of an incident in a food processing facility where LN_2 was used to as part of a food grinding operation. The supply of LN_2 ran out, and a lethal explosion occurred. This was identified due to the difference in boiling point of liquid nitrogen (–196ºC), versus liquid oxygen (–183ºC). When the flow of LN_2 stopped, liquid nitrogen was no longer available to keep the surface inert. But since oxygen will condense into liquid form below –183ºC, it meant that the product became flooded not with an inert gas, nor with an atmosphere of 21%, but with a layer of 100% oxygen. The frictional heating of the process was then sufficient to cause an ignition of the substance in a 100% oxygen environment. In general, oxygen impurities in the LN_2 tank may also need to be taken into account; these will evaporate last and the mixture will effectively become oxygen enriched at the end.

Table 164 Ignition properties of vegetable oils as determined by Koseki et al.

Oil	Flash point (ºC)	AIT (ºC)
castor	307	415
coconut	294	360
cottonseed	333	420
linseed	334	415
rapeseed	321	405
sesame	336	419
soybean	320	400

Oils

Animal and vegetable oils exposed to air are oxidizable and consequently can self-heat. This tendency is much accelerated if the surface area is increased by applying oils onto rags (see under *Fibers covered with oil*, above) or onto sawdust (see under *Wood—Oiled sawdust*, below). Under most circumstances, mineral oils do not show self-heating.

VEGETABLE AND ANIMAL OILS

Ignition problems with cooking oils fall into two areas: autoignition of improperly operated cooking pans, and self-heating, commonly due to soaking of cloths in oils. The flash points of cooking fats were measured at FRS by Stark and Mulliner, who also took into account the effect of repeated use of the fats[1517]. Their results are given in Table 163; it may be noted that the results obey quite well the rule-of-thumb that a hot surface must exceed the AIT by about 200ºC for ignition to be likely (see Chapter 7). They also conducted some tests where food cooking, not just solely heating/cooling cycles were used. These tests gave results nearly identical to the cycling tests without food.

Table 163 Properties of cooking fats measured at FRS

Fat	Flash point (ºC)		Fire point (ºC)		AIT (ºC)		Hot surface ignition temp. (ºC)	
	Virgin	After 8 heating cycles	Virgin	After 8 heating cycles	Virgin	After 8 heating cycles	Virgin	After 8 heating cycles
corn oil	254	227	NA	321	309	283	526	542
drippings	254	241	NA	331	348	276	553	537
hydrogenated cooking fat	260	210	NA	331	355	273	568	554
lard	249	218	NA	326	355	282	541	568
olive oil	234	218	NA	316	340	280	562	543
peanut oil	260	243	347	335	342	280	552	535

The maximum temperature to which cooking fats should be raised for proper cooking is around 205ºC, thus serious temperature excesses must be incurred before ignition can be anticipated. The test results also indicate that differences among various types of cooking fats can typically be ignored. It can also be concluded that, for any type of fat, used cooking fats are slightly more hazardous than virgin ones.

Several other investigators have also reported flash points or AIT values for cooking fats[1518,1519]; their results and conclusions are broadly similar to the FRS study, which has been the most ambitious. More recently, researchers at Japan's National Research Institute of Fire and Disaster[1520] measured properties for a number of vegetable cooking oils (Table 164); their data are probably more reliable than older data, much of which is collected in Chapter 15.

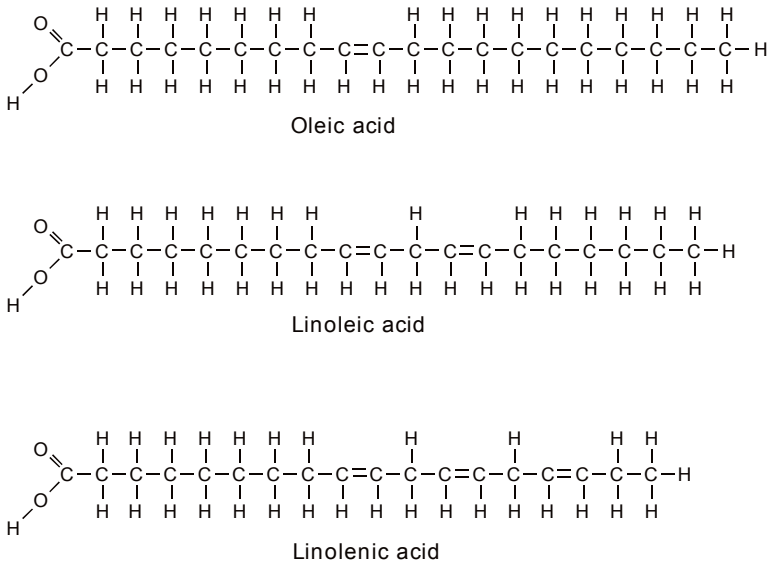

Figure 108 Fatty acids found in linseed oil (all shown as *cis* isomers)

Stark and Mulliner also noted the sequence of events leading to ignition of fats in a cooking pan. In their experiments, they brought the test substance up to temperature exceeding the AIT with a lid closed on the pan. Upon lifting the lid, vapors at first ascended as a simple rising plume. Shortly before ignition, the pattern acquired a toroidal aspect, with vapors rising upward from the edge of the pan and descending towards the center of the pan. A relatively clear central zone was formed, apparently due to air entrainment. The vapors then became more opaque and whiter, and ignition occurred. No frothing, boiling, or ejection of liquids was noted. None of the tests showed a piloted-ignition character, that is, the gas flame below the pan did not cause the ignition.

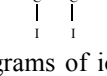
Chemically, oils of vegetable and animal origin are mixtures of glycerides of fatty acids. The common fatty acids include palmitic ($C_{15}H_{31}COOH$), stearic ($C_{17}H_{35}COOH$), linolenic ($C_{17}H_{29}COOH$), linoleic ($C_{17}H_{31}COOH$), and oleic ($C_{17}H_{33}COOH$). The propensity to self-heating of the glycerides of these acids is directly related to their ease of oxidation. The latter, in turn, is determined by the number of unsaturated bonds (C=C bonds) present, since oxygen most readily attacks the double bond. Palmitic and stearic acids are saturated and thus tend not to self-heat. Oleic acid has one C=C bond, linoleic acid has two, while linolenic acid has three. Since animal and vegetable-origin oils had been available for a long time, their self-heating problem was one of the earlier ones studied. The first studies of self-heating of oil-soaked rags, as discussed in Chapter 9, date to 1781 and involved boiled hempseed oil and pine soot.

Starchy foodstuffs cooked in *rapeseed (canola) oil* and left in a colander have been documented to be the cause of a self-heating fire which occurred in a restaurant specializing in (East) Indian foods[1521]. The foodstuffs had the consistency of dry breadcrumbs. A sample of the batch that was unburned was tested in a laboratory oven at 140ºC and led to a smoldering ignition. Used rapeseed oil was determined to have an iodine number of 103. Some *essential oils* (these are oils obtained from odorous plant materials) have been reported to be quite prone to self-heating, when dispersed onto fibers or similar substances[1522].

Linseed oil is perhaps the substance that is most famous for causing self-heating ignitions. It is not edible, but is extensively used in the paints industry and also is occasionally found in cosmetics. Linseed oil is obtained from crushing the seeds of the flax plant. Since it is a natural product, its composition can vary significantly. It is largely made up of the glycerides of three unsaturated acids: linolenic, oleic, and linoleic acids (Figure 108), with a small amount (6 – 10%) of saturated acids. There is typically[1523] about 15% of linoleic acid, 20 – 25% of oleic acid, while the fraction of linolenic acid depends on the iodine number (see below) and ranges from about 48% (for iodine number of 175) to 60% (for iodine number of 195). Linseed oil has traditionally been the most preferred vegetable oil in the paint industry since other oils have a much smaller, if any, fraction of linolenic oil. The oxidation potential is increased by having a concentration of the double bonds close to each other. When linseed oil undergoes 'drying,' the side-chains of the fatty acid react with oxygen by crosslinking (polymerizing)[1524]. The oxidized, cross-linked linseed oil becomes hard and this elastomeric substance that is formed is known as linoxyn. The chemical reactions involved are numerous and complicated and many details are still not solved[1525,1526,1527]. The reaction proceeds in three basic steps:

(1) Initially, naturally-present antioxidants (primarily tocopherols) are consumed; this is not accompanied by visible physical changes.

(2) Then a period of rapid oxygen consumption ensues, leading to the creation of hydroperoxides and conjugated dienes.
(3) Finally, a complex series of autocatalytic reactions takes place, during which hydroperoxides are consumed and the cross-linked film is formed. In addition, cleavage reactions produce some low-molecular-mass byproducts in this stage. Cleavage and cross-linking reactions continue even after the material 'dries' and leads to eventual browning and embrittlement.



Sastry[1528] gives extensive details on the reactions involved. From a functional point of view, the polymerization is precisely what is desired, since it makes this a 'drying' oil. But the reaction generates heat and this can lead to spontaneous combustion. When the oil has 'dried,' it is no longer soluble in organic solvents; thus, if hardened residues are sampled, an identification of the original linseed oil will not be possible. Linseed oil gains weight in hardening, since oxygen is taken up from the air; when hardened, the weight will typically increase by around 14%[1527]. The oxidation process evolves a modest amount of CO_2 (about 5% of the original mass) and about a similar amount of volatile acids. Fully-dried linseed oil has a composition of approximately $C_{57}H_{96}O_{20}$.

The drying characteristics of fatty acids, including but not limited to those in linseed oil, depend on: (1) the number of double bonds present; this is sometimes equivalently stated as the number of ethylene groups; (2) the isomeric form of the ethylene groups, whether *cis* or *trans*; and (3) the relationship of the ethylene groups to each other—conjugated or isolated. The double bonds are conjugated if they are separated by one single C–C bond. Greater drying propensity is associated with a higher number of double bonds, conjugated arrangement, and a *trans* isomerism. *Tung oil* exhibits self-heating behavior similar to linseed oil but its reaction mechanisms are different and tung oil takes up only 3% oxygen upon drying[1527]. This is due to the fact that the primary constituent of tung oil is *α*-eleostearic acid, $CH_3(CH_2)_3CH{=}CH{-}CH{=}CH{-}CH{=}CH(CH_2)_7COOH$ and it has conjugated bonds.

For use in paints, linseed oil is usually sold as '*boiled*.' Boiled linseed oil used to be heat processed in the presence of a suitable metal salt. This would liberate acetic acid and form linoleates (salts of linoleic acid). Product labeled as 'boiled linseed oil' today is normally not actually boiled, but merely catalyzed using catalysts ('driers') such as salts of cobalt, copper, zirconium, chromium, or manganese, which serve the same purpose[1529]. Lead is particularly effective as a drier, but is no longer used in consumer paints due to toxicity reasons. The metal salts are often accompanied by an organic peroxide as an oxidizing agent, and function by inactivating the naturally-present antioxidants (tocopherols) in the oil. There is also a variety of linseed oil known as 'burnt,' which has been used in the printing industry and has less of a self-heating tendency than raw or boiled linseed oils[1530]. It has often been stated that addition of iron or iron rust to linseed oil exacerbates its self-heating potential. There is some very old work[1531] to support this notion, but the idea cannot be viewed as quantified. Apart from boiled linseed oil, commercial wood-finishing preparations usually also contain mineral spirits.

The oxidation of *peanut oil* has been studied using a dynamic DSC technique[1532] and showed a first-order reaction, with E = 62.2 kJ mol^{-1}, $A = 3.43\times10^4$ s^{-1}, and C = 2300 J kg^{-1} K^{-1}. However, the same authors[1533] then did more extensive studies on several vegetable oils (rapeseed, corn, soybean, and peanut) comparing isothermal and dynamic DSC techniques and found that the data produced by the two techniques are notably dissimilar, with imputed E values differing by up to 20 kJ mol^{-1}. The conclusion was that the process has to be treated as autocatalytic. A more detailed study on mustard oil[1534] showed that the oxidation needs to be modeled as two sequential reactions, with the first reaction being autocatalytic and the second being a first-order reaction. They then studied[1535] linseed and three other oils and also found that their reactions are strongly autocatalytic. Similar studies on individual fatty acids[1536] also showed two peaks in the DSC curves and an autocatalytic character. The first peak corresponds to the formation of hydroperoxides, while the second to the further oxidation of the initially-formed reaction products[1537]. The process cannot be represented by a single activation energy. For linseed oil, they found three different values of E: 132.7 kJ mol^{-1} (at onset), 73.1 kJ mol^{-1} (first peak), and 75.7 kJ mol^{-1} (second peak). Corresponding values of pre-exponential factors were: 1.92×10^{14}, 1.83×10^{6}, and 8.08×10^{5} s^{-1}.

THE IODINE NUMBER TEST

The oldest technique for characterizing the self-heating potential of vegetable and animal oils is the *iodine number* (also called *iodine value*) test[1538]. In this test, an iodine solution is added to the drying oil until a permanent mauve color is observed. The iodine acts only on the double C=C bonds, converting them to  bonds. If the oil sample is 100 g, the number of grams of iodine necessary for the color to break through is defined as the iodine number and it corresponds to the concentration of C=C bonds. If all the bonds are saturated, then the substance should show a zero iodine number. But the number of C=C bonds, while indicative of self-heating potential, is not the only factor governing self-heating. The iodine number test is usually conducted using the Wijs[1539] modification of the Hübl method. It was developed over 100 years ago; the current procedures are specified as the American Association of Oil Chemists' Method Tg 1-64. The test is sensitive to small details of procedure and the standard must be followed if reproducible results are to be obtained. Experimental comparisons between self-heating results in the Mackey tester and iodine number values confirmed that other factors must be considered[1078,1540], including the position of the double bond and

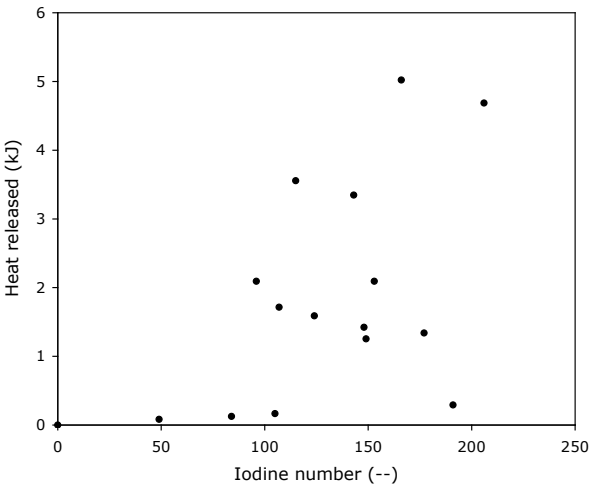


Figure 109 Relation for various oils between iodine number and heat released in a test where air is bubbled through a 20 g sample held at 100ºC

steric factors. For example, boiled linseed oil is more prone to self-heating than raw linseed oil, yet its iodine number is lower. Additionally, the iodine number indicates the *amount* of oxidation possible, whereas the kinetics of the problem, i.e., the *rate* of oxidation, also needs to be considered.

Perilla oil has an iodine number of 196-201, linseed oil 175-195, tung oil 163-173, hempseed oil 145-167, menhaden oil 139-180, poppyseed oil 133-143, soybean oil 137-143, safflower oil 129-150, sunflower oil 119-135, rosin oil 112-115, corn oil 111-130, cottonseed oil 108-110, mustard oil 96-107, peanut oil 97, castor oil 82-86, olive oil 79-88, neatsfoot oil 70, butter 26-42, and coconut oil 8-10[1521,1541,1542]. Peanut and corn oils are claimed to self-heat to criticality only if starting from a warm condition, while coconut oil has not been found to exhibit self-heating problems[1092]. Palm kernel fat has an iodine number of 15 – 18, yet sacks of palm kernels are known to have sustained self-heating fires[43]. When a drying oil has hardened, not all of the bonds become saturated; an iodine number of 31 has been reported for hardened linseed oil[1538].

Animal oils usually have iodine numbers around 50 and tend not to have self-heating problems; it is noted, however, that lard oil (iodine number 56-74) does tend to self-heat[1542]. The oils of marine animals, however, while showing some very high iodine numbers (e.g., cod liver oil has 160-180), are generally of low hazard with regards to self-heating since they contain large amounts of natural anti-oxidants. Lewis[1542], however, notes that fish oil is susceptible to self-heating.

Recently, Schildhauer[1543] proposed that chemiluminescence be used as a superior technique to replace the iodine number test in characterizing vegetable oils. It has been known since the 1970s that vegetable oils undergoing oxidation produce a weak chemiluminescence. Since this is a measure of the actual reaction rate (rather than the potential for a reaction to occur), he considers it to be a more direct measurement. The merit of this scheme will be better assessed once other laboratories undertake to reproduce his findings.

Virtala et al.[1197] developed a technique to measure the heat release of oils in a calorimeter where air was bubbled

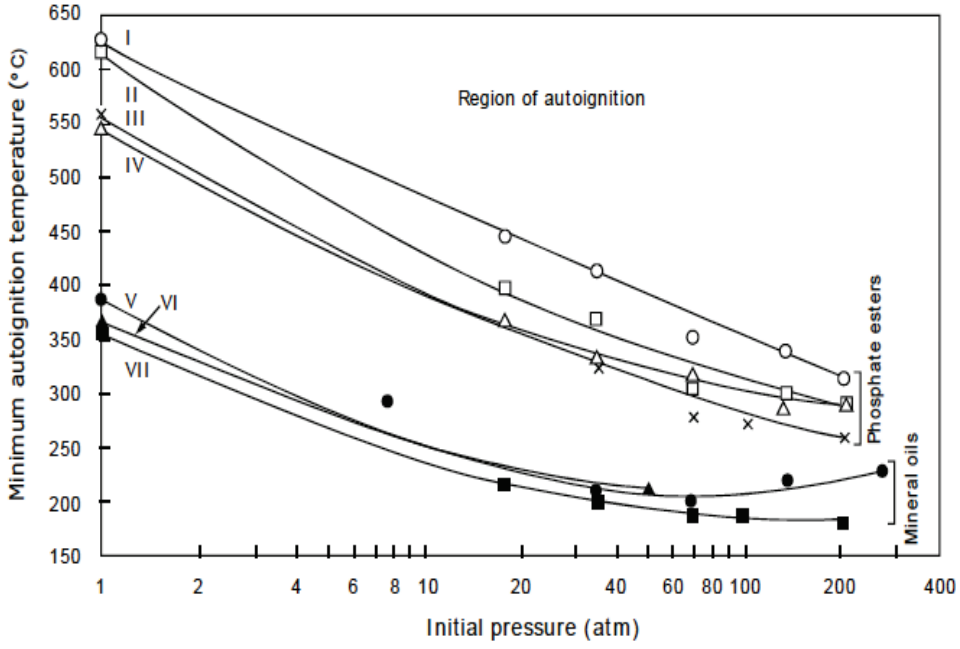

Figure 110 The effect of pressure on the AIT of mineral and synthetic oils[4]. Roman numerals identify different commercial products.

through the test oil; they also obtained iodine number values for the same substances. The results (Figure 109) indicate that iodine number is, at best, only a qualitative indicator of self-heating propensity. Today, the most common way to examine oils is the way that actual accidents will probably occur: as oiled rags.

MINERAL AND SYNTHETIC OILS

The AIT of oils generally decreases with increasing pressure (Figure 110). This characteristic especially emphasizes the hazards of industrial processes where oils are used under combined high pressure and high temperature. If extrapolations are needed to be made from such experimental data, linear relationships can often be obtained if P/T is plotted as a function of $1/T$, where T is expressed as absolute temperature (K).

Ohlemiller and Cleary[123] investigated the effect of contamination with gasoline on the flash point and fire point of motor oil. Using a non-standard open-cup test apparatus, they found that the flash point dropped from 165ºC for pure motor oil to room temperature (22ºC) when 10 – 17 vol% of the mixture was gasoline. The fire point dropped from 215ºC for pure motor oil to 22ºC for a mixture with 20 vol% gasoline. Dissolving as little as 0.3% methane[461] into motor oil (which readily happens at increased pressures) lowers the AIT to 130ºC. Dissolving 5% diesel fuel into motor oil lowers the flash point from 220ºC to 170ºC. Ferguson[457] conducted similar tests for diesel oil mixed into an additive-type paraffinic-base lubricating oil. His results (Figure 111) show that for contamination levels up to 20% there is negligible effect on the AIT, but that the open-cup flash point drops rapidly.

Modak[1544] attempted to ignite 50 mm deep layers of several oils with welding spatter. A steel rod located 0.5 m above the liquid pool was continually melted with an oxyacetylene torch for 60 s. No. 6 fuel oil briefly ignited, but only flamed for 10 s. No. 2 fuel oil, SAE 30 motor oil, turbine lubricating oil, and a fire-retardant grade of hydraulic fluid did not ignite at all. Modak then repeated the tests using thinner layers of 4 mm depth. Again, no ignitions observed. Ignitions also did not occur by directly playing an *oxyacetylene torch flame* on the surface of the four shallow pools for 15 seconds.

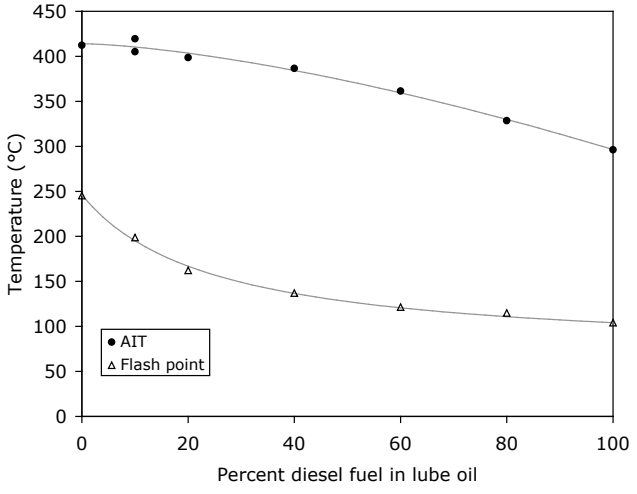

Figure 111 Effect of adding various amount of diesel fuel to lubricating oil

A large compilation of ignition data for commercial oils and lubricants on the marketplace prior to 1968 has been published by Kuchta and Cato[1518]. The relationship between molecular structure and AIT of a variety of lubricating oils was explored by Frank et al.[1545] See also: *Air compressors and compressed air systems*; *Diesel fuel*; *Fuel oil*.

Oil-water emulsions

Oil spills from marine accidents may become emulsified. Such an emulsion is expected to have different ignition properties than pure oil. An experimental ignition study of diesel-oil-water emulsions using the Cone Calorimeter was reported by Moghtaderi and coworkers[1546]. It was found that emulsion layer thickness within the range of 10 to 40 mm did not affect ignition times. The emulsions behaved as thermally thick materials, with a critical heat flux of 6 kW m^{-2} when plotting irradiance versus ignition time to the –0.5 power. For irradiance values lower than about 20 kW m^{-2}, boiling set in prior to ignition. Increasing the water fraction in the emulsion caused longer times to ignition.

Organometallic compounds

A wide variety of organometallic compounds are pyrophoric or highly reactive. Examples include triethyl aluminum ($C_6H_{15}Al$), trimethyl aluminum (C_3H_9Al), and ferrocene ($C_{10}H_{10}Fe$). Urben[3] provides extensive listings along with literature references. Also see: *Metal carbonyls*

Otto fuel II

This liquid monopropellant, named after its developer Otto Reitlinger, is composed of propylene glycol dinitrate ($C_3H_6N_2O_6$), 2-nitrodiphenylamine ($C_{12}H_{10}N_2O_2$), and dibutyl sebacate ($C_{18}H_{34}O_4$) and is used by the US Navy to propel certain torpedoes. Its fire point[1644] is reported as 129ºC.

Oxidizing chemicals

There is a very wide assortment of chemical that act as oxidizers and many of these are able to cause fires or explosions, if inappropriately combined with certain combustibles. In this section, some oxidizers are discussed which have proven to be especially problematic. Potassium permanganate, $KMnO_4$, is a solid which can ignite various organic liquids if it comes into contact with them. The strongest reactions are with glycols, sugars, aldehydes, and methenamine[26]. Capsules containing potassium permanganate and ethylene glycol are used in Australia as incendiary devices for starting prescribed-burn fires from airplanes[1141]. Calcium permanganate, $Ca(MnO_4)_2$, is used for water sterilization, as a disinfectant, deodorant, and for various uses in

manufacturing industry. It behaves similarly to potassium permanganate, but is even more reactive[1547]. Dinitrogen tetroxide, N_2O_4, also called nitrogen tetroxide, is a liquid rocket oxidizer which is used in expendable and reusable launch vehicles (Ariane-4, Delta-2, Space Shuttle). When mixed with a number of fuels, including aniline, ethylene glycol, furfuryl alcohol, hydrazine, methylhydrazine (MMH), or UDMH, a hypergolic ignition or an explosion may ensue[1644].

See also: *Ammonium perchlorate*; *Metal oxides*; *Nitric acid and nitrogen oxides*; *Perchloric acid*; *Peroxides*; *Sodium chlorate and sodium chlorite*. General safety principles concerning ignition in pure-oxygen or oxygen-enriched atmospheres are presented in Chapter 13.

HALOGEN FLUORIDES

The powerful oxidizing agents chlorine trifluoride (ClF_3) and chlorine pentafluoride (ClF_5) react hypergolically with many metals and organic materials. Wood, paper, and cotton invariably ignite[3]. The agents are also able to ignite when coming into contact with asbestos, glass wool, sand, or refractory materials. Both compounds are gases at room temperature and pressure. They have potential application in aerospace applications for purposive ignitions[1548]. Other halogen fluorides with generally similar oxidizing properties include chlorine fluoride (ClF) and perchloryl fluoride (ClO_3F).

GASEOUS FLUORINE

Fluorine (F_2) is, in principle, one of the most powerful oxidizers, but it only rarely presents an ignition problem since it is rarely used in its pure, uncombined form. Ellern[1407] reports that its ignition potential for organic combustibles is erratic—clothing may ignite when hit by a stream of the gas, while sugar will not.

LIQUID CHLORINE

Chlorine is a powerful oxidizer and is incompatible with many materials. After a serious explosion where Cl_2 reacted with a polypropylene filter, E. I. Du Pont de Nemours & Co. Inc. advised against use of any organic materials in chlorine service without careful testing[1549]. It was judged that the reaction was catalyzed by a zinc contaminant.

WATER PURIFYING AND BLEACHING CHEMICALS

Calcium hypochlorite, $Ca(ClO)_2$, often called 'cal hypo,' is one of the most powerful oxidants that is in commercial use. Its primary uses are as a bleaching powder and as a water purification and swimming pool treatment. For use as bleaching powder, it is normally used in mild concentrations below 39% and was originally known as '*chloride of lime.*' Higher calcium hypochlorite concentrations of 65% – 78% are contained in products to be used as swimming pool treatment chemicals and for water purification purposes. These latter products are sometimes designated "70% available chlorine," but this is a chemical misnomer. It originated due to an old chemical analysis method where atomic chlorine (rather than Cl_2) was presumed to be the reactant. The mass fraction of chlorine in pure $Ca(ClO)_2$ is 50%, thus, even pure calcium hypochlorite cannot release more than 50% chlorine. Instead, "70% available chlorine" must be understood to mean that the product contains 70% $Ca(ClO)_2$ and 30% of impurities. Cal hypo containing approximately 70% $Ca(ClO)_2$ is often commercially designated as "high-test calcium hypochlorite," HCH. The material is also produced in a hydrated form and then contains approximately 65% $Ca(ClO)_2$ and 5 – 8% H_2O. Apart from water, the impurities are mostly NaCl, $CaCl_2$, $Ca(ClO_3)_2$, $Ca(OH)_2$, $CaCO_3$, and H_2O. Bleaching powder grade material commonly contains $CaCl_2{\cdot}Ca(OH)_2{\cdot}H_2O$, CaO, and $CaCl_2O_4$ as impurities. Calcium hypochlorite is normally packaged for sale as granules or pellets. The determination of "available chlorine" is described in ASTM D 2022[1550].

Commercially, low-strength calcium hypochlorite is most commonly found as the anhydrous product, but high-strength product is most commonly sold in the form of the dihydrate, $Ca(ClO)_2{\cdot}2H_2O$, and labeled as "65% available chlorine." Under the UN scheme[1650], if the anhydrous product contains over 39% chlorine, it is identified as UN 1748, while if it has 10 – 39%, it is identified as 'bleaching powder,' and classed as UN 2208. The hydrated product is classed as UN 2880 if it contains 5.5 – 10% moisture. If it contains more than 10% moisture, shipping regulations permit it to be classified as UN 1479 (miscellaneous oxidizing solids). Less strict regulations pertain to this class, although, as shown below, the moister material is more prone to self-heating.

Anhydrous calcium hypochlorite was found to be the most reactive oxidizer in a test program that compared the performance of 16 oxidizers[1551]. But it is not necessary for a partner fuel to be present in order for an exothermic reaction to occur. Calcium hypochlorite is a self-heating substance and elevated temperature or excessive storage sizes can cause thermal runaway without need for a reaction partner. Some metal contaminants (iron, manganese, cobalt, magnesium) can accelerate self-heating. The spontaneous decomposition of cal hypo in storage is known to manufacturers, who estimate that 2 – 5% of chlorine is lost per year in storage[1553].

It is reported that potential for calcium hypochlorite to cause unexpected ignitions was already being studied in 1878[353]. In manufacturing, the product is produced in slurry form and then dried. Explosions during drying have been noted[1552]. Fire incidents on land have been less common with the bleaching powder grade. But numerous fires and explosions have been reported in connection with shipping and warehousing of swimming pool grade material[1553]. A certain number of incidents have been identified as being due to a hypergolic reaction between calcium hypochlorite and some other substance. These include soap, various oils,

gasoline, turpentine, other diverse organic liquids, and a wide array of other substances[3,26]. A large warehouse burned down when a small amount of cal hypo was spilled on a wood pallet[1554]. Even though the spill was cleaned up, the pallet ignited about 40 minutes later. Ignitions have also been reported from the use of a dirty scoop[1558]. A single drop of glycerin is enough to ignite the bulk material, as is the application of a lit cigarette[1553,1555]. A fireball is produced if cal hypo is combined with brake fluid[1556]; this is perhaps the most energetic reaction partner identified. In other fires, however, self-heating of the material itself has been the cause.

Large-scale rack storage fire tests have indicated that, once ignited, combustible materials in contact with calcium hypochlorite burn exceptionally fiercely[1557]. Applying small quantities of water to calcium hypochlorite fires has been known to make them worse. Wetting is also exothermic and can cause violent reactions; this is avoided in the use of the product by adding it to water, not vice versa. A comprehensive literature review of reactions, hazards, and case incidents has been published[1557]. A number of explosions have occurred when workers removed lids from drums, there having been no previous indication that the contents were unstable and would explode[1565]. Clancey[1558] studied a dozen fires and explosions that occurred in ships carrying anhydrous calcium hypochlorite during 1967-1973. The explosions are typically quite weak, with peak over-pressures of only ca. 1 atm. Investigations suggested that the primary cause of the accidents was impurities in the product, but details were not elucidated. Products from factories producing higher purity product appeared to rarely, if ever, spontaneously ignite in shipping.

For a number of years subsequently, there were not many serious marine losses. But the problem returned with grave severity in the 1990s. Between 1991 and 1999, eight ships suffered fires or explosions due to self-heating of cal hypo—MV RECIFE, TIGER WAVE (MAAS), CONTSHIP FRANCE, MAERSK MOMBASA, SEA EXPRESS, DG HARMONY, ACONCAGUA, and CMA DJAKARTA. The cargoes were commonly the hydrated form, although not in all cases. Packaging was typically as drums stored in standard shipping containers of 6 m length. The basic problem appears to stem from the misclassification by UN of the cal hypo family as 'oxidizing solids,' Class 5.1, rather than as 'self-reactive solids,' Class 4.1 or 'substances liable to spontaneous combustion,' Class 4.2. This classification creates the incorrect impression that the material is stable in the absence of a reaction partner. As a consequence of this classification, the IMDG Code permitted at the time of these incidents a maximum packaging of 180 kg in fiber drums and 250 kg in steel drums and specifically permitted storage in below-deck areas. The anhydrous product had to be stowed "away from sources of heat," whereas the hydrated product could be stored where temperatures did not exceed 55ºC for more than 24 h. These packages are also allowed to be stored in containers of up to 40-ft size.

The International Group of P&I Clubs (IGP&IC), which represents shipping insurance companies, responded to the marine disasters by recommending[1559] to IMO that the Code be changed so that the material could only be shipped in drums and not bags or sacks, that drum size be limited to 45 kg, that temperatures not be allowed to exceed 35ºC, that drums not be shipped in containers over 20-ft size (and be stored clear of living quarters), and that the material to be transported be tested and certified as free from dangerous contaminants. By use of drums, a certain amount of ventilation is inherently provided, due to the circular shape. IGP&IC considered also asking that steel drums be used, but concluded that the advantage of non-combustibility is offset by the fact that the material can cause steel to rust, and rust promotes decomposition reaction. IGP&IC also noted[1560] that test results were available showing the SADT for a single 45 kg package is about 52ºC and that the value would be much lower for a container holding a number of these packages. Thus, in their view, even according to existing IMDG Code provisions, cal hypo should be transported according to Control and Emergency Temperature requirements, which come into effect if a 50 kg package has an SADT of 55ºC or less. Some of the larger packages transported had SADTs of less than 50ºC, which would require temperature control according to US regulations.

The US delegation to IMO[1561] endeavored to minimize the implications of the problem and argued against making restrictions on package size, on limiting the temperature at the place onboard ship where the product is to be stored (while agreeing to restrictions on keeping goods away from heaters and steam pipes), and on purity certification for products. Remarkably, they argued against the recommendations to stow clear of living quarters. Part of their argument rested on the facts uncovered in the investigation of two of the ship fires which implied that the product was placed too close to a source of heat onboard; however, the argument did not explain the other six fires. The Canadian delegation[1562] also argued against any increased requirements in the Code on the basis that they disbelieved that cal hypo was a self-heating material. The European Chemical Industry Association (CEFIC) also argued that no changes were needed[1560]. Despite the re-iterated urging of a group[1563] representing essentially all of the world's marine insurance interests (International Union of Marine Insurance, International Chamber of Shipping, and IGP&IC), IMO instead adopted the mild provisions suggested by Germany. These changes, adopted in 2000 as Amendment 30-00 to the IMDG Code, specifically forbade bags, IBCs and bulk packagings, and required segregation from certain other cargoes, but did not reduce the permissible size of drums nor establish a more realistic temperature limit. Requirements were also made that the material not be transported below-deck.

The self-heating properties of 72.5% anhydrous commercial calcium hypochlorite in granular form were studied by Uehara et al.[1564]. Multiple reactions were found possible:

$$Ca(ClO)_2 \rightarrow CaCl_2 + O_2$$

$$3\ Ca(ClO)_2 \rightarrow 2CaCl_2 + Ca(ClO_3)_2$$

followed by:

$$Ca(ClO_3)_2 \rightarrow CaCl_2 + 3O_2$$

and in the presence of moisture:

$$Ca(ClO)_2 + CaCl_2 + 2H_2O \rightarrow 2Ca(OH)_2 + 2Cl_2$$

Of these, however, the first one was found to be, by far, the dominant one. Other studies have identified that, under some circumstances, chlorine monoxide (dichlorine oxide), Cl_2O, is formed, with the latter being a violently unstable gas[1565]. For a flaming ignition to be seen, it was found necessary that organic material be present. Explosive decomposition, however, could occur upon heating with or without organic partners. Based on oven-cylinder testing, Uehara's results give E = 123 kJ mol^{-1}, QA = 6.48 × 10^{17} kW kg^{-1}, and P = 58.35. They also determined the values Q = 608 kJ kg^{-1}, C = 1088 J kg^{-1} K^{-1}, λ = 0.437 W m^{-1} K^{-1}, and ρ = 1000 kg m^{-3}. Given these constants, for a 1 m^3 cube, critical conditions would be reached for an ambient temperature of 58ºC, which is not much above normal room temperature. For packaging in 0.4 × 0.4 × 0.4 m cubes, however, the critical temperature would be 73ºC, which should be well above any room temperature. Clancey[1553] has pointed out that these results should not be viewed as 'typical,' since Uehara obtained very different values in additional testing that was published only in Japanese.

For the hydrated product, Gray et al.[1566] consider that the primary reaction is two-step, with the first step being:

$$Ca(ClO)_2 \rightarrow CaCl_2 + O_2$$

followed by:

$$Ca(ClO)_2 + CaCl_2 + 2CO_2 \rightarrow 2CaCO_3 + 2Cl_2$$

under dry conditions, with the CO_2 coming from atmospheric sources. Under moist conditions, the second step is:

$$Ca(ClO)_2 + CaCl_2 \rightarrow 2CaO + Cl_2$$

The hydrated form, $Ca(ClO)_2 \cdot 2H_2O$, was originally promoted by Mandell[1567] as being more stable and safer than the anhydrous. But in a recent extensive study, Gray and Halliburton[1568] concluded that Mandell's small-scale tests on which this conclusion was based were poorly designed, and that the hydrated form is actually less stable and is more dangerous in shipping and storage. This is consistent with the findings from several research groups[1552,1569] who conducted a variety of thermal analysis tests and concluded that the presence of moisture in cal hypo accelerates decomposition and lowers the temperature at which exothermic activity starts. However, Gray et al. note that, while more dangerous for decomposition, the hydrated form is safer when acting solely as an oxidizer and reacting with a fuel[1568]. Gray and Halliburton determined that heating-rate dependences made it impossible to successfully predict real-scale performance from micro-scale thermal analysis measurements and that larger-scale self-heating tests needed to be done. Their extensive test program ranged from cylindrical oven baskets of 9.25 mm diameter to 200 kg drums of material. The results (Figure 112) show that there are two temperature regimes. The high temperature regime above about 117ºC exhibits characteristics roughly similar to those that Uehara found for the anhydrous product. But in the low-temperature/large-size regime that is relevant to actual transport and storage issues, E = 48.5 kJ mol^{-1}, P = 33.33, QA = 7.19×10^6 W kg^{-1}, and $QA\rho$ = 7.48×10^9 W m^{-3}. The authors also found that ρ = 1040 kg m^{-3}, λ = 0.142 W m^{-1} K^{-1} at 20ºC and 0.147 W m^{-1} K^{-1} at 35ºC for the commercial granulated form. They did obtain some data for times to ignition, but cautioned against making extrapolations from those results, since there is a possibility of chain reactions that would make extrapolations incorrect. The largest specimen tested by Gray and Halliburton, a 200 kg fiber drum (0.55 m diameter), showed a critical ambient temperature of 43.4ºC, when tested inside an external enclosure, which limits the cooling available and simulates the conditions when the drum is stored inside a shipping container. Thus, they concluded that there is an overt hazard of runaway occurring during transit through hot climates. A comparison using a polyethylene 40 kg drum (0.35 m diameter) showed a critical ambient temperature of 60ºC when tested inside a circulating laboratory oven and 55.2ºC when tested surmounted by a steel box. Halliburton[1570] then estimated (but did not validate) that the critical ambient temperature for a 20-ft shipping container filled

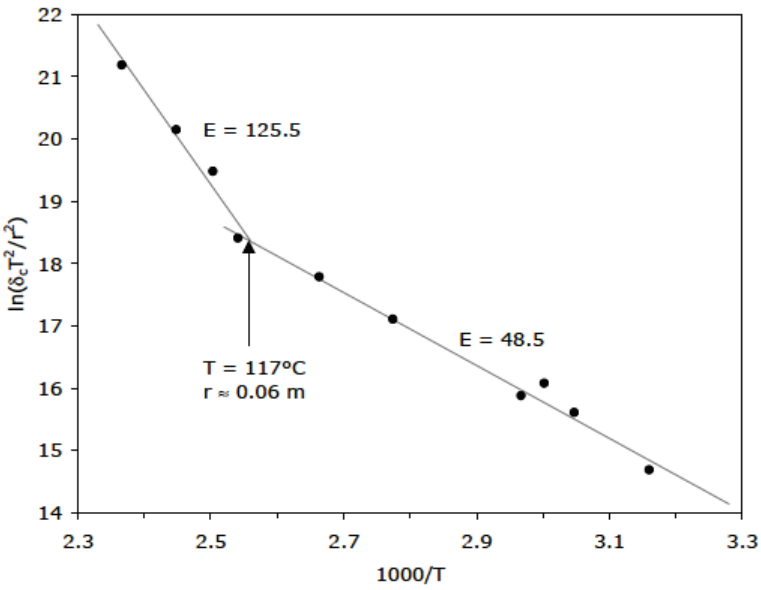

Figure 112 Hydrated calcium hypochlorite oven test results of Gray and Halliburton

with 40 kg drums would be 42.6ºC, while if the container were filled with 200 kg drums, the value would drop to 31ºC. Gray et al.[1568] further concluded that the UN SADT test (see Chapter 9) gives misleadingly unconservative results for cal hypo.

Gray and Halliburton also pointed out shortcomings in Uehara's study on the anhydrous form, noting that (1) they used a value of δ_c pertinent to infinite cylinders, not the relevant short cylinders; (2) their assumption of infinite Biot number is inappropriate; and (3) thermal conductivity was determined on finely-ground material, not on the commercially-produced granular material.

Gray et al.[1568] also noted that unpublished results that showed that a 45 kg keg of hydrated cal hypo went into thermal runaway in 3 days when held at 57ºC but that when held at 50°C it survived for 3 weeks (longer times were not tested). This contrasted sharply with the results of Uehara for the anhydrous material, where 75ºC was required for thermal runaway of a 50 kg drum. Other unpublished tests on the hydrated product showed thermal runaway in 20 min for a 50 kg container at 64ºC and 13 h for a 10 kg container at the same temperature. Small-scale tests on 400 g of material showed thermal runaway at 60ºC for one material, but no runaway for another manufacturer's sample. Simultaneously with Gray's research, a Japanese group[1571] conducted a study which was not based on self-heating theory and came forth with a benign conclusion. The Japanese workers took the IMDG Code prescription literally, conducted tests for 24 h at 55ºC, and found no thermal runaway. Behavior during a 24 h period, of course, does not suffice to determine what will happen during a weeks-long journey. The Japanese group then further stated[1560] that they also conducted testing which showed that a 50 kg plastic drum was safe at 40ºC for a 3-month period, but did not provide details.

Earlier, Clancey had reported on some large scale tests of drums of cal hypo[1553]. Upon being placed in a bonfire, a 50 kg drum exploded. This drum had a plastic liner. When tested without a liner, the lid blew off but the explosion was not as violent. Results of testing that product with the UN SADT test indicated a critical temperature of 64ºC, but from additional testing Clancey concluded that drum-sized containers could safely be exposed to a temperature of no more than 50ºC.

Other oxidizing chemicals in common use for swimming pool treatment are:

- dichlor ($C_3Cl_2N_3O_3.Na$; sodium dichloro-s-triazinetrione; sodium dichloroisocyanurate; 1,3-dichloro-1,3,5-triazinetrione, sodium salt)
- trichlor ($C_3Cl_3N_3O_3$; 1,3,5-trichloro-1,3,5-triazinetrione, trichloroisocyanuric acid)

While intended for the same purpose, calcium hypochlorite and sodium dichloro-s-triazinetrione react violently if mixed together[1572].

CARBON TETRACHLORIDE

Carbon tetrachloride (CCl_4) used to be commonly employed as a fire extinguishing agent and as a solvent. Its toxicity has eliminated it from the former role and highly restricted its use in the latter. It is also a powerful oxidizing agent, when combined with certain classes of compounds. These include boranes, several metals, metal alloys, or metal oxides, along with some compounds themselves classed as oxidizers (e.g., calcium hypochlorite, dinitrogen tetroxide, etc.). Fires or explosions can occur with such combinations[3].

AIRCRAFT OXYGEN GENERATION CANISTERS

In older days, oxygen sometimes used to be produced by 'oxygen candles' or 'chlorate candles.' The primary ingredient in these is sodium or potassium chlorate which decomposes exothermically to yield oxygen. For stable decomposition, it is also necessary to include a catalyst, which can be iron powder. An early paper[1573] describes candles cast as cylinders from these ingredients, along with barium peroxide and powdered glass fiber. The barium peroxide reacts with chlorine to avoid the production of chlorine gas, while the glass fiber helps to avoid cracking during burning. Another formulation used sodium chlorate, with 4% manganese dioxide (as reaction stabilizer) and 2.5% charcoal (as fuel)[26]; charcoal is undesirable, however, because it leads to the production of carbon monoxide.

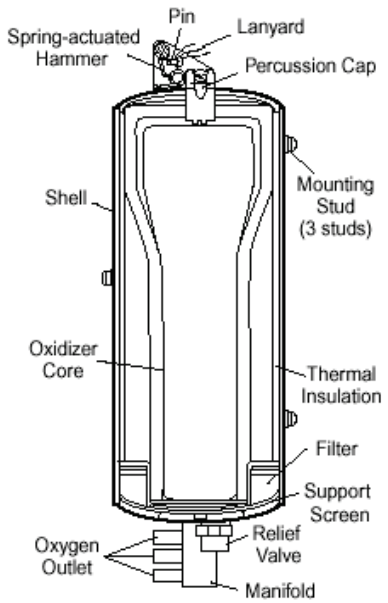

Figure 113 Chemical oxygen generator for aircraft passenger use
(Source: Flight Safety Foundation and NTSB)

To save weight, oxygen for passenger use aboard aircraft is delivered not by means of compressed gas cylinders, but rather by generating from modern-day version of the chlorate candle (for crew use, compressed gas cylinders are used). There have been approximately 20 fires[1574], including a DC-9 where 110 lives were lost[1575], when improperly stored oxygen generation canisters being transported in a cargo hold ignited and then ignited other substances. Illustrated in Figure 113, a canister (also called 'chemical oxygen generator') contains a chemical core of sodium chlorate and powdered iron, an igniter cap containing a primary explosive, a mechanical firing pin, filter media, and hopcalite (a granular mixture of oxides of copper, cobalt, manganese, and silver) to remove any CO which is formed. By replacing charcoal with iron or manganese, the formation of chlorine is avoided. The decomposition reaction is:

$$2NaClO_3 \rightarrow 2NaCl + 3O_2$$

which is exothermic and gives 92 kJ mol^{-1}. A typical canister generates oxygen for 800 – 1000 s, after which the device starts to cool down. Within the reaction zone[1575], temperatures of 550 – 850ºC can be found, but temperatures are lower on the exterior. Shafirovich et al.[1576] conducted some more fundamentally based modeling and also measured similar reaction temperatures. In FAA testing[1577], temperatures on the outside of the stainless steel canisters of only 150 – 200ºC were typically measured. However, when packed in cardboard, polyurethane foam, or polyethylene bubble pack packaging, the canisters were able to ignite the packing materials in several, but not all, trials. Independent testing[1575] showed that when a canister was wrapped in an inorganic insulating blanket, 350 – 400ºC was measured on the exterior of the canister, thus ignition of packing materials is not surprising. In actual testing of generators wrapped in bubble wrap and stored in cardboard boxes, upon triggering the generator, 9 out of 21 trials led to a flaming ignition of the cardboard box, with 2 out of 21 trials leading to a mass discharge of the generators. The initial fire developed slowly, with peak HRR not being attained until about 10 minutes after triggering the initial generator. Once ignition occurs, the subsequent fire hazard is greatly exacerbated because pure oxygen is being delivered from the canister to the nearby area. Normal operating instructions specify that a safety cap must be fitted to an oxygen generator that is shipped, moved, or stored; this cap prevents the triggering of the firing pin. The accidents became possible when these instructions were disregarded. Subsequent to the 1996 fatal crash, FAA banned passenger aircraft from carrying the canisters as cargo.

There is an unrelated category of products which are sometimes erroneously also called oxygen generators, but are properly termed oxygen concentrators. These use a molecular sieve (commonly zeolite) to separate oxygen from nitrogen in the air and do not involve high-temperature reactions.

COMPRESSED GASEOUS OXYGEN

There are numerous case incidents where unexpected ignitions occurred in the use of pure-O_2 or oxygen-enriched mixtures, e.g., Urben's compilation[3]. NFPA 53[1578], which is a general safety guide for enriched-oxygen systems, contains a number of case histories of accidental ignitions. Even simple systems, with few chances for contamination or introduction of combustible foreign matter have led to explosions. In one case, an explosion occurred when oxygen was added to a methane cylinder at a cylinder filling facility[22]. An identification of the ignition mechanism is not available for most incidents. In many cases, adiabatic compression, mechanical sparks, or static electricity have been surmised to be the ignition mechanism. In quite a few cases, the incident arose because of inadvertent substitution of an oxygen cylinder or hoseline for one of air or nitrogen. The generally-incomplete understanding of ignitions under oxygen-enriched conditions is largely due to the violent destruction which is associated with the incidents, along with the fact that much smaller energy sources may suffice for ignition than is customary under 21% oxygen conditions.

LIQUID OXYGEN

Liquid oxygen at 1 atm boils at –183ºC. Its critical temperature is –119ºC, meaning that, at any pressure, it will it be a gas at this, or higher temperatures. Bringing together liquid oxygen (LOX) with many combustible substances offers a probability that an explosion will occur. Detonations can result if liquid oxygen is mixed with powdered metals. Various incidents have been reported where a spill of liquid oxygen on an oily road surface leads to violent explosions upon accompanying mechanical impact[3]. In many cases, simply the friction of tires suffices for ignition, if LOX was spilled on an asphalt road surface[26]. In one case, an explosion occurred due to a person walking across gravel on which LOX had been spilled before[26] . NASA conducted tests[1579] to simulate the spillage of LOX on asphalt paving. The results demonstrated that explosions can readily occur, but required that the asphalt be on a firm base—when the asphalt was on a soft base, explosions did not occur. When explosions occurred, violent combustion of the asphalt consumed nearly the entire top layer. Wood can absorb a large amount of LOX and this can cause an explosion. Charcoal that contains small amounts of iron rust impurities explodes in an autoignition mode if it comes in contact with LOX, even if both substances are at the low LOX temperature[26]. Many plastics have been found to be susceptible to explosions when subjected to impact in the presence of LOX[1580]. In most cases, the explosions had a moderately low probability, with only 1 out of 10 or 20 trials leading to explosion. Curiously, the highest probabilities for explosion were almost never associated with the highest drop-hammer energies used. In the absence of impact, LOX combined with sawdust does not lead to an ignition[1581].

The violent results that can be obtained should not be surprising in view of the existence of LOX-based explosives.

These were invented in 1895 and achieved significant usage in the World War I era, with commercial applications persisting through the 1950s[90]. The fuel portion is generally any porous, absorbent combustible—charcoal, carbonized cork, lampblack, woodmeal, and others having been used. Some compositions are highly sensitive to impact, friction, static electricity and other forms of ignition. *Liquid air*, although less effective, can be used for making LOX-type explosives, so the hazards of accidental explosions with liquid air also exist.

Oxygen pumps

Centrifugal pumps for liquid oxygen sometimes ignite or explode while in service. Laboratory tests to characterize these conditions were conducted by Bauer et al.[1582]. The testing identified that factors which can lead to ignition include (a) the presence of gas in the liquid and (b) tramp metal. Ignitions, however, were impossible to provoke when the pump casings and impellers were made of bronze, thus the authors recommended the use of this metal. The possibility of tramp metal can be minimized by fitting the inlet to the pump with a strainer.

Oxygen regulators

Explosions originating in pressure regulators for gaseous oxygen (e.g., for welders' use) are unfortunately not rare. A study[1583] has identified that most accidents involve two factors: (1) heating due to adiabatic compression; and (2) the unanticipated presence of an easily-ignitable material, typically a contaminant, in the system. The two most important precautions pertinent to the user are: (a) before opening the cylinder valve, make sure that the pressure-adjusting screw is fully backed out; (b) open the cylinder valve slowly. It was also determined that safer designs use a bursting disc rather than a relief valve, since the latter contains more ignitable material that can contribute to the severity of the accident. Furthermore, it was found that 'attached-stem' designs are more accident-prone than designs where the valve stem is separate from the diaphragm assembly. Newton et al.[1584] reported that use of a polychloroprene diaphragm in oxygen regulators is likely to exacerbate an accident, in comparison with a stainless steel diaphragm. But Gusky[1583] concluded replacing a polymeric diaphragm with a stainless steel one does not necessarily improve fire safety, since a steel diaphragm can also get ignited, and if it does, it burns at a higher temperature than does a polymeric one. Of commercial designs surveyed, a 'heavy-duty,' two-stage type was found to show the least potential for operator injury.

Some designs of oxygen regulators for medical equipment use aluminum as the material from which most of the regulator's parts are made. Earlier safety recommendations[1585] considered this to be an acceptable material, but experience has indicated that ignitions, explosions, and tragic burn injuries are encountered with such designs[1586-1588]. The ignitions are considered to involve one of the following mechanisms: (1) galling of metal by opening the post valve in an aluminum-bodied cylinder; (2) particle impact; or (3) a frictional mechanism. Aluminum used in oxygen service is particularly vulnerable to ignition from all of these mechanisms. Consequently, NIOSH has recommended that aluminum not be used for this purpose[1586]. The investigation of one of the incidents also suggested that bronze sintered-metal filters used in an effort to prevent particle-impact ignitions may be ineffectual. In contrast to aluminum, NIOSH concluded that bronze or brass regulators are unlikely to ignite/explode in medical-oxygen applications. As a result of NIOSH studies, which identified 16 ignitions/explosions over a 5 year period, aluminum-bodied regulators are largely being discontinued from medical-oxygen service[1589]. ASTM recently developed a forced-ignition test, ASTM PS 127[1590] to determine the vulnerability of various medical oxygen regulator designs to catastrophic burn-through.

Paints, dyes, and related substances

Dreisbach[1591] studied the piloted ignition of paints applied onto concrete-block surfaces using the Cone Calorimeter. All paint systems included a primer coat, plus the specified number of finish coats. His results are shown in Table 165 and Table 166.

Drying oils are used in stains, alkyd ('oil-base') paints, and other surface coatings. The self-heating properties of drying oils are described in detail under *Oils*. In this section, ignition hazards associated with surface coatings are considered, both due to use of drying oils and from other causes.

Table 165 Piloted ignition times (s) in the Cone Calorimeter for latex paint on a concrete-block substrate

Coats	Heat flux (kW m^{-2})

NI – no ignition								

As discussed in Chapter 9, by the late 18th century, the problems of spontaneous combustion of paint products were being researched. Moore's 1877 book[1592] mentions losses of ships due to spontaneous combustion of stains containing rapeseed oil and fir-wood soot. Much of the problem of spontaneous combustion of paints is directly connected to the 'drying' process. The latter, for non-water-based paints, is somewhat of a misnomer, since no migration of any water is involved. Conventional ('oxidizing') alkyd paints stop being 'tacky' due to oxidative polymerization of the drying oil contained in the formulation. This type of reaction is deliberately promoted by the inclusion of a catalyst in the formulation, otherwise the paint could be impractical to use. Traditionally, catalysts have included a combination of a metallic compound (e.g., manganese naphthenate), and an amine (e.g., 1,10-phenanthroline)[1593]; the amine is sometimes termed the 'accelerator,' to distinguish it from the metallic compound. More recently, 'non-oxidizing' alkyds have been available. These types of alkyds are typically used as a plasticizer in nitrocellulose-based lacquers. They are not subject to the self-heating hazard associated with oxidative polymerization, since the oil used is non-drying (e.g., castor or coconut oil) and polymerization is accomplished by cross-linking hydroxyl groups with melamine-formaldehyde, urea-formaldehyde, or polyisocyanate resins.

The actual reactions taking place in commercial products can be complicated. For instance, some wood stains contain roughly equal parts of boiled linseed oil and mineral spirits. The mineral spirit component vaporizes at a lower temperature, and since vaporization is an endothermic process, for an initial time period this will serve to counteract the self-heating tendency of the linseed oil reaction[1594].

In addition to drying oils, some pigments themselves are prone to self-heating. Binswanger[1595] mentions lampblack, Prussian blue, chrome green, toluidine, and para reds. Chrome yellow (lead chromate, $PbCrO_4$) and chrome orange (lead dichromate, $PbCr_2O_7$) are not much used now, but these pigments can react explosively with some organics[943]. Cooke and Ide[605] report that a number of self-heating ignitions in paint spray shops have been associated with a self-heating reaction between primer containing chrome yellow and a polyester resin containing styrene monomer and an organic peroxide hardener, when both were put into one waste bin. Theoretical modeling of the self-heating of organic pigments has been presented by De Faveri et al.[1596] Sulfur-black dye is highly prone to self-heating[1790]. A wide variety of other unstable, easily oxidizable or readily decomposing materials tend to be used in paint and dye industries. Smart[347] discusses a variety of incidents. Copper phthalocyanine ($C_{32}H_{16}CuN_8$) is used in the manufacture of dyestuffs, and it has been implicated in a number of smoldering fires[1597]. Gibson et al.[1598] conducted oven-basket self-heating tests on two dyestuffs (identified only as 'synthetic dye') and found that neither obeyed the standard F-K self-heating theory. Paints containing zinc have been found to cause ignitions of grass[1599]. The reaction was taken to be:

$$Zn + H_2O \rightarrow ZnO + H_2$$

Flash point information is normally provided by the paint manufacturer. Latex paints are normally described as having no flash point. However, once water is evaporated, the remaining paint film is an organic substance and can be ignited, but ignition temperatures have not been reported for latex paint films.

Two-part paint systems that use a *hardener* involve an exothermic polymerization reaction, and this can lead to ignition, in some cases. A fire in extreme heat of the summer in a closed car was identified as being due to the reaction between polyester paint resin and hardener; laboratory testing showed that mixing 15 g paint with 15 g hardener at an ambient temperature of 50ºC sufficed to lead to spontaneous combustion[1600]. Inadvertent reactions can occur between a lacquer and a varnish, leading to spontaneous combustion in a spray booth[1601], but details have not been provided. Similarly, reactions between lacquer and alkyd paints have been known to lead to fire, due to the action of the not-yet-reacted catalyst contained in the alkyd paint upon the lacquer.

With certain particularly-exothermic paint products, *overspray*, even in small quantities, may lead to fire. Anderson[1602] documented case histories where overspray from a lacquer caused numerous spontaneous combustion fires. He also conducted tests which showed that three cups of lacquer dust mixed with one cup of sawdust led to a flaming fire in about 1.5 h. Lacquers can contain a wide variety of constituents and the chemical composition in Anderson's tests was unknown. A combination of exothermic reactions from polymerization of alkyd resins, and the decomposition of a cellulose nitrate component may be the cause. Anderson demonstrated that lacquer dust alone, placed in a paper bag, also went into spontaneous combustion, but about 3.5 h were required. The Fire Research Station investigated a series of fires due to self-heating of paint dust[1603]. It was found that paint dust resulting from the sanding of newly-painted metal surfaces was highly prone to self-heating. This included both finish coat and primer coat layers, but the investigation did not delve into the chemical nature of the paints, except to identify that a wide variety of different products were showing the same problem. In spray booth applications, spontaneous combustion fires are known to occur due to self-heating of deposits on filters, if these are not properly cleaned.

Experience indicates that *quick-drying* paints (including as overspray, upon rags, etc.) are more susceptible to self-heating. Such paints are formulated so that the exothermic 'drying' reaction would be quicker, raising their HRR, and all else being equal, raising the HRR of a self-heating-prone substance directly increases its spontaneous combustion hazard.

Eckhoff et al.[1604] studied the explosibility characteristics of polyester and epoxy powders used in electrostatic powder coating applications. When tested in the closed Hartmann bomb and using the CMI spark generator (see Chapter 5), minimum ignition energies were found to range from 'less than 3 mJ' to 25 mJ. LFL values ranged from 33 to 67 g m^{-3}. The LFL value was found to be determined by the organic content of the powder, with all specimens showing a value ≈ 33 g m^{-3}, when taking into account solely the combustible fraction of the mass. No relation was found between the MIE and the organic content, however.

Electrostatically-sprayed paints can create flammable atmospheres even if they have a fairly high water content. On the basis of experimental studies, it has been proposed[1605] that flammable atmospheres will not be present if *WC*, the water percent in the mixture (by mass) exceeds:

$$WC > 1.70\,SV + 0.96\,SO$$

where *SV* = organic solvent content (% by mass) and *SO* = organic solids content (% by mass). Electrostatic charging during *airless spraying* produces currents which are about a factor of 10 higher than during paint spraying with an air compressor[1606]. Incendive sparks can readily occur if the operator or the gun are not properly grounded. Relative humidity was found not to play a role in the electrification produced.

Aluminum-based paints are susceptible to a special hazard—if struck by a rusty steel object, a thermite reaction can cause sparks of very high temperature to be emitted. This has been a concern in mining and other industries where flammable atmospheres might exist and become ignited. Since the thermite reaction involves iron oxide, not pure iron, a thermite reaction will not occur if the steel is not rusted. Kingman et al.[1607] conducted numerous tests with various aluminum-based paints. Except for nitrocellulose-containing products, they found that preheating the painted surface to 200ºC or more was needed for obtaining incendive sparks in hydrogen/air atmospheres. Gasoline vapors in air were not ignitable at all, except from a preheated surface coated with nitrocellulose-containing paint. The reason why the non-metallic components of the paint played an important role was not made clear.

Practical advice on avoiding fires in spraying operations is given in NFPA 33[1608]. See also: *Gypsum wallboard*; *Wood and wood products*.

Paper products

PAPER

Paper is a substance where great variations are possible. Tissue paper, newsprint, glossy magazine stock, and manila (folder) paper are all papers, but their properties relevant to ignition are dissimilar. Basis weight (that is, g m^{-2}) and percent inorganic content are two significant variables. The latter is important because some paper types, mainly gloss stock, are highly loaded with clay or similar minerals. This component is not combustible and to a certain extent it serves to inhibit combustion of the remainder.

Newsprint is produced by mechanical pulping of softwood followed by bleaching. Inks, of course, may be applied to the surface. Smith[1609] measured the ignition temperature of newspaper want ads by an optical pyrometer and reported values of 260 – 290ºC, independent of flux and independent of whether test runs were piloted or not. Almost identical temperatures of 260ºC for tissue paper and 280ºC for crepe paper were obtained much earlier by C. L. Dows using an unspecified technique, as cited by Brown[189]. Since Smith's values are the only published values where a reasonably reliable testing technique was used, they should be considered authoritative. A wide variety of values were obtained by other researchers using unspecified or poor experimental techniques. These are summarized here for reference; some more extensive review of old and poor testing techniques is given under *Wood*. Graf[997] measured the AIT for a wide variety of paper types. Apart from oiled papers and Kraft paper, all others showed ignition at around 225 – 240ºC. Kraft paper ignited at 320 – 370ºC. Using an even-poorer technique, Brown[189] obtained an AIT of 184ºC for newsprint. A NIST study[1610] gave the ignition temperature of paper as 123ºC and asphalt-impregnated Kraft paper as 203ºC, but details were not given and values below 200ºC must be judged to be erroneous. The pyrolysis and combustion chemistry of newsprint was studied in a TGA apparatus[1611]. It was found that ignition for non-inked surfaces occurred at 290ºC, for black inked at 310ºC, and for colored inks at 270ºC. In follow-on experiments[1612] on the char formed by anaerobic pyrolysis of the virgin material, it was found that char of non-inked surfaces ignited at 442ºC, for black inked at 449ºC, and for colored inks at 428ºC. In was also found that washing the newsprint in water prior to testing had negligible effect on both sets of results. In an earlier study[2084], the authors examined TGA heating rates from 1ºC min^{-1} to 50ºC min^{-1} and determined that, within that range, the heating rate had no influence on the results.

More extensive and reliable data are available for the ignition temperature of wood. Paper—unless highly treated or modified—is chemically similar to wood and can be considered to ignite at the same temperature, as detailed under *Wood and wood products*, below.

For a heated metal bar to ignite paper, a temperature of 695ºC was found to be needed[1613]. Mechanical sparks from steel against a carborundum grinding wheel were found to ignite tissue paper in a flaming mode, but no ignitions could be obtained from sparks of steel-against-steel[1614]. Telephone directory pages, both flat and crumpled, are readily ignited by 38 mm fire brands; 19 mm brands can only marginally ignite this form of paper when some wind is present[1049].

Minimum irradiance values needed for the autoignition of paper products has been studied using a high-temperature tungsten-lamp heat source[1615]. Single sheets of newspaper classified ads required 38 kW m^{-2}, while a stack of multiple layers only required 19 – 24 kW m^{-2}. This is because of poor thermal contact between sheets of newspaper, with the backing sheets acting as thermal insulation, not as a heat sink. Crumpled newspaper sheets needed 25 kW m^{-2}. For alpha-cellulose filter paper, values were generally similar to newspaper sheets. White facial tissue required 59 – 67 kW m^{-2} for ignition, reflecting the very low absorptivity (estimated at 0.09) for the high-temperature radiation. The low absorptivity is due, in good measure, to the diathermancy (semi-transparent nature) of the material. Using a quartz-lamp radiant heat source[1035], stacks of 6 telephone directory pages required 21 kW m^{-2} for autoignition.

Mowrer[1038] studied the autoignition of paper products using the Cone Calorimeter in a horizontal orientation, with a dead air space located below the specimen. For tissue, he found the minimum flux of ignition to be 35.6 kW m^{-2}, while for paper towel it was 30.6 kW m^{-2} and for newsprint 27.8 kW m^{-2}. Lee[1616,1617] placed crumpled newspaper on the floor in room fire tests and found that about 20 – 30 kW m^{-2} flux was needed for ignition; however, because the flux in that environment is non-uniform both in space and time, results can only be viewed as semi-quantitative.

Several studies on the ignition of waste paper baskets from cigarettes have been discussed under *Cigarettes*, above. Holleyhead tested 20 wastebaskets stuffed with paper tissues and obtained flaming ignitions in 4 instances, with times to flaming ranging from 16 to 26 minutes[304]. In a single test, he was able to ignite a cardboard tube from a toilet paper roll by placing a cigarette inside it. Flaming occurred in 37.5 minutes. In another test series, he placed cigarettes on upper surfaces of rolls of toilet paper; 3 flaming ignitions were found during 28 trials. The times to flaming were 92, 98, and 102 minutes. Holleyhead also reported being unable to ignite corrugated cardboard in the horizontal orientation, but that a cigarette placed between vertical cardboard pieces led to flaming in 15 minutes. Cooke and Ide[605], however, obtained a flaming ignition when a cigarette was placed on horizontal cardboard in the presence of a 1 m s^{-1} wind; the ignition took 5 minutes.

Large rolls of paper are known to occasionally undergo spontaneous combustion in transit or storage. Causes include over-drying the material[1618] or storing it too hot[1619]. Spontaneous combustion is less likely to occur if moisture levels over 5% are maintained. As with many other manufactured materials, it is important to avoid storing large piles of material which is initially at an elevated temperature. Hirst[1620] mentions that "soggy heaps of waste paper" have been found to undergo spontaneous combustion; he considers that moisture is necessary and that bacterial action may be involved. Little quantitative information is available on the subject, apart from one old study. Rosenhain and Gemmell[264] conducted experiments in 1913 which were a cruder version of the FRS oven-basket testing method. Using 0.305 m cube baskets, they filled them with torn up pieces of Kraft paper and found that an oven temperature of 195ºC was needed for thermal runaway. An interesting case of spontaneous combustion of paper towels was investigated at Lawrence Livermore National Laboratory[1621]. A sealed, unopened package of paper towels was found smoldering on a storeroom shelf (Color Plate 138). The investigation determined that an unknown contaminant had been present in the unopened package. Carbon paper has been found to be exceptionally easily ignitable in a smoldering mode[317]. Eruption into flaming is possible by gently blowing[304]. Autoignition of scrap paper was reported to occur[1197] when placed around a steam pipe having a temperature of 210ºC.

CARDBOARD

Tests at the Fire Research Station[1622] indicated that the minimum flux for radiant ignition of corrugated cardboard is 17 kW m^{-2} for autoignition and 15 kW m^{-2} for piloted ignition. No effect of thickness or number of walls (2 or 3) was found. Lattimer[1623] conducted unpiloted Cone Calorimeter tests on 4 mm thick corrugated cardboard and found a minimum flux of 8.5 kW m^{-2} for igniting in a smoldering mode. At fluxes of 15 – 23 kW m^{-2} two-stage ignitions were seen, with smoldering being followed by flaming. At higher fluxes, single-stage flaming ignitions were observed. Using piloted test conditions, single-stage, direct-flaming ignitions required a minimum flux of 8.5 kW m^{-2}. Tests at NIST[1624] using the LIFT apparatus indicated a minimum flux of 14 kW m^{-2} for piloted ignition. For fluxes somewhat lower than this, no flaming occurred, but the specimen was fully consumed in a smoldering ignition; the minimum flux for smoldering ignition was not established. Cone Calorimeter ignition results obtained by Grant and Drysdale[1625] for corrugated cardboard are given in Chapter 7 as one of the example graphs and show $\dot{q}''_{\min}$ = 12.5 kW m^{-2} for piloted ignition. The authors also measured T_{ig} in their experiments and obtained 362ºC at 15 kW m^{-2} and 325ºC at 20 kW m^{-2} (average values from 3 tests). In some long-exposure tests, Shoub and Bender[1626] exposed 10 mm thick, primed or painted paperboard samples to a heat flux of 4.3 kW m^{-2}. The specimens autoignited in 0.58 – 4.75 h. Test details are discussed in Chapter 7. Smith[1609] measured the piloted ignition temperature of cardboard by an optical pyrometer and reported a value of 320ºC, independent of the heat flux over the range 21 – 105 kW m^{-2}; his reported values under autoignition conditions were evidently incorrect.

Corrugated cardboard is ignitable by fire brands of 19 mm size if a modest wind is present; 38 mm brands cause ignition without a wind[1049]. A case history was reported[45] where autoignition of cardboard drums occurred due to filling with a hot product at 160 – 200ºC. The authors label this as a self-heating occurrence, but the temperature is high enough

that external heating alone might be considered the primary cause, with contributions from self-heating.

PAPER VAPOR BARRIER

A case has been reported where a bituminized Kraft paper vapor barrier ignited from the friction of a workman's drill and caused a house fire[1627].

Peat and organic soils

Organic soil* and peat are roughly interchangeable terms and are defined as soils with an organic content greater than 20% and a layer thickness greater than 0.41 m. Peat will commonly have organic contents in excess of 90% and be found in layers more than 1.5 m thick. It often has a moisture content over 100%, yet is fairly prone to ignition by lightning[1157].

Fresh peat comprises, by mass, about 48 – 50% carbon, 5% hydrogen, 0.5 – 1% nitrogen, 0.5 – 1% hydrogen, 38 – 42% oxygen, and 3 – 10% ash. As plant matter, it decomposes in storage. Aged peat will contain approximately 58 – 60% carbon, 5% hydrogen, 1 – 3% nitrogen, and 30 – 35% oxygen. Thus, with decomposition the carbon content rises, oxygen content falls, and the heat of combustion also rises. The net heat of combustion of dry peat is approximately 20 – 23 MJ kg^{-1}. Peat deposits are often ignited from an ongoing wildland fire. The burning is of a smoldering type, with much smoke but little visible flames being seen. Peak temperatures of only ca. 475ºC are found[1628]. Salgado et al.[1629] measured the ignition temperatures of several organic soils and reported values of 230 – 236ºC. But since they conducted their tests in a thermal analysis apparatus using a poorly described technique, not much confidence can be placed in these values.

High organic content, low moisture content, and low density are the main factors which influence the ease of igniting organic soil from an ongoing above-surface fire. A number of studies have been published where the maximum moisture content permitting ignition to take place was explored, but the data are extremely variable. As a rough predictor, it has been suggested[1630] that for soils of around 110 kg m^{-3} density, ignition can take place if:

$$MC < 110 - 25R_I$$

where MC = moisture content (mass percent, dry basis), and R_I = inorganic ratio = inorganic mass /dry organic mass. Thus, for example, if inorganic ratio were 3.0, then only soils with MC < 35 would be expected to ignite, while if R_I = 0.2, then all soils with MC < 105 would be expected to ignite.

The above predictive equation is simple, but it does not work very well when soil density varies. Hartford proposed a relation that takes density into account and also acknowledges the probabilistic nature of the ignition problem. Her equation is:

$$P_{ig} = 1/\left[1 + \exp\left(-19.3 + 0.17MC + 1.72R_I + 0.0231\rho_B\right)\right]$$

where P_{ig} = probability of ignition (--), and ρ_B = bulk density (kg m^{-3}) of soil. Later, Frandsen[1631] and Lawson et al.[1632] conducted probabilistic evaluations of the ignition problem. Unfortunately, a different predictive equation was needed for each type of organic soil, implying that some important variable was still unaccounted for. Figure 114 shows the moisture dependence of 6 different organic soils according to the equations of Lawson. The values for inorganic content and density were set equal to average values for the soil type studied.

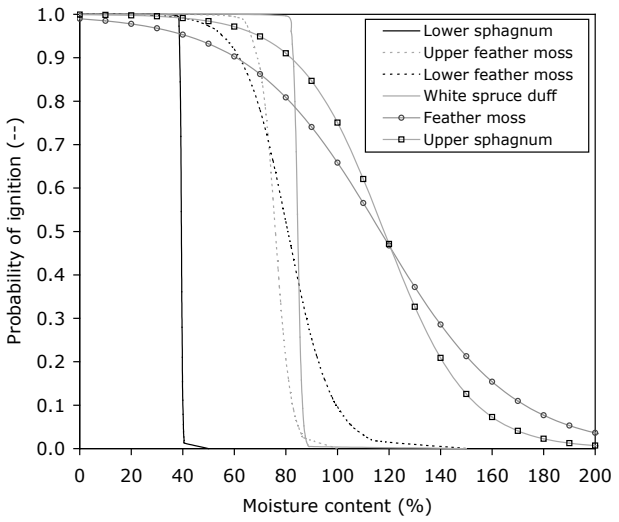

Figure 114 Probability of ignition of various organic soil types, as a function of moisture content

Peat does not require an external source of ignition to ignite and, in fact, is one of the substances well known to undergo self-heating. The self-heating of peat is a complex phenomenon because it involves chemical exothermicity, moisture

Table 167 Peat samples tested in a microcalorimeter by Jones

Sample	Mass tested (mg)	Condition	Temp. range (ºC)	E (kJ mol^{-1})	A (s^{-1})
C	660	as received	28 – 46	101	4×10^{7}
D	950	as received	25 – 60	99	2×10^{7}

* Soil which is not organic soil is referred to as *mineral soil*.

effects, and biological heating. The latter takes place below about 80ºC only, while chemical heating effects are mainly found above 100ºC. Since peat is used in some places as a commercial fuel, most of the reported work has focused on pressed and powdered peat, not peat in nature. Most of the research on peat self-heating has been done in Russia and this work is not readily available in English. The most comprehensive study, which references a number of the key Russian findings is a report from the national fire research laboratory of Finland[1633]. One of the chemical reactions that contributes to self-heating is a dry distillation. This produces not only CO_2, but also methane and other combustible hydrocarbon gases. A series of small-scale measurements on the self-heating properties of peat were reported in an earlier study[1634] from the same Finnish laboratory. The density and the moisture content affect the results, and the authors found that a single correlating variable was useful: $r\rho(0.9 - MC/100)$, where r = radius (m) of the pile, ρ = density (kg m^{-3}), and MC = moisture content (%). Piles as small as 4.9 liters were seen to have critical temperatures of 120 – 140ºC.

Jones[1635] measured the self-heating properties of Irish peat using a microcalorimeter. His results are summarized in Table 167. It is clear that oven-drying greatly alters the self-heating behavior. For the 'as-received' specimens, however, he found a huge variation in the values of E and A, and this most likely is because, due to multiple reactions present, use of F-K theory is inappropriate.

For large piles, self-heating tends to be concentrated in a zone which is 0.5 – 1.0 m below the surface[1633]. This is due to the fact that deeper regions do not get adequate oxygen supply, while the region very close to the surface receives adequate convective cooling. The self-heating zone then moves toward the surface, where open fire can break out. Fire spots also tend to appear in cracks, if the pile has cracks.

One technique that is suitable to restrict the potential for runaway heating is the use of airtight plastic film for covering the material. This is especially helpful since the bacteria involved are aerobic[1633]. Another technique, as with all materials, is to restrict the pile size. Since biological activity can occur up to 80ºC, the pile size should be limited by limiting the critical temperature to a value suitably in excess of 80ºC. For a spherical pile, such a limit may be reached at a radius of around 22 cm. This is a very small pile size, and this indicates that other measures need to also be considered to prevent spontaneous combustion. Wetting down a pile is a questionable strategy; thermal conductivity and, therefore, heat losses may be increased. However, biological activity is also encouraged.

Tests have shown that welding sparks and cigarettes both were able to ignite 15 out of 20 specimens, which comprised 6 different peat types. Peat dust layers show an ignition temperature of 210 – 270ºC[1633] during short-term heating. If a layer is heated for more than two hours, the ignition temperature drops to 150 – 160ºC, due to chemical changes within the material that are not well characterized. The ignition times for radiant heating of a peat dust layer depend greatly on the nature of the specimen. The results for two types are shown in Table 168.

Table 168 Ignition times for 5 mm peat dust layers

Heat flux (kW m^{-2})	Ignition time (s)	
	Type Oulu	Type Hämeenlinna
10	230	N.I.
20	31	45
30	7	7

Several cases have been reported of small flower pots undergoing spontaneous combustion. In one case[1636] a 4-inch flower pot holding a dead plant is reported to have spontaneously combusted in a locked house when the owners were away. It is said that, in a careful investigation, all other causes were ruled out, including smoking materials or intruders. Attending firefighters found a vigorously smoking pot, which erupted into open flaming when they broke it apart. In a similar case[1637], a dead plant in a 1-gallon container was found to be the origin of a fire. In another case[1638], fire originated in a 12-inch pot that only contained 1-year old potting soil. The latter was identified to consist of peat, perlite, dolomite lime, and possibly copper or aluminum flakes. While organic soils can readily self-heat, the small sizes of the containers, combined with the limited ambient temperatures that can be reached in the home, suggest that flower pots will not go into spontaneous combustion to due the self-heating of organic soils. Contaminants or ingredients having very strong self-heating properties would be needed to cause self-heating in these small-size containers, but studies to explore this possibility have not been made. Cases are well-known where disposal of a cigarette into a flower pot caused a smoldering ignition. Planting mixes comprising mainly peat moss, along with perlite or vermiculite and a fertilizer, are especially prone to being ignited from cigarettes[1639].

Perchloric acid

Anhydrous perchloric acid, $ClHO_4$, is unstable in air and consequently is not used in that form. Commercial grades are water solutions containing 60 – 72%, by mass, of perchloric acid. The substance does not burn by itself, but it is a strong oxidizer and is often used in laboratories for that purpose. Because of its oxidation potential, a number of explosions have been documented[1640]. Laboratory testing using small quantities in test tubes showed that combinations of perchloric acid with a wide variety of organic solids commonly led to ignition temperatures in the range of 130 – 200ºC. Small amounts of iron added to the mixture often lowered the ignition temperature substantially, in some cases down to 90ºC. A number of the mixtures exhibited high-

order detonations upon ignition. Diluting the acid down to a 40% concentration tended not to reduce the ignition hazard, although mixtures that detonated using a 60% acid concentration did not detonate at lower concentrations. At concentrations greater than 77%, room-temperature ignitions are possible, but concentrations this high are not commercially distributed[26].

Perfluorocarbons

Perfluorocarbons, which are substances with the general formula C_xF_{2x+2}, function as extinguishant agents in atmospheres where oxygen and hydrocarbon fuels are present. But in a study on one of the perfluorocarbons, perfluorobutane (C_4F_{10}), Ohtani[1641] found that in other atmospheres, explosions have occurred. In the presence of silane, perfluorobutane acts as an oxidizer, while in a fluorine/nitrogen atmosphere, the compound acts as a fuel. In the latter case, it is oxidized by fluorine to yield CF_4.

Peroxides

Peroxides are compounds that contain the –O–O– structure, which is a relatively unstable configuration for a molecule. Peroxide compounds are grouped into inorganic and organic peroxides. The latter are generally more hazardous, since the molecule contains a fuel portion, not just an oxidizer.

INORGANIC PEROXIDES

Hydrogen peroxide, H_2O_2, is the most common inorganic peroxide, and is used for antiseptic purposes, hair bleaching, and various industrial applications. It decomposes as:

$$2H_2O_2 \rightarrow 2H_2O + O_2$$

The decomposition properties have been studied by Liaw et al.[1642], who determined that the reaction is of first order, with $E = 91.8$ kJ mol^{-1}, and $A = 2.15\times10^9$ s^{-1}. If the reaction is solely decomposition, i.e., fuel is not available for further reaction with the liberated oxygen, only a very low adiabatic flame temperature of 1000ºC can be reached[26]. Under some cases, liquid hydrogen peroxide can be made to detonate, but this requires a concentration greater than ca. 92%. Solid crystallized hydrogen peroxide can also be detonated, but neither type of explosion is likely to be accident-caused. Concentrated H_2O_2 vapors can be exploded and marginally detonated[26]. The perception that hydrogen peroxide is an unstable compound that readily decomposes stems from experiences with impure material, since many impurities catalyze decomposition; highly purified H_2O_2 has good stability. Small amounts of rust falling into a container of H_2O_2 with greater than 70% concentration can lead to a violent decomposition.

Ignitions or explosions involving hydrogen peroxide are much more likely to happen in the presence of a fuel, rather than as a pure decomposition event. If concentrated H_2O_2 is spilled onto rusted iron, concrete, dust, or clothing, a fire may result; an explosion is possible if the liquid is partially confined[157]. Breakage of a container with a 70% solution and subsequent reaction with a lubricant caused a sizable fire and explosion[26]. The National Transportation Safety Board[1643] reports a flaming fire with a 50% solution and a smoldering fire with a 35% solution that were caused due to breakages or spills on board airliners. Spills of 32% or greater concentration solutions onto combustibles can lead to ignition if the ambient temperature is 25ºC or higher and humidity is low[26]. The drugstore variety is generally a 3% concentration and poses no hazards. Hydrogen peroxide is compatible with certain aluminum alloys, polyethylene, PTFE, and Kel-F plastics. Extensive listings of incompatible materials have been published in a US military handbook[1644]. The loss of the Russian submarine KURSK has been blamed on the use of hydrogen peroxide in a torpedo drive unit. In the US, hydrogen peroxide is recently making a comeback as a rocket propellant because it is advertised as "nontoxic" (in comparison to dinitrogen tetroxide).

The peroxides of a number of metals—sodium, lithium, and barium—show strong oxidizing or explosive properties. Potassium superoxide, KO_2, is a more potent oxidizer than potassium peroxide (K_2O_2). Some explosions have occurred when this compound formed simply by exposing potassium to air[26]. Médard[26] reviews the explosion hazards of a number of other, less common, inorganic peroxides and related compounds.

ORGANIC PEROXIDES

Organic peroxides are substances with the formula R–O–O–R'. They tend to be thermally unstable and decompose into two fragments:

$$R–O–O–R' \rightarrow R–O^{\bullet} + R'–O^{\bullet}$$

The fragments are free radicals which can react further. Organic peroxides are classed as oxidizing agents, since the decomposition fragments react by oxidizing other substances. Organic peroxides are widely used in the polymer industry, where they can serve as initiators of polymerization, since they produce radicals needed to start the reaction. When used as a component in a multi-component adhesive or coating, the organic peroxide is often called a *hardener*. Organic peroxides may be liquids, powders, or pastes. When in paste form, explosions are generally less severe than for the dry solid. Decomposition of organic peroxides can be accelerated by the presence of catalysts such as $AlCl_3$ or iron salts. A huge variety of organic peroxides could be synthesized, but only a modest number are useful as commercial products. Castranas et al.[1645] published a general safety survey, with known hazards briefly described and extensive references supplied. Peroxides are sometimes ranked according to their active oxygen content, which is the percent of the compound (by mass) represented by the –O–O– groups. The US Dept. of Transportation forbids shipment of certain organic peroxides that have an active oxygen content greater than 9%. Phlegmatizers are sometimes added to organic peroxides to reduce their explosive potential. These are substances—commonly phthalates, phosphates, or maleates—that reduce the vapor pressure, raise the flash point, and decrease the sensitivity to shock.

Bowes reported on self-heating and thermal decomposition studies of benzoyl peroxide[1646] and lauroyl peroxide[1647]. The reactions are complex and not fully quantified; the reaction products include both liquid and gaseous components. Thus, the thermal history of the material does not follow a simple, single-reaction theory. In later work, Bowes concluded[445] that experimental explosion results for benzoyl peroxide could be adequately represented by the use of the self-heating constants E = 183.3 kJ mol^{-1}, P = 83.78; however, since the response clearly does not conform to the theory, the usefulness of such treatment is dubious. Data from large-scale burns of organic peroxides have been published[1648] with the specific details being given on radiative fraction, in order to enable calculations to be made of target ignitions from such burning fuels.

Kayser[1649] examined the self-heating of several organic peroxides using small samples placed in an oven for 20 h at 55ºC. Lauroyl peroxide sustained thermal runaway in an 0.5 g quantity. Benzoyl peroxide, *tert*-butyl acetate, *tert*-butyl hydroperoxide, di-*tert*-butyl peroxide, cyclohexanone peroxide, and methyl ethyl ketone peroxide were stable in 1.0 g quantities. She also determined that polyethylene material was non-reactive with the peroxides and did not act to promote exothermic behavior.

The UN Model Regulations[1650] contain a table giving extensive properties and safety measures for most commercially common organic peroxides. Bond[1651] has tabulated self-heating and other properties for a variety of organic peroxides. Tamura et al.[1652] reported on a large series of organic peroxides tested in the Japanese Revised Time-Pressure Test. Zitrin[1653] reports that the organic peroxide TATP (triacetonetriperoxide, $C_9H_{18}O_6$) has been used by some terrorist groups. Médard[26] provides an extensive discussion of the properties of organic peroxides, along with reports of accidental explosions.

Pharmaceuticals

Koltsov[1654] has reported on Russian research where the self-heating of a large number of powdered vitamins and pharmaceuticals was studied using oven tests with cubic baskets. Unfortunately, only data reduced according to a crude Russian estimating formula were provided.

Phosphines

Phosphine, PH_3, is spontaneously flammable in the air if there are even traces of diphosphine, P_2H_4, present[1655], or if it is moisture-free[3]. Diphosphine is also spontaneously flammable by itself. At room temperature and pressure, it has been found[1781] that pyrophoric ignition will occur if the ratio of phosphine to oxygen (assuming the remainder to be nitrogen) exceeds a certain value. The authors' data can be represented as:

$$phosphine\ \% \geq 0.28 + 3.57\left(oxygen\ \%\right)^{0.62}$$

The above relation specifies the maximum amount of oxygen that can exist for pyrophoric ignition to occur and is applicable for phosphine volume fractions of 6.5% or less. Clearly, there also has to be some minimum of oxygen, greater than zero, but this limit was not explored, nor were phosphine levels over 6.5%. Thin, ghostly flames are sometimes seen above marshes and are known as *marsh gas*, will o' the wisp, foxfire, or jack o' lantern. The fuel gases causing these flames comprise methane, phosphine and diphosphine[1398]. Fires onboard ships have been reported[1656] due to excessive generation of phosphine from *magnesium phosphide*, which is used as a fumigant.

Phosphorus

White or yellow phosphorus oxidizes rapidly in air, and can ignite at slightly above room temperature. There are two oxidation modes—in the slow mode a green glow is seen, while the fast mode gives a yellow flame. The slow oxidation mode takes place at 16 – 38ºC if the air is adequately moist[1657]. Above 38.5ºC, flaming occurs. The ignition temperature is pressure sensitive, and decreases if pressure is lowered. In one series of tests, the Bureau of Mines[1378] tested 4 g quantities of white phosphorus and found that it ignited in air at the lowest temperature used, 32ºC. The oxidation reaction is:

$$4P + 5O_2 \rightarrow 2P_2O_5$$

Contact with finely divided charcoal or lampblack promotes ignition. An incendiary preparation, sometimes known as Fenian Fire, can be made with phosphorus by dissolving it in carbon disulfide. The dissolved solution is applied as a film and resists igniting only until the CS_2 evaporates, at which point spontaneous combustion occurs. Rat poisons containing phosphorus used to be common, and cases have been reported where a small amount of phosphorus reacted with organic materials to cause a fire[2078]. Phosphorus fires are difficult to extinguish and tend to re-erupt after initial extinguishment.

Red phosphorus is an allotrope which is prepared by anaerobic heating to 240 – 253ºC. It is not pyrophoric, but can be ignited by impact or friction[3]. It has been reported[943] that its ignition temperature is 240ºC. Powders of red phosphorus are subject to oxidative self-heating, consequently, antioxidants have been developed specifically for red phosphorus[1658]. Other allotropic forms of phosphorus, such as violet or black, are rarely encountered.

Pillows

Ramsay and McArthur studied the ignition of pillows[1659]. All pillows were tested covered with 50/50 polyester/cotton pillow cases of 172 g m^{-2} weight and placed on sheets of similar fabric located atop a simulated polyurethane foam mattress. Their results are summarized in Table 169. The authors concluded that details of the coverings mattered little, with behavior being determined by the fillings.

Table 169 Ignitability of pillows

Filling	Covering	Ignition from cigarette		Ignition from methenamine pill

Pipe insulation

The theory of self-heating-caused ignitions of pipe insulation is presented in Chapter 9. Here, some experimental findings and some practical advice are provided. Bowes[1660] reported on oven-cube tests and on 'pipe simulator' tests with two different pipe insulations, a mineral wool and a calcium silicate/asbestos type. Both were coated with a low-viscosity transformer oil not containing antioxidants. The tests were difficult to conduct in a repeatable manner, since a uniform coating of oil is not possible to achieve. Some pipe insulation systems use a fabric-type cover on the outside. In pipe simulator experiments with such specimens, self-heating could not induce glowing, much less flaming ignition, at pipe temperatures up to 300ºC. This demonstrates the importance of restricting oxygen supply in order to control self-heating.

Gugan[1661] reviewed a number of case histories of self-heating fires associated with pipe insulation. He pointed out that the oils or other materials likely to contaminate pipe insulation in real-fire incidents are rarely distributed in a uniform manner, and this fact can significantly diminish the ability to use laboratory tests for prediction. Furthermore, he pointed out that the standard theory requires assuming a known value for λ, the thermal conductivity of the contaminated insulation material. It is well-known that the effective thermal conductivity of porous insulation materials increases greatly with temperature[1662]. The conductivity to consider, by the way, must be the 'effective' one, which includes contributions from convection and radiation taking place within the porous structure, since the latter two effects are not negligible in lightweight, porous insulations. The problem is especially difficult in the pipe insulation case due to the strong temperature gradients necessarily present, even before any self-heating has started.

The amount of liquid which is deposited on the insulation material clearly will influence the self-heating process. A small amount of liquid will not provide much HRR; a very large amount, however, will tend to fill the pore structure and prevent oxidation. Thus, for oxidizable liquids, an intermediate loading should exist which creates the worst-case condition. But Britton[1663] showed that, within limits, actual self-heating results are not highly sensitive to the amount of liquid loading; he considers loadings of 150 – 350%, by mass, to be appropriate for test purposes. This lack of major sensitivity explains why there is significant disagreement in the literature concerning how much liquid corresponds to a worst-case loading. He also reports an extensive set of experimental data on various liquids soaked into calcium silicate and mineral wool insulation. The variables included loading and temperature, but all tests were run only with 51 mm cubes; thus the standard variables E and P could not be deduced. The fluids included amines, glycols, organosilane esters, and a variety of heat transfer fluids. Britton concluded that the results of the self-heating tests could be roughly correlated by Lindner's[1664] variable Z:

$$Z = \frac{AIT}{AIT - FP}$$

where AIT is the autoignition temperature (ºC), and FP is the flash point (ºC). Generally, liquids with $Z < 1.35$ did not show self-heating in the oven-cube tests, while those with $Z > 1.61$ did. The region of $1.35 < Z < 1.61$ was a zone where rankings were contradictory. Britton attributes this to the use of NFPA 325 values for the AIT. The latter are compiled as the 'lowest published values,' which means there are significant inconsistencies due to different experimental techniques or laboratory variations. Fluids which have a low Z are ones which have either a low flash point, a high AIT, or both. Liquids having a low flash point show a *lower* self-heating hazard because such liquids are also very prone to evaporate. If the liquid readily evaporates, then enough of it will not remain in the insulation in order to undergo thermal runaway.

Two categories of liquids are special cases and Z values for them should not be expected to give indicative results. (1) liquids which react with ambient air moisture (e.g., trichlorosilane), since these can generate products which are less volatile than the parent compound. (2) liquids which react to form peroxides (e.g., tetralin and 2-ethyl hexaldehyde).

Britton also reports case histories where methyldiethanolamine soaked into calcium silicate insulation and high molar

Table 170 Plastic materials comprising the first item ignited in fires

mass polyethylene glycols soaked into mineral wool insulation caused fires. Another fire involved tetralin used as a heat transfer fluid on an unspecified insulation. Tetralin is particularly problematic since it forms tetralin hydroperoxide upon exposure to air, with the latter being an unstable compound which shortly decomposes.

In some cases, the evaporation behavior, and not just oxidation, of the liquid can play a strong role in determining conditions for thermal runaway. Effectively, if the fuel can vaporize faster than it self-heats, then it will not create a thermal runaway hazard. Brindley et al.[1665,1666] performed modeling where fuel vaporization effects were included. This work indicated that the classical Frank-Kamenetskii theory is only applicable to low-volatility, highly-exothermic fluids; if applied to situations where this is not true, grossly over-conservative predictions may be obtained. In the Brindley theory, a large number of physicochemical constants are needed to perform the computation, and the values for quite a few of them will generally be difficult to get. Thus, a practical hazard-computation scheme has not yet emerged, although there is an expectation that further analysis of experimental results could produce one.

Hilado[1667] reports on tests where fourteen different insulation types were soaked in ethylene oxide. The order, best to worst, when tested for the self-heating propensity was: glass beads, glass fibers, mineral wool, perlite, and calcium silicate. Quantitative conclusions are hard to draw, however, because non-standard testing techniques were used. A way by which the self-heating problem can be eliminated is to use *cellular glass* insulation, since this material does not have a pore structure into which a liquid can penetrate. However, it is expensive, difficult to work with, and in some industrial situations it may not be usable because it

cannot achieve a fire endurance rating due the melting temperature of glass. For ordinary insulation, installing an impermeable cover on the surface can help. Another material which can help is a perlite insulation which is treated with a water-repellant; however, water repellants on mineral wool are not effective and do not eliminate wicking[1663].

Plastics

A British survey examined the ignition of plastic materials in residences[1668]. A total of 396 incidents that occurred in 1969 in which plastic was the material first ignited were studied. The salient findings are shown in Table 170 and Table 171. A number of authors have reported ASTM D 1929 (Setchkin furnace) data on plastics, and many of these

s_r – repeatability standard deviation
s_R – reproducibility standard deviation

results are tabulated in Chapter 15 without further elaboration. For most of these data, repeatability and reproducibility are unknown. Masařík[1669-1671] reported on several roundrobins where precision of results was determined. These results are shown in Table 173.

The ignition temperatures of thermoplastics are typically 150 – 300ºC higher than their melting points, and no specific relation exists between these two properties[1672]. The decomposition temperature, by contrast, is typically only slightly lower than T_{ig}. However, decomposition temperature is not a basic property of plastics but, rather, depends greatly on the apparatus used and the definition adopted, thus, it is not much used in fire safety studies.

Several studies on the radiant ignition of plastics have been used as examples in Chapter 7, and detailed information is given there. Hallman[440] conducted extensive tests on the piloted, radiant ignition of plastics using radiation from a flame source. His primary results are summarized in Chapter 15. Also given are the values of B_{ig} and $\dot{q}''_{cr}$ derived from his data. Apart from the few specimens indicated, Hallman generally did not explore the minimum flux for ignition. Most of his results provided good fits to the thermally-thick data plotting procedure of Janssens. A few materials showed deviations at the high or the low end of the heat flux scale. Those cases are noted in the Table. The 3 mm

thick specimens were analyzed as thermally thin. In addition to the data shown, Hallman also obtained ignition results for several proprietary formulations and for exposure conditions where the specimens were heated with high-temperature (3000 K) lamps. Also provided in Chapter 15 is a table of extensive results obtained in the Cone Calorimeter by Scudamore et al.[1673]

Grand[1674] compared the radiant ignition behavior of FR plastics to their non-FR counterparts using the Cone Calorimeter. His results are shown in Table 172. For several of these materials, he also determined the piloted ignition temperature in the ASTM D 1929 test.

Morimoto et al.[1675] reported autoignition temperature data for a large collection of polymers. Their results are not listed in Chapter 15, because their values were typically on the order of 100ºC higher than those of most other workers. Their test rig was roughly similar to the Setchkin furnace, but they used very small samples (0.2 g), and apparently this caused unduly high T_{ig} values to be reported. No polymer in their study showed T_{ig} < 430ºC, and most showed values of 500 – 700ºC.

Starchville conducted Cone Calorimeter tests on electrical tubing and conduit, as discussed in Chapter 7. His results for minimum flux for ignition are given in Table 176. Holbrow et al.[1037] tested several 3 mm thick plastics in the Cone Calorimeter for autoignition. They obtained the results shown in Table 177.

The fire properties of PMMA have been more extensively studied than for any other plastic. Kashiwagi and Omori[1676] studied the piloted ignition of PMMA and found that the ignition temperature depended on the molar mass of the material—a low molar mass specimen showed 330ºC, while a high one gave 265ºC. This trait was polymer-specific, and molar mass was not found to affect the results for polystyrene (365ºC). The molar mass effect was not related to thermal properties, but was identified, instead, to be due to multiple, exothermic decomposition reactions in the high molar mass material. In Chapter 7, results of Babrauskas indicated $\dot{q}''_{min}$ = 8 kW m^{-2} for PMMA, while two different types of PMMA tested by Thomson[1677] showed values of 9.5 and 10.6 kW m^{-2}. The values of piloted T_{ig} measured by Thomson under various conditions were very close to 311ºC. Hopkins and Quintiere[1678] found ignition temperatures of 250 – 355ºC; this wide spread of data apparently repre-

sents different testing conditions, rather than different samples, but details were not given. Henderson[2111] reported T_{ig} = 345ºC in the Cone Calorimeter, but with few details being given. For the thermochemical properties of PMMA, Staggs[1679] recommends the following values: $A = 1.0226\times10^6$ s^{-1}, E = 97.02 kJ mol^{-1}, ρ = 1190 kg m^{-3}, λ = 0.22 W m^{-1} K^{-1}, C = 2104 J kg^{-1} K^{-1}, ε = 0.95, H_v = 420 kJ kg^{-1}.

Braun and Allen[1770] reported $\dot{q}''_{min}$ = 30 kW m^{-2} for polycarbonate tested in the LIFT apparatus and the identical value was also reported by Quintiere and Harkleroad[2113]. Wang et al. examined the ignitability of several grades of PVC in the Cone Calorimeter and in the Edinburgh University apparatuses[1680]. Their results are given in Table 174. Clearly, there are huge differences between the grades.

O'Neill[1681] reported test results on several plastics which were tested in a variety of test methods, including the minimum heat flux, as determined by the Cone Calorimeter, the IEC 60695-2-13 glow-wire test[1682], the to IEC 60695-2-2 needle flame test[1683] and UL 94. The needle flame and glow-wire tests were conducted on 1 mm thick samples, the thickness for the Cone Calorimeter tests was not specified. The results are shown in Table 178.

Briggs and Morgan[1684] conducted a variety of ignition tests on 5 different plastics. Their results are given in Table 175. The glow wire test was according to IEC 60695-2-13 test[1682], while the needle flame test was according to IEC 60695-2-2[1683]. The results do not suggest that there is a great deal of correlation among results from the diverse tests, thus, use of a test that reasonably simulates the desired fire condition is important.

In an early study, Delmonte and Azam[1685] characterized the hot-surface ignitability of plastics by holding plastic samples for different times to molten sodium hydroxide. The latter substance was picked as giving more reproducible results than molten metals. Their results are shown in Table 179.

Hedges et al.[1686] tested several plastic films for hot-surface ignitability by gluing them onto metal strips that were resistively heated at high rates. In addition, a pilot flame was located in the pyrolysate stream. Their results are shown in Table 180. Filippov et al.[1687] tested the ignitability of plastics by pressing a 2.5 mm Nichrome heater onto their surface; their results are given in Table 181. Another study[1688] by the same authors showed that there is only a small difference of the heater diameter, for example, when the diameter was increased to 3.9 mm, the ignition temperature for polycarbonate dropped from 1125 to 1110ºC.

SELF-HEATING OF SOLID PLASTICS

Monomers used for making plastics (e.g., styrene, methyl methacrylate, vinyl acetate, ethylene oxide, etc.) polymerize exothermically upon initiation. Heat, light, shock, or a catalyst can serve as initiators[2087]. In general, polymerization reactions in plastics-manufacturing are exothermic, so they can only be conditionally stable: an upset to operating temperatures, flow rates, etc. can cause thermal runaway and ignition. Biesenberger et al.[1689] presented a theoretical model and experimental results for thermal runaway of styrene polymerization. Acrylic resin monomers are especially reactive and a history of fires and explosions in chemical plants involving these resins has been published[1690]. Some thermoset plastics require heat curing for their manufacture. The curing process is exothermic and the potential exists for thermal runaway. Buckmaster and Vedarajan[1691] presented a modified Frank-Kamenetskii theory for analyzing such processes.

A case history has been documented[45] of autoignition events in a continuous vertical drier processing nylon flock for carpets. Most of the events occurred as glowing hot spots, which fell and ignited other material. Tests elucidated that if high temperatures are rapidly reached, melting occurs and self-heating is precluded. But if nylon fibers are exposed over a longer period of time to temperatures of 130 – 170ºC, charring occurs and a matrix is preserved which is air-permeable. Using oven tests at 170ºC of 100 mm cubes, it was shown that in thermally-aged specimens glowing hot spots formed in 6 h.

The process of making *fiberglass* with polyester resins has been known to lead to self-heating problems, since the curing reactions involving an organic peroxide (e.g., methyl ethyl ketone peroxide) catalyst and a cobalt 'accelerator' are exothermic. Several fire investigators[1692,1693] published results of limited testing where they documented that they could create self-heating but not spontaneous combustion by over-catalyzing the resin. The temperatures reported in tests have been high enough, however, being 200ºC in one series of tests[1694], that conditions may not need to be much different for overt flaming to occur. In any case, such attempts at negative proof must be viewed with caution. Brydson's treatise on plastics[1695] points out that catalyst and accelerator coming into direct contact can form an explosive mixture. Thus, fires may also be due to accidental direct mixing of catalyst and accelerator, rather than over-catalyzing of the resin.

Jones[1696] studied the exothermic oxidation of *polystyrene* in a microcalorimeter and found that detectable heat output was seen starting about at 55ºC, but that the reaction rate was several orders of magnitude less than in materials with a pronounced self-heating tendency, such as coals, carbons, and cellulosics. Mok et al.[1697] studied the self-heating of methacrylate-butadiene-styrene powder and reported self-heating variables E = 138 kJ mol^{-1}, and P = 62.0; the latter value, however, is very high and may not be correct. ABS resin in powder form can smolder and shows autocatalytic behavior in thermal decomposition[1597]. Oven-basket testing indicated a critical temperature in the range of 110 – 125ºC for 50 mm cubes. Self-heating of ABS resin has caused a warehouse fire and a Japanese report has been published[1698].

A case history is reported where a quilt made of *polypropylene* fibers self-heated to a smoldering ignition in a clothes dryer[1699]. Laboratory tests at the American Institute of Laundering were able to reproduce the conditions.

ELASTOMERS AND FOAMS

An elastomer is defined as[1700] "A macromolecular material that returns rapidly at room temperature to approximately its initial dimensions and shape after substantial deformation by a weak stress and subsequent release of the stress." In everyday English usage, elastomers are called "rubber" or "flexible plastic foam." Plastic foams may also be rigid, and in that form are commonly used as thermal insulation.

A large number of tests on foam plastics were reported by the Products Research Committee[1701], a US plastics industry effort in the 1970s that was coordinated by the National Bureau of Standards. Their ignitability results are given in Table 183. Cleary and Quintiere[1706] reported that 15 kW m^{-2} was needed in the Cone Calorimeter under piloted conditions for the ignition of rigid polyurethane foams, both regular and FR.

Fernando et al.[1702] measured the ignition of a non-FR, furniture-grade polyurethane foam in the Cone Calorimeter. They found a minimum flux for ignition of 7 kW m^{-2} for piloted tests and 28 kW m^{-2} for autoignition. At the low flux of 7 kW m^{-2}, it was noted that there was some surface discoloration directly below the spark electrode, indicating that at such a low flux there may be some local heating from the spark. Kallonen[1703] tested a variety of rigid foam plastics using the ISO 5657 test method. Her results are given in Table 182.

Table 184 Piloted ignition properties of several polyurethane foam types

Type	Density (kg m^{-3})	Crit. MLR (g m^{-2} s^{-1})	T_{ig} (ºC)	Ignition time (s) at various fluxes			
				10	15	26	37
non-FR	21	0.61	324		29	9	4

non-FR, solid	1040	1.21	271		205	57	21

NI – no ignition
a – flash point value; surface temperature at sustained ignition not given

Annamalai and Sibulkin[1704] tested a number of plastic foams for ignitability with a very small (25 W) propane flame applied to the specimens. Polystyrene and polyethylene foams did not ignite due to melting—the foam melted out of the reach of the flame. Latex foam ignited in 0.5 s, and non-FR flexible polyurethane foams ignited in 2 – 10 s. Non-FR rigid polyurethane foams ignited in 0.3 – 2 s. A sample of flexible PVC foam ignited in 38 s. FR polyurethane and polyisocyanurate foams did not ignite from the flame. When a radiant flux of 2 kW m^{-2} was added, some of the FR foams which did not ignite from the gas flame alone then did ignite. In the case of one rigid FR polyurethane foam, it required a radiant flux of 6 kW m^{-2} before ignition was achieved.

Values of $\dot{q}''_{\min}$ for polystyrene foams, both expanded and extruded, regular and FR, are typically[1706] 15 kW m^{-2}, although values from 8 to 23 kW m^{-2} have been reported[2121].

Drysdale and Thomson[1705] tested the piloted ignition properties of several polyurethane foams using the Edinburgh University radiant heat apparatus, which is similar to ISO 5657 test and has been described in Chapter 7. Their results are shown in Table 184. The mass loss rates found at ignition for many of the samples were surprisingly lower than values determined in the same apparatus by Thomson for other plastics, as discussed in Chapter 7; the reason for this is not clear. Polyisocyanurate and phenol formaldehyde (phenolic) foams are moderately difficult to ignite in a radiant-heating mode. The minimum heat flux was found to be 21 kW m^{-2} for polyisocyanurate[1706,2113] and 30 kW m^{-2} for phenol formaldehyde[1706]. But UK tests[224] showed that phenol formaldehyde insulating foams can readily start smoldering from a cigarette, even though they do not ignite from a match or an electric arc; polyisocyanurate insulating foams are capable of sustaining smoldering, but need an ignition source greater than a cigarette to start smoldering. Saito et al.[1707] dropped 10 – 14 mm steel balls heated to 700 – 1300ºC onto phenolic and polyurethane foams from a height of 1 m. No ignitions were achieved with a 10 mm ball heated to 700ºC, but a 10 mm ball heated to 1000ºC sufficed to cause ignition.

A variety of elastomers tend to show *self-heating* problems. These primarily occur under three types of conditions:

(1) when processing machinery is run at excessive temperatures;
(2) when the product is mal-formulated or processed improperly (apart from excessive temperatures);
(3) when the product is stored too hot or in too large a volume.

A case has been reported[1708] where an improperly-manufactured batch self-heated instead of cooling down upon leaving the production line and led to a large-loss fire. In another case[1709], polyurethane foam ignited in a manufacturing facility since an inhibitor was accidentally omitted from the formulation. Fires have also occurred when the materials were in storage[1710] although details are not available. Oxidative self-heating of such substances has long been known. For example, a 1967 study[1711] identified that self-heating can occur due to oxidation of diene and triene bonds in rubbers.

A detailed case history of a self-heating fire in a rubber-manufacturing factory was reported by the Hungarian researcher Pap in 1965[1712]. Pap studied the specific material (not fully identified) that caused the fire, plus several commercial formulations. Thermal analysis tests were performed on natural rubber, polychloroprene, an SBR rubber and a polybutadiene rubber. The thermal analysis tests showed that polychloroprene rubber starts exothermic decomposition at around 200ºC, natural rubber at around 230ºC, polybutadiene rubber (BR) at 370ºC, and styrene-butadiene rubber (SBR) at 380ºC. Tire-making rubbers that contained carbon black and an oil were found to start decomposing at 200ºC. He noted that the thermal decomposition process involves both exothermic (oxidation, cyclization) and endothermic (depolymerization, evaporation) reactions, and the actual self-heating process will depend strongly on the heat balance established within the material. For the material involved in the factory fire, he showed that oxidative reactions predominate, and that fire would not occur if oxygen were excluded. But the temperatures found in micro-scale thermal analysis tests do not replicate the temperatures at which thermal runaway occurs in larger samples. The manufacturing process wherein the fire occurred involved a mixer operated at 150 – 160ºC. Pap simulated this environment with a 200 L drum sample. Thermal runaway in this large-scale test did not take place at 180ºC, but did take place at 200ºC, implying a critical temperature of around 190ºC for the 200 L size. Pap also documented that the self-heating of the rubber was not uniform throughout, and he found red-hot nodules upon taking apart the self-heating material; once in contact with free air, these turned into an intensely flaming fire.

Kuzminskii published a review paper on self-heating of elastomers[1713] where he noted that polydiene elastomers do not need oxygen for self-heating, since the process of cyclization can occur anaerobically. But, with access to oxygen, polydiene elastomers are "extremely unstable." Vinyl-cyclohexene was found to be the predominant cyclization product. He concluded that copolymerization is the most effective way of stabilizing the product, with as little as 10% of copolymer serving to prevent development of a cyclization chain reaction. Copolymerization, in his assessment, is much more effective than active fillers, stabilizers, or cross-linking agents in reducing self-heating. Metals such as iron or cobalt act as catalysts to promote self-heating of polydiene elastomers. He also found that the self-heating of silicone rubbers is more pronounced under low-oxygen conditions. This is because their self-heating is dominated by hydrolysis and access to copious oxygen helps to remove moisture from the material.

Table 186 Self-heating properties for elastomers determined by Gross and Robertson

Material	E (kJ mol^{-1})	AQ (W kg^{-1})	ρ (kg m^{-3})	λ (W m^{-1} K^{-1})	C (J kg^{-1} K^{-1})
crepe rubber	98	4.8×10^{9}	920	0.12	2100

foam rubber, natural	116	2.9×10^{15}	108	0.040	2100
foam rubber, synthetic	110	1.6×10^{14}	129	0.04	2100

Emmons[1714] examined whether Goodyear's SBR rubber Plioflex was prone to spontaneous combustion while in storage. In small-scale tests using 70 mm cubes in the oven-basket method he found a critical temperature of 300ºC; he also noted that below about 220ºC the specimen's behavior was endothermic and that standard F-K theory would not be applicable to the material, due to the presence of the endothermic reaction. The SBR bales come wrapped in polyethylene film, so Emmons also conducted experiments where the oven cube sample was wrapped in polyethylene film. These tests revealed minimal endothermic behavior, showing that the endothermic reaction was being suppressed by not allowing the vapors to exude from the specimen faces. He also conducted large-scale experiments using a 'hot work' mode. In one case he loaded a 1-m cube box with the SBR material at 74ºC, then placed it outdoors for 14 days. Internal thermocouples showed cooling rather than self-heating. In another test, he placed an instrumented box of the SBR material at 74ºC initial temperature into a warehouse, surrounded by other boxes of the same material. Likewise, in that case there was cooling rather than self-heating. The conclusion was that the material can be safely stored at 74ºC in sizes up to the ones tested.

Weickert[1715] reported on DTA tests done to characterize the self-heating of an SBR rubber. In the DTA graphs, he identified two peaks, the first being due to oxidation and the second due to decomposition. He also showed that when the rubber is ground up, the oxidation peak is increased and the onset of exothermicity takes place earlier. Exothermic activity was generally first seen in DTA tests on SBR at around 110ºC and he found that the self-heating kinetics could be represented by a 2nd-order Arrhenius expression.

Shikhanov and co-workers briefly examined the spontaneous combustion hazards associated with a spontaneous polymerization which can occur in the processing equipment for diene thermoplastic elastomers in general and specifically butadiene, isoprene, and butadiene-piperylene rubbers[1716,1717]. Using a Russian test method that involved oven-testing of 35 mm cubes and failure criterion of 100ºC, they tested numerous scrapings of polymerized material from processing machinery and found that more than half showed critical temperatures below 100ºC. The conclusion was that, compared to the highly hazardous ones, moderately hazardous elastomers show a smaller number of C=C bonds, more extensive cross-linking, and a higher molar mass. Further quantifying behavior by using oven-basket tests of varying sizes, they concluded that 'highly hazardous' materials were ones where a 0.7 mm thick layer was able to go to a thermal runaway situation in 200 h or less at ambient air conditions. The production wastes of the kind examined by Shikhanov were clearly highly prone to self-heating, but it must be noted that these were not products whose manufacture was completed.

Self-heating data based on a small-specimen study in an adiabatic furnace were obtained by Gross and Robertson[109]. Their results are shown in Table 185.

During the 1950s, *latex foam* (foam rubber) became popular in consumer items such as pillows, pads, toys, upholstered furniture, and ladies undergarments. Some of these items are intended to be washed, and if subsequently dried in clothes dryers, self-heating fires occurred[1718] and NFPA issued a warning advisory[1719]. By the 1970s, latex foam was replaced by polyurethane foam in most applications, with the latter not showing these problems. Fabrics coated with

Table 185 Self-heating parameters for polyurethane foams

latex can self-heat, if copper impurities have become mixed into the latex. Case histories of this have been reported[1720] and it was found that copper is such a powerful catalyst for the oxidation of latex that large temperature excursions were registered in the Mackey test.

A warehouse fire was found to have occurred due to self-heating of polychloroprene patient examination gloves[1721-1723]. Laboratory testing produced an estimate that an 0.325 m cube of material would be sufficient to lead to thermal runaway at 35ºC. This small critical size suggests that the material may have been improperly formulated or manufactured. In coal mines, conveyor belts made of polychloroprene are often used. Because of the size and configuration, the belts do not exhibit self-heating problems. However, roller wear causes polychloroprene dust particles to accumulate, and such layers can self-heat. Wachowicz[1724] investigated this self-heating for three different formulations of polychloroprene and found exothermic peaks at 230ºC, 320ºC, and higher. When subjected to some *ad hoc* self-heating tests, the material showed thermal runaway, with glowing occurring at ca. 550ºC. Open flaming, however, never erupted, which the authors attribute to the presence of large amounts of FR agents in the elastomers.

Polyurethane foams can self-heat to ignition, but reported incidents are typically limited to (1) mis-formulated or mis-manufactured batches[1725,1726]; (2) stacking of not yet fully-reacted product in excessively large stacks[2087]; or (3) use as insulation materials in solar collectors. The warm-material stacking situation occurs because the foaming reaction is highly exothermic and runaway can occur if the volume is too large before the reaction has run to completion. In a Canadian study[1727] it was concluded that a sphere of $r = 10$ m would be required for critical conditions to be reached in an unspecified type of polyurethane foam stored at 40ºC. Fires have occurred with polyurethane foam insulations used in solar collectors, and Loftus investigated the self-heating characteristics of foams in that connection[1728]. The temperatures reached in the collectors vary greatly, but in the worst case, under no-water-flow conditions, temperatures of ca. 200ºC are possible. The self-heating situation in solar collectors is complicated, since plywood is used atop the foam, and this is also a substance that can show exothermic behavior. Loftus evaluated the materials individually, using an adiabatic calorimeter. The results for 8 different polyurethane foams are given in Table 186. The results indicate a high possibility of criticality. For example, for specimen H42 at 120ºC the critical thickness is only around 50 mm.

Franke et al.[45] reported a case history of spontaneous combustion involving a rubber formulation based on butadiene-acrylonitrile rubber and PVC granules. A fire occurred due to a blockage of a mixer, with material of around 165ºC being plugged up. This material presumably did not require oxygen for self-heating, since access of air to a closed mixer is limited.

Taken together, the studies on self-heating of elastomers point to the following conclusions:

- Most elastomers show exothermic temperature regimes and thus may be capable of self-heating under certain circumstances. The propensity to self-heating depends on the chemical nature of the elastomer, on its additives (e.g., inhibitors), and on any self-heating promoters that may be present, e.g., iron, copper, or cobalt. In addition, as with any self-heating material, the amount of material and the storage temperature are crucial factors.
- Chemical reactions which may cause self-heating include:
  –oxidation of diene and triene bonds
  –formation of hydroperoxides
  –epoxidation of double bonds, and the crosslinkages resulting from it
  –formation and decomposition of polymeric peroxides
  –oxidative cleavages of C–C bonds via ketone and alcohol formation;
  –hydrolysis.
- When elastomers self-heat, they commonly do this in a non-homogeneous way, that is, isolated hot spots or nodules become generated within the material.

Potassium chlorate

Potassium chlorate, $KClO_3$, is a powerful oxidizer commonly used in pyrotechnics. The decomposition of potassium chlorate produces oxygen and this property has occasionally been exploited. Pure potassium chlorate is non-detonable, but it can react explosively with a number of substances. A mixture of potassium chlorate and sulfur explodes[26] if heated to about 160ºC. In olden times, this mixture was used as a pyrotechnic formulation, until its hazard became known. Similar hazards exist in use of potassium chlorate with aluminum powder. Potassium chlorate is less stable than sodium chlorate, and numerous explosions have occurred with it, caused by shock, friction, or heating. In practice, this combination is highly hazardous at any temperature, unless passivated by including a carbonate or bicarbonate in the mixture[1436]. The presence of moisture causes the chlorate* to react, yielding ClO_2, Cl_2, and O_2, and these oxidizing agents then react with the sulfur. Other contaminants besides moisture may also be involved. Reactions with most organic and many inorganic substances are likely to be explosive. Spills[1729] on the floor of potassium chlorate powder can be ignited by action of footsteps, if organic dust is also present. Conversely, $KClO_3$ can be used as an extinguishing agent, if applied to flames in the form of a fine powder. The action here involves the activity of the K^+ ion. Potassium chlorate and red phosphorus, when

* This type of reaction is a hazard with a wide variety of chlorates, not just potassium chlorate.

brought together dry in powdered form, react explosively[1436]; they are not likely to explode on contact if combined moist, however. See also: *Pyrotechnics*.

Potassium perchlorate has similar properties, but is more stable. In one case, however, a wood ventilation hood self-ignited after a long-term exposure to potassium perchlorate dust[26]. Potassium bromate is more reactive than potassium chlorate, but is less commonly used.

Powdered milk

In factories producing milk powder, the dominant causes for fires[1730] are: (1) self-heating; (2) friction or external heating; (3) malfunction of equipment; and (4) improper operating or control procedures. The final step in producing milk powder is spray-drying at an elevated temperature. This has caused a number of dryer fires due to the self-heating properties of milk powder[1731]. Explosions are also not rare in the industry, especially dryer explosions[1731]. Fires in storage silos sometimes are due to introduction of smoldering clumps of material[1732]. External ignition of milk powder has only been studied by Raemy et al.[1733], who found an AIT of 150ºC under 25 atm of pure oxygen and 170ºC under 5 atm. Studies do not exist on the AIT in normal air. The self-heating of milk powder has been studied by numerous researchers, as compiled in Table 187. Part of the reason why rather different results were obtained may be due to differences in the particle size distribution of the samples tested. In addition to the data summarized here, Duane et al.[1734] also examined a variety of milk powders with various fats added. The added fats affected the self-heating properties, but it was found that this could not be correlated to their values of iodine number. A higher fraction of unsaturated fats was found to lead to lower critical temperatures of self-heating. Raemy et al.[1733] studied in more detail some of the exothermic reactions occurring in milk powders. O'Connor conducted testing using DSC and determined Q = 421 to 582 kJ kg^{-1} (depending on product type) and that the order of the reaction is 0.6; however, the chemical constants obtained with DSC were rather different from values obtained with oven-basket testing. Gray[1735] noted that the parameters derived from self-heating tests can be strongly influenced by moisture; Rivers et al.[1736] performed numerical modeling of the problem and demonstrated that even 1 – 3% moisture of the powder is highly beneficial towards reducing the self-heating hazard.

Power steering fluid

Ohlemiller and Cleary[123] investigated the effect on the flash point and fire point of power steering fluid when contaminated with gasoline. Using a non-standard open-cup test apparatus, they found that the flash point dropped from 170ºC for pure power steering fluid, to room temperature (22ºC) when 14 vol% of the mixture was gasoline. The fire point dropped from 210ºC for pure power steering fluid to 22ºC for a mixture with 17 –19 vol% gasoline.

Propane

Okamoto et al.[1739] conducted experiments to determine the hot-surface ignition temperature for propane/air mixtures. Using a 5 vol% concentration of propane, they found that a temperature of 780ºC was needed for ignition. Such results are dependent on the size of the heated surface and their experiments were conducted using a heated glass cylinder of 12.5 mm diameter and 250 mm length, having an exposed surface area of 9818 mm^2. See also: BLEVEs in Chapter 13 and *LNG and LPG* in this chapter.

Propylene oxide

Propylene oxide (C_3H_6O) is a member of the chemical family of oxiranes and generally has similar properties to ethylene oxide. It is subject to exothermic polymerization and can be detonated[3]. For 5 g pure propylene oxide samples heated in a glass vessel[958] exothermic activity was found to commence at around 100ºC.

Pyrotechnics

Pyrotechnics is a general term of which fireworks is only a subset. Pyrotechnic devices that are not fireworks include such items as automotive airbag inflators, which are discussed above. Unwanted ignitions of pyrotechnics are generally of two general types: (1) Ignition and fire or explosion in connection with manufacturing, shipping, or handling. (2) A normal activation of a pyrotechnic device which results in some undesired ignition, for instance of clothing. McIntyre and Rindner[1740] collected statistics on accidents in the course of manufacturing military pyrotechnics (Table 189). Friction initiations were commonly due to

Table 187 Self-heating constants for milk powder

Powder	Temp. range (ºC)	ρ (kg m^{-3})	λ (W m^{-1} K^{-1})	C (J kg^{-1} K^{-1})	E (kJ mol^{-1})	P	AQ (W kg^{-1})
skim milk[1737]	135 - 170	670	0.33	1949	97.1	40.0	9.43×10^{12}
skim milk[1731]	142 - 171				79.0	48.5	4.16×10^{13}
skim milk[1732]	138 - 173	600	0.072	1547	79.3	42.5	3.52×10^{10}
whole milk[1737]	130 - 145	551	0.16	2012	160.4	59.3	8.63×10^{20}
	145 - 165				75.3	34.3	2.41×10^{10}
milk w. 30% fat added[1738]	130 - 200				81.1	43.2	
milk w. 44% fat added[1734]	135 - 175	508	0.127		99.6	48.0	1.46×10^{13}

problems in reaming or die-pressing operations. In the accidents, fires outnumbered explosions by more than 4 : 1.

The contents of fireworks are sometimes taken out and utilized in efforts to manufacture homemade bombs. The Royal Canadian Mounted Police[1741] provided the statistics given in Table 188. As can be seen, accidental explosions were far outnumbered by criminal actions. In the majority of the bombings, the filler material was identified as black powder, so it is not clear whether this necessarily came from disassembly of fireworks or from other sources.

Table 188 Breakdown of RCMP-attended pyrotechnics incidents in 1991, excluding thefts and recoveries

Activity	Percent
bombing	45
attempted bombing	17
hoax device	17
IED found	13
attack on safe or deposit box	5
accidental explosion	3.2

Most countries these days use the UN Regulations[1650] in classifying pyrotechnics. In the UN scheme, pyrotechnics fall under the general category of explosives (see *Explosives*). Pyrotechnics will not fall under the most-hazardous classes of explosives and would only be classified as 1.3G, 1.4G, or 1.4S. Division 1.3 comprises substances which show major hazards of radiant heat or violent burning, but only minor blast or projectile hazard. Division 1.4 comprises explosives with only small hazard in the event of ignition or initiation during transport. The 'G' designation indicates a 'small' hazard outside the package, in case of inadvertent activation during transport, while 'S' denotes no hazard outside the package, except if under external fire attack. Actual testing (which has some subjective aspects) and classification is done by the national government. Thus, for example, in The Netherlands[1742] most pyrotechnics are classified into Division 1.4S. Rockets which can produce fiery projectiles for a distance more than 15 m are classed into Division 1.3G, however, these can also be shipped as 1.4S if packages are overwrapped with wire mesh to restrain projectile action. In the US, by contrast, consumer fireworks are normally classed as 1.4G, while display fireworks as 1.3G; a minor amount of pyrotechnics not sold to consumers are considered theatrical or special-effects fireworks and are classed as 1.4S.

Table 189 Accidents in US manufacturing of military pyrotechnics, 1950 – 1976

Source of initiation	Percent
friction	54
impact	11
static electricity	8
pressure	6
heat	2
chemical reactions	2
electric (other than static electricity)	2
undetermined	15

Many of the reactions that fireworks can undergo are not fully understood. One major difficulty arises from the fact that a pyrotechnic composition is a physical mixture of two or more chemical compounds. Chemical compounds are reproducible entities. That is, if a laboratory makes an experiment with compound "A," and a second laboratory repeats the experiment with compound "A," the results should very closely agree, provided both have used substances of high purity. Physical mixtures, however, are not very well reproducible and depend on grain size, grain shape, the state of homogeneity of the mixture, etc. Moisture sorption from the air is often a particular difficulty, since a number of pyrotechnic substances are sensitive to moisture. Self-heating reactions are known to occur (e.g., with mixtures of ammonium perchlorate and magnesium powder), but systematic self-heating studies have rarely been made.

Some substances used for manufacture of pyrotechnic devices also show unwanted ignition problems as a pure material, before mixing or preparation. Such substances include very finely divided metals, which can self-heat due to oxidation from atmospheric oxygen.

Of even greater safety concern than oxidative self-heating is a propensity of some molecules to break up into two fragments, since no reaction partner is required for this. Most pyrotechnic oxidizers show endothermic decomposition characteristics, that is, external energy input is required for the decomposition to occur. But some exhibit exothermic decomposition; for example, potassium chlorate is subject to the exothermic decomposition reaction:

$$2\,KClO_3 \rightarrow 2KCl + 3O_2$$

Acids, sulfur, and metal oxides (e.g., manganese dioxide) tend to accelerate such decomposition of potassium chlorate and, in some circumstances, can cause an unwanted explosion. Mixtures of potassium chlorate with red phosphorus explode readily upon the slightest friction or impact[1755]. Mixtures of potassium chlorate with Al or Mg powders are likewise highly hazardous. If potassium chlorate is combined with sulfur, a hazardous mixture can result, and such combinations have been banned in England since 1894. Chapman et al.[1743] studied these mixtures, in various proportions, to determine the ignition temperatures. They found the lowest value, 120ºC, for 8 – 10% sulfur. Using their technique, pure $KClO_3$ showed ca. 150ºC, while pure S was not measured. Tanner[1744] explained the mechanism of the reaction between sulfur and potassium chlorate. He noted that problems rarely occur with crude sulfur. This is the raw product and it has a purity of 99.8 to 99.9%, but still possess a residual surface coating of asphalt. This surface impurity minimizes the oxidation at the surface. If refined sulfur ('flowers of sulfur') is used, reactivity with

$KClO_3$ becomes much greater. The refined product, when exposed to moist air, forms a layer of polythionic acid on the surface. The latter is $H_2S_nO_6$, with *n* typically being 3 to 5. Its role is the liberation of SO_2, which is needed in the further reaction steps. The whole sequence is:

$$H_2S_nO_6 \rightarrow H_2SO_4 + SO_2 + (n–2)S$$
$$SO_2 + 2KClO_3 \rightarrow 2CLO_2 + K_2SO_4$$
$$2ClO_2 + 4S \rightarrow 2SO_2 + S_2Cl_2$$

The last two equations represents a chain propagation reaction with respect to SO_2, since its presence is needed for initiation, but afterwards more is produced than is consumed. The first equation is the chain initiation step. Some sulfur compounds, e.g., thiourea, exhibit similar sensitivity as do formulations using elemental sulfur[1745]. Tests for mixtures of potassium chlorate with 15 – 25% thiourea indicated ignition temperatures of 142 – 153ºC, vastly lower than for the two constituents, neither one of which was ignitable, by itself, below 400ºC. In the opinion of Hardt[1436], the single most-hazardous and unpredictable pyrotechnic mixture which is in current-day use is the one contained in toy caps, which comprises potassium chlorate, red phosphorus, and a calcium carbonate inhibitor.

Since potassium chlorate has intrinsic stability problems and requires care in preparation and use, where possible, it is recommended that preparations use potassium perchlorate instead[1746]. But despite these concerns, it must be noted that it is one of the most common ingredients in the manufacture of matches, so there is no doubt that mixtures using it can be designed to be safe.

Mixtures containing both ammonium and chlorate salts are classified as forbidden explosives by the US Dept. of Transportation due to their hazard. This is because an exchange reaction can occur in which ammonium chlorate is formed. For example, ammonium nitrate and potassium chlorate could react to form some ammonium chlorate. The latter is an unstable compound and could lead to an unwanted explosion.

Mixtures containing titanium and black powder can readily be ignited by impact (for Ti > 20%) and by friction (for 3% < Ti < 70%); this sensitivity has led to accidents in the UK[1745].

Firecrackers, as originally produced in China, traditionally contained 80 mg of black powder, but currently are more likely to contain flash powder than black powder[1747]. M80 was a Dept. of Defense designation for firecrackers in military applications. The composition is potassium perchlorate (64%), aluminum (22.5%), sulfur (10%), and antimony sulfide (3.5%).

Snap caps (also called snappers, pop-pop snappers, bang snaps, etc.) are tiny noise-making devices consisting of a few grains of gravel dipped in a silver compound and hand-wrapped in cigarette paper. They have only a limited burning capability, since they contain a minuscule amount of pyrotechnic composition which is usually silver fulminate, $Ag_2(CNO)_2$. For snap caps sold in California, regulations[1748] require them to contain no more than 0.25 grams of gravel impregnated with no more than 1 mg of pyrotechnic compositions; they also require that the paper wrapping be fire-retardant, but there does not seem to be any evidence that regular paper could ignite upon discharge of the device. In retail sales, snap caps are commonly packed in small cardboard boxes holding about 50 individual devices, cushioned with sawdust.

In an interesting study, Conkling[1749] devised twenty different tests for examining whether snap caps could ignite clothing. The tests included throwing an entire boxload of 50; burning a display pack of 40 boxes on a barbecue grill; dropping display packs from a height of 15 feet onto a brick surface; discharging poppers into a gasoline-covered metal pan; throwing single and multiple poppers against dry vegetation. No ignition could be obtained of any combustible target presented in these tests. For clothing testing, Conkling wrapped 50 poppers in a T-shirt, placed it on a brick and hammered it; this was done twice, with and without packaging sawdust around the poppers. No charring or ignition of the fabric resulted. McLain[1750] additionally points out that (a) snap caps are not capable of igniting vapors of diethyl ether nor of petroleum ether (a solvent of relatively low flash point); (b) heating snap caps for 2 hours in an oven at 75ºC does not set them off; and (c) no burns or injury results even if one goes off while being handled.

A series of tests examining whether common consumer fireworks would ignite shredded newspaper has been reported[1751]. Bottle rockets, Jumping Jacks, smoke bombs, and sparklers caused ignition; firecrackers (32 to 38 mm long varieties) and snap caps did not.

A number of pyrotechnic compositions are subject to spontaneous combustion if moisture enters a mixture. For instance, zinc powder and $CaSi_2$ both react exothermically with water.

Conkling provided ignition results for some pyrotechnics[1752]. Table 191 shows spark sensitivity, as measured in the BM apparatus[1753], while Table 192 gives ignition temperatures as measured in a DTA apparatus. Conkling[1754] also reported ignition energies for a number of potassium nitrate/metal and potassium perchlorate/metal compositions, where the metals used were flake aluminum and magnesium/aluminum (50/50) alloy. In this study, the ESD ignition energies obtained were much lower, typically 15 – 500 mJ, with the actual value depending greatly on the physical details. Adding 10% sulfur lowered some values further. Conkling concluded that electrostatic discharge from a person might suffice to explode some of these compositions.

Table 190 Hazard rating scheme for pyrotechnics proposed by McLain

Mix	Uses	Class

McLain proposed[1750] that the hazard of pyrotechnic mixes be classified by a two-way matrix scheme. The sensitivity to ignition of a mix is denoted by a letter, A being most sensitive and D being least sensitive. The destructiveness to be expected if an ignition occurs is denoted by a number for 6 (most hazardous) to 1 (least hazardous). The physical hazards associated with the numeric ratings are:

6 Detonates from open burning. Small critical mass. Capable of sympathetic detonation.
5 Relatively unconfined burning (e.g. in open-end mixers or a small building) can produce low-order but destructive explosions.
4 Bulk powder subject to deflagration progressing to low-order explosion.
3 Large and quick fireball.
2 Fire hazard to personnel.
1 Slight fire hazard to building and surroundings.

Pyrotechnic mixes as classified by McLain are given in Table 190.

Shidlovskiy[1755] reported ignition temperatures for a number of binary oxidizer/fuel mixtures (Table 193). Practical formulations, of course, generally involve more than two reactants, but these simplest mixtures give some idea of trends to be expected. The mixtures were all in ratios so as to be oxygen-balanced, but other details of the preparations were not specified. The results show that—when combined with most fuels—potassium chlorate produces much lower ignition temperatures than the other oxidizers. Apart from compositions involving metal or graphite dusts/powders, the other values are fortuitously similar to ignition temperatures of pyrolyzing solids, despite an entirely dissimilar mode of ignition. Shidlovskiy also reported that the ignition temperature of black powder is 310ºC, but details were not given.

Radiant heating in different parts of the spectrum for ignition of pyrotechnics was attempted by de Yong and Lui[1756] using a xenon lamp source and spectral filters. With samples being 30 mg pills, they reported either non-ignitions or enormous minimum heat fluxes (hundreds of kW m^{-2}) and the authors were not able to explain these results. With non-pyrotechnic solids, such results would suggest an insufficiency of mass for generating a combustible fuel/air mixture. But since pyrotechnic compositions supply their own oxidizer, the interpretation is not clear.

A large compilation of ESD data was presented by McIntyre[1740]. Values typically ranged from 0.225 J to greater than could be measured in his apparatus (11.02 J). The exceptions are given in Table 194.

Table 194 Pyrotechnic compositions found by McIntyre to be exceptionally easily ignited by electrostatic discharge

Composition	ESD energy (J)
67% potassium perchlorate, 33% titanium	0.005
65% potassium perchlorate, 32% antimony sulfide, 5% gum arabic	< 0.05
64% potassium perchlorate, 22.5% flake aluminum, 10% sulfur, 3.5% antimony sulfide	< 0.1

McLain conducted hot-spot ignition tests on a number of pyrotechnic compositions by touching an incandescent Pt-Ir wire to the surface of the test substance. Their results were described in terms of power needed for supplying the hot wire. For 9 compositions tested, all of the results were within the range of 2.5 to 6.3 W. He also obtained ignition temperatures which ranged from 450 to 630ºC. These values are all quite high and reflect the difficulty in igniting a solid at a single hot point. For radiant ignition, he reported an ignition temperature of 321ºC for black powder, but few

Table 195 Pyrotechnic compositions tested for cookoff behavior

Composition	Test results
aluminum (20%), copper oxide (80%)	no damage
aluminum (15%), lead chromate (85%)	no damage
aluminum (40%), ammonium nitrate (60%)	no damage
aluminum (60%), potassium perchlorate (40%)	destroyed
magnesium (50%), sodium nitrate (50%)	mild damage in one test, destroyed in another
magnesium (39%), sodium nitrate (50%), EVA (11%)	mild damage
magnesium (61%), Teflon (34%), Viton (5%)	no damage
potassium chlorate (22%), lactose (21%), kaolin (12%), orange dye (45%)	no damage

other values were provided.

Pyrotechnic compositions using gum arabic are subject to spontaneous combustion due to bacterial activity. Bacterial action on aging gum arabic causes generation of acetic acid, which ignites the fuel/oxidizer composition[323].

Pyrotechnics are mostly insensitive to cookoff. That is, if confined within a pipe bomb or similar arrangement, a violent explosion will occur with only a few types of compositions. de Yong and Redman[1757] tested a wide variety of compositions and obtained the results indicated in Table 195.

Radio and audio equipment

The flammability of radio and audio equipment in the US is governed by one of three UL standards, as described in Table 196. This table summarizes the requirements for non-high-voltage equipment. The requirements for the latter (i.e., televisions receivers) are discussed under *Television sets and computer monitors*. UL 1270[1758] has been withdrawn as of January 2002 and, in 2006, UL 1492[1759] will also be phased out. UL 6500[1760] is derived from IEC 60065[1761], but the flammability requirements are completely different. The requirements for enclosure materials in the UL standards are not necessarily evident from the wording of the standard and have been subject to interpretation by the Laboratory. For UL 1270, the V-2 specification only refers to "required parts" and generally manufacturers have been permitted to use HB materials. It is understood that according to UL 1492 and UL 6500, enclosures are more likely to be made of V-2 materials, even though the wording of UL 6500 is not especially restrictive.

Table 196 Main flammability provisions of UL standards for plastic parts in radio and audio equipment

Component	UL 1270	UL 1492	UL 6500
enclosure	V-2, 12 mm flame, 20 mm flame[a]	V-2	V-2
any plastic housing that has a separate interior fire enclosure for line-voltage parts			HB
in contact w. live electric parts in circuits		V-2	V-2
all other plastics	HB		HB

[a] – the 12 mm flame and 20 mm flame tests, per UL 746C are equivalent only to an HB, not a V-2 performance

Railroads

The propensity for railroads to cause vegetation fires was studied by Cowles[1762]. He found the major categories to be:

- hot brake shoes
- engine exhaust particles
- journal boxes
- welding and grinding associated with track repairs.

Brake shoe fragments have been found up to "several inches long." Composition brake shoes were found less likely to act as ignition sources than older cast iron shoes. Exhaust particles have been found to be cast up to 12 –15 m away from the engine. Journal box overheating was found to be on the decline, since roller bearings have been replacing journal bearings. In addition, Cowles found that railroad rights-of-way create a microclimate more conducive to ignitions. Temperatures are higher and humidities lower and, in addition, wind effects are sometimes increased. DeBernardo[1763] identified the following as additional, relatively minor ignition sources associated with railroads:

- engine-powered equipment (e.g., bulldozers) and tools (e.g., chainsaws)
- signal flares
- smoking materials.

Hot particles are ejected due to wheel slip against the track. But these long, slim steel shavings normally fall down at the track, do not get propelled significant distances, and are rarely a cause of fire[1764]. Dynamic braking involves running the traction motors as generators and dissipating the produced power in a resistor grid. A resistor grid can fail by explosive arcing and shower molten metal up to 30 m or so.

Rayon

Walker et al.[197] studied self-heating of viscose rayon in an oven test and saw critical self-heating at around 169ºC oven temperature for a 6 L cylinder. They also refer to a fire in Germany where staple rayon ignited when trapped in a drier for a long time at 150ºC. See also: *Fabrics*.

Refrigerators

Compared to other types of electric appliances, refrigerators are more likely to have metallic construction and minimal number of heat-producing parts. Common causes of ignition of refrigerators include: (a) failure of the appliance cord or receptacle; (b) failure of the defrost heater igniting combustible materials; and (c) failure of the condenser motor or attached wiring, igniting lint or nearby combustibles. A drain pan made of ABS is commonly found under the condensor and it can get ignited in the latter case. An unusual ignition source led to a rash of fires in Europe and Japan during the mid-1990s. This anomaly was due to faulty starting devices that were fitted to compressors by a manufacturer holding a large share of the market for refrigerator compressors[1765]. These small devices, made largely of plastic, contain a Positive Temperature Coefficient (PTC) thermistor which is wired in series with the starting winding of the compressor. At room temperature, the device represents a low resistance, but the resistance increases greatly when

hot, reducing the current to the starting winding. The failures were found to involve largely older units which were sitting in moist environments. The ceramic thermistor element itself would overheat and ignite the surrounding plastic, from which a jet of flame would spurt out, since plastic was being pyrolyzed at the ceramic/plastic interface and had to develop an overpressure before it could escape to the atmosphere. Even though the PTC device is only about 40 g (Color Plate 139) a sizable fire could result (Color Plate 140). A laboratory study[1766] confirmed the tendency of these PTC devices to fail in an arc-tracking mode. The problem was solved when the manufacturer redesigned the starting devices in 1999.

Since the adoption internally of policies to eliminate ozone-destroying chemicals, changes to refrigerants have been made. In Europe, small refrigerators and air conditioners nowadays commonly use isobutane as the refrigerant. Propane has also been used in various countries as a refrigerant fluid. These are notably flammable hydrocarbons, but a systematic fire incident study is unavailable. A research study[1767], however, has been published that examines a number of leak scenarios, accompanied by measurements of concentrations. In many cases, even very small (5 g min^{-1}) leaks produced gas concentrations that were within the flammable range, at least at some location within the room and during some time period after the start of the leak.

Rice husks

The self-heating of rice husks was examined by Raj and Jones[1768], who conducted small-scale oven cube tests. Their results were: ρ = 140 kg m^{-3}; E = 105 kJ mol^{-1}; P = 46.31.

Roofing materials

The minimum flux for piloted ignition of asphalt roofing shingles has been reported as 12.6 kW m^{-2} in one study[1769], 13.0 in a second[1998], and 14.5 kW m^{-2} in third[1770]. For fiberglass shingles, a value of 23.0 kW m^{-2} was found[1770]. When the shingles are in an orientation other than horizontal, the asphalt tends to melt and slide off the shingle at a heat flux[1998] of about 2.5 kW m^{-2}, which is much lower than needed for ignition; consequently, the sloughed material may ignite later in a different place.

When roof coverings on flat roofs are installed, the two ways that this is most commonly done is by (a) torch-down, or (b) mop-applied operations. Torch-down is an operation where a special propane torch is used to apply a flame to the underside of a single-ply roofing membrane, which is thereby partly melted and consequently adheres when laid down upon the substrate. The roofing membrane is designed so that it does not catch fire itself, but ignition problems commonly arise with the substrate. The membrane is usually torched-down onto an insulating board which may be wood fiber or 'perlite.' Wood fiberboard is readily ignited in a smoldering mode, and this has often proven to be unnoticed by workmen[1771]. "Losses from torch-related fires have indeed been enough for some insurance companies to stop underwriting torch-applied modified bitumen jobs"[1772]. While perlite is an inorganic, mineral material, the boards described as 'perlite' in the construction industry, in fact, contain a sizeable proportion of wood fibers. Thus, they are also subject to smoldering ignition. Since many hours may elapse before a smoldering fire becomes visible, a fire watch is mandated for torch-down roofing operations. NFPA 241[1773] mandates a 1 h fire watch. It is not at all clear that any material that was ignited in a smoldering mode would necessarily exhibit observable combustion within a 1 h period, and some jurisdictions sensibly require a longer time period.

Conventional multi-ply, built-up roofing is mop-applied, whereby a mop soaked in hot asphalt is used. In normal used, the mop temperatures are not sufficient to ignite common combustibles. However, asphalt-saturated mops have been known to undergo spontaneous tion[1773,1774]. This usually requires that the mop strings be spread out to allow access to air, and overt flaming usually does not happen in the absence of wind. Generally, petroleum products show a low potential for self-heating, but the high temperature at which the mop is used (and may be left at the end of the day) is presumably the reason why runaway self-heating is possible. Moore[262] noted that tarred felt is subject to spontaneous combustion, but did not provide details.

Roofers' tar kettles occasionally are cleaned of the carbonaceous deposits that build up along their inner surfaces. Spontaneous combustion incidents have occurred in the process where thin layers of the built-up material were partly dislodged by water streams and left overnight[1775]. It was speculated that a reactive char had formed in these layers that proceeded to oxidize upon exposure to oxygen. Other modes of ignition for tar kettles have been discussed by Hill[1776].

Polymeric-membrane type roof coverings are applied by an electric heat 'welder;' smoldering ignition case histories have not been reported with these systems.

Sanding machines

Tests have been reported on a disc-type sanding machine to see if sanding certain materials might result in incendive sparks[1006]. When carbon-steel or mild-steel pieces were held against the sanding wheel, sparks caught on fluff were able to ignite the fluff in a smolder mode. The fluff was obtained from a sanding operation on a rubberized-cotton conveyor belt. Sanding of carbon-steel pieces on a coarse disc was also able to ignite methane/air atmospheres. The potential for sanded material removed from painted surfaces to self-heat is discussed under *Paints, dyes, and related substances*.

Saunas

Saunas in the home are popular in the Nordic countries. Their interiors are constructed of wood planks and modern-day saunas typically employ an electric heater, thus ignitions commonly reflect some malfunction, misuse, or misinstallation of the heater. The high humidity environment makes reliability of electrical devices especially challenging. Finnish statistics[1777] indicate that saunas are the second-most likely electric appliance to result in fire, preceded only by electric stoves.

Shredded materials

Radiant ignition tests on excelsior (long shavings of softwood) were performed by Garg and Stewart[1778], and their results are discussed in Chapter 7, as illustrative of porosity effects. Peacock and Vaishnav[1106] tested numerous types of Easter grasses (artificial decorative grass) for ignitability with a wooden match. They found that untreated cellulosic grasses ignited readily, but ones treated with FR agents did not ignite at all. Polypropylene grasses—both untreated and treated—ignited with some difficulty. The untreated ones burned to completion, while the treated ones did not sustain ignition after the match flame went out.

Siding, plastic

Luzik[115] reported on the radiant, piloted ignitability of fiberglass-type (glass-reinforced polyester) siding that is used for industrial buildings. The basis weight of the product was 1870 g m^{-2}. Using the Factory Mutual apparatus, data obtained are shown in Table 197. Flame spread testing on the same siding indicated exceptionally rapid flame spread rates.

Table 197 Ignition times for fiberglass siding

Heat flux (kW m^{-2})	Ignition time (s)
20	141
30	55
40	33
50	22
60	15

Dietenberger[1779] measured the radiant, piloted ignitability of 0.9 mm thick PVC siding. For a heat flux of 55 kW m^{-2}, t_{ig} = 18 s was found. Flaming ignition was also obtained at higher heat fluxes. But for heat fluxes below 55 kW m^{-2}, the product shrank to a charred mass, then the charred mass ignited much later. At 35 kW m^{-2} (the lowest flux tested), t_{ig} was 380 s.

Silane and chlorosilanes

Silane (SiH_4) and chlorosilanes (SiH_nCl_{4-n}) are widely used in semiconductor manufacturing. Under certain conditions, silane is pyrophoric in air and can autoignite at temperatures as low as ca. –100ºC[1780]. Pyrophoric ignition can occur even at very low oxygen concentrations. At room temperature, but for very low oxygen concentrations, it was found that pyrophoric ignition controlled by the silane/oxygen ratio[1781], assuming that the remainder is nitrogen. Over the range of 0 to 0.3% oxygen, it was found that pyrophoric ignition occurs if the silane/oxygen ratio (vol/vol) exceeds 9.5.

It has also been found that pyrophoric ignition occurs when silane is discharged at *low* velocities into air, but not at high ones. Silicon dioxide and water are the primary combustion products when burning in air; however, under some conditions hydrogen is formed. Water vapor acts as an inhibitor of the silane + oxygen reaction. For mixtures which are not pyrophoric, the flammability limits of silane are ca. 1.37 – 96%. For highly rich mixtures, the reaction is exothermic decomposition instead of oxidation. If silane is added to a hydrogen/air mixture, even small amounts can increase hydrogen's flammability limits to about 1.37 – 98%. It is considered that silane/air mixtures can detonate, but in most case histories it is not clear if detonation or merely very rapid deflagration had occurred. Silane reacts with halocarbons and halogenated refrigerants, so use of a halon extinguisher would lead to exacerbation instead of extinguishing of the fire. At high temperatures, silane can undergo decomposition reactions in which elemental silicon, in the form of a fine powder, is the reaction product. Such silicon powder is highly flammable in air. When the latter burns, SiO is formed as one combustion product. SiO itself is pyrophoric in air. Other explosion studies have been reviewed[1782].

Monochlorosilane is not commonly used, but mixtures of chlorosilanes which include monochlorosilane are pyrophoric in air, and this tendency has been exploited as one technique of skywriting[1780]. Dichlorosilane (SiH_2Cl_2) has flammability limits of 4.7 – 96% and is not pyrophoric in air. Its AIT using ASTM E 659 method is 44ºC for a worst-case quantity of 4.5 mL used. For less rich samples, the AIT rises rapidly, being 120ºC for 0.5 mL. Upon contact with certain contaminants, a violent explosion can result even from tiny quantities of dichlorosilane. Its minimum spark ignition energy is 0.0154 mJ and it is considered liable to detonate under certain conditions. Trichlorosilane ($SiHCl_3$) has flammable limits of 7.0 – 83%. The AIT is 182ºC. Britton[1780] points out that the statement made in the 1988 edition of Sax's **Dangerous Properties of Industrial Materials** concerning trichlorosilane (and also dichlorosilane) being pyrophoric is erroneous, as is the very low AIT published there. The minimum spark ignition energy for trichlorosilane is 0.017 mJ.

Hsieh et al.[1783] obtained AIT values for a series of substituted trichlorosilanes: ethyltrichlorosilane ($C_2H_5SiCl_3$) 405ºC, *n*-propyltrichlorosilane ($C_3H_7SiCl_3$) 360ºC, isobutyltrichlorosilane ($C_4H_9SiCl_3$) 329ºC, octyltrichlorosilane ($C_8H_{17}SiCl_3$) 221ºC, vinyltrichlorosilane ($C_2H_3SiCl_3$) 263ºC, phenyltrichlorosilane ($C_6H_5SiCl_3$) 544ºC, and 3-chloropropyltrichlorosilane ($ClC_3H_6SiCl_3$) 396ºC. Some

substances can decompose to produce silane. One such substance, triethoxysilane, $HSi(C_2H_5O)_3$, has been documented to cause fires or explosions in a disproportionation reaction that produces SiH_4[1784]. The Uniform Fire Code has a special standard[1785] governing installations using silane.

Since germanium and silicon have rather similar chemical properties, *germanes* tend to behave similarly to silanes, although they have not been studied much since the semiconductor industry no longer has much use for germanium. Digermane, Ge_2H_6, may ignite at room temperature[1407].

Silicon

Grosse and Conway[1382] found an ignition temperature of 775ºC for silicon powder burning in pure oxygen at 1 atm. Silicon dust in air[1394] can be ignited at 775ºC. Matsuda presented extensive explosibility studies of silicon dusts conducted in several Japanese test methods, along with the Hartmann apparatus[1786].

Silicone fluids and polymers

Silicones are compounds which have a structure with a backbone comprising silicon and oxygen atoms. Common formulations are of the type $(CH_3)_3Si\text{-}O\text{-}Si(CH_3)_2\text{-}O\text{-}\ldots\text{-}Si(CH_3)_3$. The radiant ignition of silicones has been extensively studied[1787]. For liquids, the minimum heat flux for ignition varies with the viscosity (or molar mass) of the fluid, ranging from 0.5 kW m^{-2} for a fluid with viscosity of 1×10^{-6} m^2 s^{-1}, to 15 kW m^{-2} for a fluid with a viscosity of 1×10^{-3} m^2 s^{-1}. Unmodified elastomers can show $\dot{q}''_{\min}$ = 11 to 14 kW m^{-2}, but with FR additives this can rise to ca. 20 kW m^{-2}. Hshieh has published large tabulations of the flash points[1788] and LFL values[1789] for silicone compounds.

Skins and leathers

The ignition of leather-upholstered furniture is discussed under *Upholstered furniture and mattresses*. Leather shrinks appreciably when exposed to heat and this can affect its ignition performance, both in testing and under actual fire conditions. Smoldering ignition of leather can occur from dropped cigarettes. A case is reported where transition to flaming took about 5 hours[304]. Animal skins can self-heat by a mechanism similar to that described under *Wool*. Self-heating fires in tanneries have been attributed to a combination of use of neatsfoot oil in conjunction with chromium-based preparations, which promote catalytic oxidation[1790].

Soaps

Soaps are alkali metal salts of long-chain monocarboxylic acids. It has been reported[40] that soap flakes used for clothes washing are prone to self-heating. This is primarily of historical interest, since synthetic detergents, instead of soap flakes, are used these days for clothes washing. Soap flakes made from olive oil are known to self-heat[40]. In addition, cases are known of spontaneous combustion of soap flakes containing only saturated fatty acids; the latter was attributed to over-drying, followed by exothermic uptake of moisture.

Sodium chlorate and sodium chlorite

Sodium chlorate, $NaClO_3$, is an oxidizer which is used in matches, oxygen candles, explosives, leather tanning, weed killing, and bleaching. It is susceptible to exothermic decomposition upon shock or heating. Explosions can occur due to accidental mixing with sugar, which may not be distinguished by eye from the white-powder appearance of sodium chlorate. If involved in fire, sodium chlorate is likely to explode[1791]. Sodium chlorate is highly reactive with organic substances and many inorganic ones. A mixture of sodium chlorate and nitrobenzene has sometimes been used as a terrorist explosive; home-made bombs are sometimes constructed using a sodium-chlorate based weed killer and sugar[1792]. A Japanese fire has been attributed to a reaction between a pesticide powder containing sodium chlorate with another powder containing sulfur[1793]. The S.S. MAHIA exploded in 1947 when its sodium chlorate cargo was ignited by unknown means[1794]. An explosion destroyed a ship in 1971 when vegetable oil seeped into a cargo of sodium chlorate[26]. Thomson reviewed a number of other accidents[1792]. Many properties of sodium chlorate are similar to those of potassium chlorate. HSE subjected sodium chlorate to a large assortment of reactivity and explosion tests and surveyed the literature for other findings[1795]. The results indicated that the substance, alone or in combination with fuels, is not particularly explosive, but can detonate if combined with a fuel under some circumstances. It is not fully clear why it has been somewhat hard to cause explosions with sodium chlorate in laboratory testing, but unfortunately not so hard in various accidents. Aggressive measures (e.g., detonators) have *not* been needed in the latter. Using an Accelerating Rate Calorimeter and assuming first-order decomposition kinetics, kinetic constants E = 300 kJ mol^{-1}, $A = 1.9\times10^{20}$ s^{-1}, and Q = 284 kJ kg^{-1} were found, but the actual order of the reaction was considered to be closer to 1.44. Another kinetics study showed E = 297 kJ mol^{-1} and $A = 2.3\times10^{18}$ s^{-1}. The material is only modestly reactive until rather high temperatures are reached, with around 550ºC needed for rapid reaction. Rust, in addition to fuels, promotes violence of reaction.

In most respects, sodium chlorite, $NaClO_2$, exhibits similar reactivity and combustion/explosion hazards. Sodium chlorite is primarily used as a bleaching agent. Sodium chlorite is non-explosive by itself, but a mixture of sodium chlorite and sawdust has been found to be about as sensitive as TNT to detonation in the drop-weight test[26].

An case of friction-caused ignition has been documented by Yallop[323]. A man playing tennis suddenly found his leg enveloped in flame. It turns out that the tennis court had been treated with sodium chlorate for killing weeds, and his rubber-soled shoes caused enough frictional heating to create a reaction between the rubber (fuel) and sodium chlorate (ox-

idizer). In another case[3], a shoe contaminated with sodium chlorate weed killer exploded when a welding spark fell onto it.

Sodium dithionite

Sodium dithionite (sodium hydrosulfite, $Na_2S_2O_4$) may ignite due to a violent reaction with water[3]. In addition, it is a self-heating powder which shows a complicated reaction, even though no atmospheric oxygen is consumed in the reaction. Henderson and Tyler[1796,1797] studied the material in hotplate tests and found a critical temperature for self-heating of ca. 188ºC for a 5 mm layer. They also found that it exhibits two exothermic peaks and cannot correctly be treated by standard self-heating theory. Additional studies have been reported by Reddy et al.[1798] Decomposition, fire, or explosion accidents involving sodium dithionite are not rare—EPA[1799] catalogued 17 such incidents in one 11-year period. Many of these started when water leaked into a container where sodium dithionite was stored.

Solder and soldering irons

Carroll[1800] attempted to ignite excelsior, wood shavings, oily rags and newspaper with molten solder and reported that they could not be ignited, even with 'large quantities' of solder being poured on them.

Soldering irons can easily cause smoldering ignitions of smolderable substances. Tests have also been reported on soldering irons placed against wood boards[271]. A unit running at 325ºC was not able to ignite a wood board, but an iron at 425ºC caused flaming in 3.5 h when the smolder front broke through to the back of the board. Using a soldering iron at 400ºC caused a paper towel to start flaming in 12 minutes[1801].

Soots, lampblack, other 'blacks'

Soots of various sorts include lampblack (made by burning low-grade heavy oils in limited oxygen conditions), carbon black (from natural gas or liquid hydrocarbons), vegetable black (made by burning and grinding plant matter), and bone black (prepared by anaerobic heating of animal bones and hoofs). These substances are less common today, but were widely used in the 19th century in paints and as clarifying media. In the 19th century literature[1802] their self-heating propensities have commonly been discussed. Some of the problems apparently were when oils prone to self-heating would be mixed into a porous soot material. Even apart from acting as substrates, the porous nature of soots suggests that their self-heating propensities might share some similarities with those of charcoal. They share the trait that, when freshly made, they must be 'weathered' if they are not to be excessively prone to self-heating[943]. The latter is simply a process whereby volumes smaller than would dangerously self-heat are exposed to air, allowed to undergo exothermic sorption of moisture and oxygen onto the large surface area of the substance, then cooled off.

Soybeans

Soybeans and soybean products are highly prone to self-heating. Self-heating at lower temperatures is due to microbial heating. At higher temperatures, exothermic reactions are due to oxidation and thermal polymerization of their unsaturated oils, in which they are exceptionally rich[38]. When charred soybeans are encountered, agronomists distinguish two types of damage. *Binburned* soybeans are those which attained elevated temperatures only due to microbial heating, while *fireburned* soybeans have been chemically oxidized or polymerized[1803]. Soybeans which sustained a maximum temperature less than 195ºC are considered to be only binburned. The distinction is important because insurers may pay for fireburned product, but not binburned. A UL study examined the self-heating and dust explosion hazards of various forms of soybean products[34].

Spas

A number of fires in spas were found in New Zealand. Investigation[1804] revealed two common modes of failure: (1) An air lock develops in the heater unit in a product designed so that the heating element and the temperature high-limit switch are both located at the top of the pipework. The heater then overheats and the plastic casing ignites. (2) Water flow stops due to pump failure. This condition is supposed to be sensed by a pressure switch, which is intended to disconnect the heating element if the pressure drops, but the switch may not respond due to an air lock condition or a piping blockage.

Stearic acid

Despite its very low iodine number (1 – 3), Monakhov[1076] reports that this fatty acid can self-heat when fibers are coated with it.

Steel turnings

Steel turnings generated in machine shop operations, also other processes which produce steel in finely divided form can lead to self-heating problems. Water is ineffective towards the extinguishment of such fires, since at high temperatures iron reacts with water to produce hydrogen gas, which itself is flammable.

Styrene

Styrene (C_8H_8) is an organic liquid that is used to manufacture polystyrene and related plastics. By itself, it has a propensity to exothermic polymerization, while in the presence of oxygen an explosive interpolymeric peroxide may be produced[3] if styrene is heated to 40 – 60ºC. The critical temperature of a railcar load of styrene is at or below room temperature[1805]. The reactivity problems are normally avoided by adding a small amount of 4-*tert*-butyl catechol as an inhibitor. The latter is effective only if there is some dissolved oxygen in the liquid styrene, thus industrial storage schemes often involve an aeration procedure. Styrene vapor is liable to autoignite in the presence of polymerizing

liquid, but the vapor is relatively unreactive if no liquid phase is present[1806].

Sugar

Refined sugar melts at 160ºC and decomposes (caramelizes) at 170-180ºC. The sugar itself does not ignite, but the decomposition products of caramelized sugar ignite at about 460ºC. Raw sugar, however, is stated to be able to burn directly[1807]. Refined sugar has not been found to be prone to self-heating[1808].

Sulfur

Sulfur (S_8) is a unique substance with several physical forms ('allotropes') and with varied chemical traits. With the right chemical partners, it is able to act as either fuel or oxidizer. For pyrotechnic purposes, only the α allotrope is used. Furthermore, the grade known as "sulfur flour" is normally specified. It is a highly pure form, crystallized from molten sulfur. Sulfur purified by sublimation—termed "flowers of sulfur"—is a highly pure form, but its purity makes it much more reactive than the crude grade[1746]. Hazards of sulfur reaction with potassium chlorate are discussed under *Pyrotechnics*, above.

Sulfur liquefies at 95 – 120ºC, depending on the allotrope[90]. All forms have a boiling point of 444.7ºC. Liquid sulfur is easily ignited in air, but there is not good agreement on the exact values of the flash point nor the AIT. Urben[3] reports that the flash point of pure sulfur is 188ºC, but impure sulfur may ignite at 168ºC. Fedoroff[90] reports an open cup flash point of 207ºC, closed cup 227ºC, and an autoignition temperature of 232ºC. Shimizu[1809] reports an AIT of 223ºC. Lancaster reports an AIT of 260ºC for flowers of sulfur and 190ºC for sulfur flour. Liquid sulfur accidents most commonly occur in the course of transportation accidents involving the molten material. Molten sulfur is transported at 150 – 200ºC, thus in a road tanker collision[1810] when spillage occurred, the sulfur ignited "immediately."

The major causes of sulfur dust fires are: autoignition, static electricity, metallic sparking, bare electricity-carrying wires, and open flames[90]. Sulfur dust has a reported minimum ignition energy of 3 mJ, which is a very low value for dusts. Sulfur dust is so easily ignitable from electrostatic discharge that ignitions have occurred simply during sieving of the dust[1811]. The flammability limits for the dust are approximately 35 – 1400 g m^{-3} . An AIT of 167ºC in the Godbert-Greenwald furnace has been reported for dust clouds of 20 µm particles[1812].

At elevated temperatures, sulfur reacts violently with many metals, especially if they are in finely-divided form—aluminum, copper, iron, tin, zinc, etc. Incandescence, ignition, or explosion can take place. These reactions are exploited in some pyrotechnic and propellant formulations, but will be a hazard if unexpected. Water can initiate some of these reactions with metals. With some metals, e.g., copper, iron, magnesium, or mercury, an exothermic reaction can take place starting from room temperature[3]. Reactions with some non-metals—boron, phosphorus, lamp black—that lead to spontaneous combustion can occur at room temperature. In general, sulfur can react exothermically with almost any element apart from gold, platinum, iridium and the inert gases. In 1822 a sulfur-bearing soil was identified which was prone to spontaneous combustion[1813]; this was attributed to reactivity with metals. Sulfur in its mineral form used to be known as *brimstone*, suggesting the reactivity that occurs. A fire occurred when paper sacks containing sulfur and sodium nitrite were placed into a rubbish container[3]. NFPA has a standard, NFPA 655[1814], which gives advice on the safe handling of sulfur.

Surge suppressor MOV devices

Surge suppressors are any devices which are intended to reduce the damaging potential to electronic equipment of excessively high voltage power line spikes. The most common and lease expensive variety relies on metal-oxide varistors (MOVs). These devices are sacrificial and will fail (and may self-ignite) after absorbing a certain amount of excess-voltage spikes. Olson[1815] conducted testing showing that the failure can result in the device dropping down to about 15 Ω resistance, which is sufficient to cause ignition of plastic casings, but does not result in circuit breaker tripping. Open flaming resulted in less than 5 min when an MOV device exhibited such medium-resistance failures. Their failure modes have also been described by Goodson[1816]. One way of minimizing the potential for such fires is by installing a TCO close to the MOV device. UL has a standard on the construction of MOVs[1817]. Expensive surge protectors usually use other technologies that do not entail sacrificial behavior or potential fires.

Surgical tubing

A number of accidents occur in hospital operating rooms where oxygen is supplied to a patient via tracheal tubing and the tubing ignites. Wolf et al.[1818] measured the AIT of several tubing types in a 100% oxygen atmosphere (Table 198).

Table 198 Ignition temperatures in pure O_2 for several types of surgical tubing

Rubber	AIT (ºC)
PVC	428
PVC*	397
red rubber	371
silicone rubber	381
* industrial, not surgical, grade	

Tanks

It has been pointed out in endless instructional materials (e.g., Smart[347]) that tanks which have held an ignitable liquid cannot be safely readied for welding, brazing, etc. by simply running water through them, although this does not stop accidents of this type from occurring. Liquid residue is likely to remain, and it takes very little residue for the LFL to be attained, especially if the temperature is raised. NFPA

327[1819] describes safe ways that steam cleaning or chemical cleaning can be accomplished.

ASPHALT STORAGE TANKS

Ignitions in asphalt storage tanks can occur due to a wide variety of causes, as described in a recent survey[1820]. Many occur due to faults of heaters, welding operations, ignition sources being present near the tank's vapor vent, etc. However, a number of fires and explosions have been found perplexing, since overt causes were not identified. Asphalt storage tanks are specialized in that they must be heated to 190 – 230ºC in order to keep the asphalt sufficiently fluid. The closed-cup flash point of asphalt is normally around 260ºC, so if tank temperatures are significantly lower than that, explosions should not result. Investigations have shown[1821] that flash-point testing of asphalts can often produce unconservative results due to losses of light fractions in sampling. Explosions have occurred even in tanks that are normally inerted (with nitrogen, steam, or flue gases), since opening to air is required in cleaning operations. Industry experience has led to a rule of thumb that oxygen concentrations should not be dropped below 5%, since anaerobic conditions promote the formation of pyrophoric iron sulfides[1820]. Because elevated temperatures are needed for normal tank operation, it was hypothesized that self-heating might be causing the unexplained ignitions, but tests indicated minimal exothermic activity in the temperature region of interest[1822]. Instead, it was concluded that the smoldering-type reactions that occur on a tank's inside surfaces decrease the available oxygen and foster anaerobic conditions suitable towards the generation of pyrophoric iron sulfides. An actual ignition can then result when the tank is opened up, additional oxygen becomes available, and it can react with the iron sulfides. A mathematical model has been proposed[1823] for treating the self-heating aspects, but it has not been validated. The best preventive measure is considered to be regular tank cleaning, which will not allow significant deposits to build up that could form iron sulfides. See also: *Iron sulfides*.

Tar (wood)

Pine tar has a flash point of 54ºC and has a self-heating propensity[1542]. Its boiling range is 240 – 400ºC.

Telephones, cellular

In recent years it has sometimes been claimed that use of cellular telephones can cause ignitions in flammable-vapor atmospheres, e.g., at filling stations. Tokyo Fire Department conducted extensive experiments[1824] to simulate such a scenario. Six models of cellular telephones were operated by a remote control device in an atmosphere containing 12% methanol vapor. No ignitions occurred during this series of experiments which included 924 outgoing transmissions, 800 incoming calls, and 3000 times of removing (with phone energized in standby mode) and reattaching the phone's battery. A further test series involving 1000 removals and reattachments of a phone's battery in a carbon disulfide/air mixture, also did not cause ignition. These findings are not surprising, in view of: (1) The devices use a low voltage battery, typically in the range 3 – 6 V. These are very marginal voltages for igniting a flammable mixture by means of a contact spark. For a resistive circuit, Figure 43 in Chapter 4 suggests that a current of around 25 A would be needed; this level of current is simply unavailable from a battery of a cellular telephone. Due to physical size reasons, the device cannot have large capacitors or inductors. For a capacitive circuit, Figure 39 in Chapter 4 again indicates that ignition is not expected, due to absence of either a huge capacitance or a large voltage. Similar data for an inductive circuit are shown in Figure 41. (2) While not specifically designed for flame arrester action, nonetheless the close spacings within a cellular telephone suggest that even if an incendive spark could be generated, there is likely to be an effectively flame-trapped path between it and the exterior environment.

Television sets and computer monitors

In Japan, informal statistics showed that consumer complaints of fire hazards from television sets far exceeded those for any other category of electrical appliance[1825]. It was also found that the two highest causes of fires with television sets involved (1) high-voltage transformer failures, and (2) cracks occurring at soldered joints. A study examining TV fires throughout Europe[1826] identified predominant causes:

Main causes

- bad solder joints
- worn power switches
- failures of heavy (over 10 g) components subjected to line voltage or high voltage and to electromechanical stress
- overheating caused by an imbalance in the thermal expansion coefficients of circuit components.

Secondary causes

- line-voltage filter capacitors, possibly breaking down due to power supply instability
- power transformer
- cathode ray tube, including coil and high voltage connector
- power cord.

The study pointed out that failures of soldered joints often involve a crystallization which takes place gradually over time; however, the exact metallurgical process is not well understood.

In Denmark, a study was made on used TV sets of 3 – 20 years which had *not* been involved with fire[1827]. In nearly 1/3 of the specimens, faults were found which could lead to a subsequent fire. The faults included cracked insulation on electric wires (29% of the sets), defective solder and cold solder joints (29%), incipient breakdown of components (9%), and signs of overheating (6%). In addition, 14% of the sets were found to have such high levels of dust accumulation that safety concerns were registered. The authors

concluded that the dust hazard was indirect—if ignited, a dust layer would cause such a short-lasting fire that components of the TV set would not be ignited. Instead, the hazard is because of the hygroscopic properties of dust layers, which can cause leakage currents in moist environments and consequent fires due to arc tracking. The Danish study also reports that bad solder connections have been noted in actual TV fires, but the investigations have not been broad enough to draw statistical conclusions.

Table 199 Characteristics of ignition sources used by Troitzsch

Ignition source	Mass (g)	Flame height (mm)	Burn time (s)	HRR (W)
methenamine pill	0.15	5 – 10	80 – 105	40 – 55
small candle (tea candle)	14	10 – 15	NA	30
regular candle, 21 mm Ø	53	15 – 30	NA	60
rag soaked in isopropanol	413	200 –300	210 – 240	1600 – 1900
isopropanol, 200 mL	160	600 – 800	120 – 180	2700 – 4000
NA – not available				

A US study[855] done in the 1970s identified that, at that time, the top two ignition sources were high-voltage transformers and switches/relays/plugs/sockets. Laboratory tests on TV chassis (i.e., excluding cabinets) showed that local ignition sources failed to propagate fire through chassis components. The authors also studied the effects of dust, lint, grease, and fluff deposits in televisions sets. They found that the heat of combustion of this material averaged 20 MJ kg^{-1}. Testing showed that the material only exhibited transient flashing and did not lead to sustained burning. Another study on circuit malfunctions in television sets conducted in the 1970s[1828] showed that temperatures of 200 – 500ºC are often found on circuit components (e.g., resistors) under malfunction conditions. At the higher end of this temperature scale, however, temperatures tend not to be sustained, since a fuse blows or the part burns out and circuit continuity is lost. The authors, however, were apparently not aware of the arc tracking potential identified by the Danish researchers.

When a fire impinges on a picture tube, the outcome may be an implosion, but it may simply crack and fill with air and not be a violent event. If an implosion does occur, however, it may impel burning material from the immediate vicinity of a burning TV set onto other objects, thereby causing secondary ignitions. A UK test[1829] demonstrated that the implosion of a TV picture tube led to the ignition of a couch about 1 m away.

In the US, in the early 1970s CPSC found that 20,000 TV fires per year and 800 life-threatening ones comprised an "unreasonable risk." UL responded by requiring enclosures rated V-2 under the UL 94 test in 1975, V-1 in 1977 and V-0 in 1979. By 1994, the number of TV fires had dropped to 1300/year. The requirement pertains only to fire enclosures, not necessarily external cabinetry, although typically TV sets in the US market have had V-0 rated cabinets. The same does not hold true for rear-projection televisions, where the outer cabinet is normally not considered a fire enclosure and which consequently is only HB-rated. UL standards governing TV sets changed through the years. Originally, it was UL 492, then UL 1410. UL 1492 is currently in effect, but in 2006 it will be withdrawn and re-

Table 200 Test results on television sets and PC monitors

ID	UL 94 rating	Thick. (mm)	Meth. pill	Small candle	Reg. candle	Rag on top	Rag below	200 mL alcohol	Notes
TV-01-28-28	HB	3.2	Y						
TV-03-25	HB	3.2	Y						p
TV-04-25	HB	3.2	Y						p
TV-02-25	V-2	2.6	Y						F/O
TV-06-14	V-2	2.0	Y						
TV-09-25-JAP	V-2	2.4	N	N	N	N	N		
TV-07-25-US	V-2[X]	3.0	N	N	N	N	N	N	
TV-05-25	V-1	2.9	N	N	N	N	N		
TV-08-25-US	V-0	3.2	N	N	N	N	N	N	
PC2	V-2	3.2	N	N	N	N	N	Y	c
PC4	V-1	3.2	N	N	N	N	N	Y	c; s

PC1	V-0	3.1	N	N	N	N	Y		a

Y – ignited
N – did not ignite
(blank) – not examined
[X] – slightly short of V-2 performance
F/O – room flashover
a – ABS
c – PC/ABS
p – polystyrene
q – unknown material
s – especially severe fire
v – PVC

placed by UL 6500[1760] which is already in use. The latter two standards are not just for TVs but also encompass radio/audio equipment, while UL 6500 further adds musical instrument equipment. The flammability of wood cabinets, except for the back panel, is unregulated. Computer monitors are treated by UL separately under UL 1950; this has been described above under: *Computer and information technology equipment*.

In Europe, the pertinent standard is IEC 60065[1761], and that standard currently has no flammability requirements for enclosures, provided that certain high voltage and other electrical components have internal protection. Traditionally, manufacturers there produced televisions with V-0 or V-1 rated cabinets. But a campaign against fire-retardant agents organized by political/environmental groups caused this to change and by 1995 most manufacturers had removed FR agents from their plastics. Furthermore, revisions were made to IEC 60065 to take away even the HB requirement which existed earlier. Fire statistics indicate this disparity in ignition performance: the number of television fires, per million TV sets, is about 30 times higher in Europe than in the US[1830]. UL 6500 is largely based on IEC 60065, but the flammability requirements are different and UL 6500 retains a requirement for V-0 rated cabinets. Eventually, it is projected that IEC 60065 and IEC 60950 (on computer equipment) will be merged into a document that is patterned after ECMA-287[1831].

An extensive study of fire tests on TV sets and computer monitors was run by Troitzsch[1832], who presented a graded series of ignition sources to full-size test articles (Table 199). But if a specimen failed a smaller ignition source, larger sources were not tested. He also conducted tests using the UL 94 series. The results are given in Table 200. Unless specified, all cabinets were made of high-impact polystyrene (HIPS). The data show that a V-1 rating is needed so that reasonable resistance to the smallest flaming ignition source, the methenamine pill, would be obtained. With regard to differences between V-1 and V-0 ratings, the results are unclear. In general, it appears that the UL 94 series is not a consistent determinant of performance when actual end-use articles are presented with realistic flame sources. The ratings in class V-2 are especially glaring, since it seems that almost any level of performance might be found in products rated V-2. As a safety minimum, the test results do indicate that TV sets, computer monitors and probably other appliances with plastic housings rated V-0 can be expected, to a high probability, to resist flaming sources the size of candle flames, or smaller.

Similar testing was also done by Simonson[1833]. She tested three computer monitors using V-0 rated enclosures, one HB-rated, and one that failed to meet V-2 but was not tested for HB requirements. She also tested a computer keyboard meeting V-0 requirements. The V-0 rated equipment did not propagate fire when tested with a match, a candle, and a small wad of burning paper. The monitors rated HB (or lower) led to a severe room fire when ignited with a match.

Tents

The ignitability of tent fabrics is commonly tested by the industry standard CPAI 84[1834]; ASTM D 4372[1835] is similar. Tent fabrics are also tested by NFPA 701[1836], which is not similar.

Textile wall coverings

Harkleroad conducted LIFT tests on a series of textile wall coverings[1837]. These are products that visually resemble carpets, but are not identified as such by the manufacturing industry, due to different testing and marketing requirements. The majority of the specimens showed very similar ignitability properties. Minimum heat fluxes for piloted ignition were 19 – 26 kW m^{-2}, computed T_{ig} values 440 – 490ºC, and effective thermal inertias of 0.7 to 0.9 $kJ^2\ m^{-4}\ s^{-1}\ K^{-2}$.

Thatch

The effect of an FR treatment on the ignition of roof thatch was explored by Eboatu et al.[1838], who studied four different grasses commonly used in Nigeria for thatching roofs, along with calcium phosphate-calcium sulfate monohydrate as the FR agent. Non-FR specimens could be ignited with a cigarette lighter flame instantaneously. By applying the FR treatment at a 16 g L^{-1} concentration, ignition times were raised to over 20 s. The ignition times of the FR specimens depended strongly on the type of grass used.

Thermostats

See: *Electric appliances and electronic equipment: High-limit switches* and *Electric outlets, plugs and connections: Miscellaneous connection failures*.

Tinder

Nowadays, the term 'tinder' is applied to any lightweight, easily ignitable materials. But until the 19th century, tinder was a vital component of making fire, and it came in one of two variants[1364]. The most useful type was known by the French term *amadou*, and was prepared from one of two fungi, *fomes fomentarius* or *phellinius igniarius*. These fungi grow on trees, and the tinder was prepared by treating with lye, then beating and rubbing. Sometimes *amadou* was treated with chemicals to make it more flammable. *Amadou* was sometimes also known as *punk*. A less desirable tinder was made from carbonized linen or cotton.

Tires and wheels

Tests by the Ontario Fire Marshal's office[1839] showed that an automobile tire could be ignited by a match, applied to the bottom of the tire for only 8 s. However, the small-flame ignition of tires will depend on the chemical composition of the rubber and the geometry of the tread, and some tires may be difficult to ignite. The same authors also demonstrated that flames from newspapers, a grass fire, and a gasoline fire can ignite tires. In some early tests, the Fire

Research Station[1840] determined that the minimum heat flux for ignition of rubber tires is 16.5 kW m^{-2} under piloted conditions and 40 kW m^{-2} for autoignition. The latter value is probably inaccurate, for the same reason that early FRS data on the autoignition of wood are systematically high. Jurng et al.[1841] tested the ignitability of small (0.7 g) chips of tire rubber in a high-temperature convective furnace and found an AIT of 527ºC. Brookes[1846] found the AIT of truck-tire rubber to be 422ºC at 1 atm, but this dropped to 240 – 270ºC at 6.9 atm. White[1842] tested a tire sample using the ICAL apparatus and obtained an AIT of 550ºC when exposed at 60 kW m^{-2} and 600ºC when exposed at 40 kW m^{-2}; he also reported a piloted ignition temperature of 396ºC when exposed at 25 kW m^{-2}.

Fires of heavy-equipment (truck, bus, etc.) tires[605] tend to occur due to failed wheel bearings, brake dragging, or excessive rubber flexing when the tires are underinflated or the vehicle is overloaded. Flaming is prone to break out when the vehicle has stopped, since at that point the convective cooling stream of the air flowing by has stopped. Due to the extremely high loads, ignition from friction can be a serious problem for aircraft tires. High ambient temperatures and underinflation of tires are the most common factors leading to ignition or explosion. For example, a DC-8-61 charter flight leaving Jeddah, Saudi Arabia on 11 July 1991 sustained a tire fire due to underinflation, with a loss of 261 persons on board. Investigation suggested that pressures recorded in tire maintenance records had been altered[1843]. Tire fires due to overinflation have also been reported[1844]. Another loss due a tire fire was on 31 March 1986 when 166 persons died in a Mexicana Airlines B-727-264 which was departing the Mexico City airport. In this incident, a tire exploded due to overheating of the left main-gear brake. Investigation revealed that the tire had been inflated with air rather than nitrogen, making an internal tire ignition easier. In some cases, tire fires lead to only minor losses. Emergency braking of a Delta Air Lines Flight 54 at Honolulu Airport on 7 August 1997 started a tire fire. Only minor injuries were sustained and the airplane was repaired.

A small fraction of tire explosions involve combustion effects and not simply a physical explosion. A number of such incidents been reported in heavy construction and mining equipment when the equipment accidentally contacts a high-voltage power line[1845]. Current flowing to the ground through tires—which have an appreciable conductivity due to carbon black—causes heating and pyrolysis of the rubber material, leading to a combustible atmosphere being formed in the void space which then explodes.

Several explosions have been caused by welding truck rims without first having removed the tire. In one incident, the tire was neither deflated nor removed before the welding commenced. An explosion took place about 3 – 5 minutes after the work was finished, killing two workers[1846]. It was determined that the tire was lubricated with a compound, based largely on alcohol, that had a low flash point (56ºC). Laboratory reconstruction determined that the high temperatures created by the welding were sufficient to ignite a quantity of the lubricant that was on the inside of the rim. The burning lubricant then heated other portions of the inside of the wheel and pyrolyzed enough tire rubber to create a flammable mixture not in direct contact with the burning zone. The mixture later ignited and this caused the explosion. In another incident, welding was conducted on a truck rim where the tire had been deflated, but not dismounted. The tire was then reinflated and an explosion occurred shortly thereafter. The investigation revealed that rim temperatures were high enough (over 700ºC) as a result of the welding that pyrolysis started once the tire was remounted. Explosion was possible because increasing the pressure lowered the AIT of the pyrolysate. Pyrolysis-caused explosions need oxygen, and tires that are nitrogen filled (aircraft, F-1 race cars) are not subject to this mechanism.

Numerous fires or explosions have occurred due to the use of a product to repair and repressurize a punctured tire. These products used to consist of an aerosol can containing a flammable gas (a non-flammable gas is used in current products) and leak sealant substance. This creates a flammable atmosphere within the tire, and accidents generally coincided with a further repair operation being performed on the tire.

Tire shavings are subject to spontaneous combustion[1847]. Shredded tires can self-heat and lead to fire, if stacked in sufficient quantities. This has happened both in production facilities and in places where tire shreds are used as a road fill. In one case investigated by the author, a facility was producing tire shreds by grinding tires into pieces of about 12 mm size. The grinding process raises the temperature of the rubber and exit temperatures were about 115ºC. A pile about 1.2 – 1.8 m high and 3.0 – 3.6 m wide was stacked. About 4-½ days later fire erupted. Humphrey[1848] reported four cases of thermal runaway in production facilities, but these did not lead to open flaming. The stack heights in these were much higher (6 – 15 m), but the materials were more coarse (50 – 100 mm size). He also reports two cases of fires in road fills and one case of thermal runaway that did not lead to flaming. Stack heights ranged from about 2 m to 13 m. Apart from the basic exothermicity of the oxidation of rubber (see *Plastics: Foams and elastomers*), Humphrey suggests that several additional factors can be involved: (1) Oxidation of iron. Iron will be present unless all fragments of steel in the tire can be removed from the scrap. (2) Microbial oxidation of sulfur (which is a component of tire rubber) and iron. (3) Microbial oxidation of petroleum products, possible if contamination is present. Microbes may also play a role once sufficient heating has taken place so that a pyrolysate liquid flows out of the pile. It has also been observed[1849] that rainfall may promote the thermal runaway of tire scrap piles. This can enhance both rusting of the iron and biological reactions, the latter possi-

bly due to flow of nutrients. The problem of self-heating of road fill made from shredded tires was considered to be sufficiently serious that an industry recommendation[1850] has been published urging heights no more than 3 m, along with minimizing the amount of finely-ground material and limiting oxygen ingress. Limiting the height (and not stacking hot material) is essential. However the roles of particle size and oxygen access are more debatable. Hermetic sealing would prevent oxidative self-heating, but this is unlikely to be practical. Ventilation increases the availability of oxygen but also carries heat away from the reaction. Thus, its role is complex and it may not be possible to give a reliable rule-of-thumb. Similarly, up to a certain point, making the material finer increases the surface area and increases the access to air. But further reduction in diameter of the particles can reduce the air flow through the pile and limit self-heating due to limiting oxygen availability.

Toasters

Toasters may ignite kitchen cabinets or other nearby combustibles if a food item is overheated and begins to flame. Commonly, toasters are equipped with a bimetallic thermostat that is supposed to operate the pop-up mechanism. Occasionally, the mechanism fails. The consequences of failure have been documented to be particularly severe in the case of jelly-filled snack foods. Flames of 0.5 – 0.75 m high have been documented to emanate from the toaster under these conditions[1851]. According to Fitz[1852], to provide adequate safety against unwanted ignitions, toasters should have both a bimetallic thermostat and a timing device. Either of these devices must activate a trip-free mechanism that will de-energize the toaster in the event the bread carriage is jammed in the down position. The timing device is needed because the bimetallic thermostat may not sense sufficient heating if one of several heating elements becomes de-energized, yet the product being toasted continues to be heated to flaming by the remaining elements.

Town gas

Town gas is manufactured gas, derived from coal or oil. It used to be common in the UK until the 1960s and was also used in some locations in the US prior to World War II. The primary constituents are CO and H_2, with small amounts of saturated hydrocarbons, and very small quantities of CO_2 and unsaturated hydrocarbons. A typical composition included about 40 – 60% H_2 and 10 – 25% CO; in the US, the fraction of CO was less, 6 – 12%. The explosive range of US-type town gas[1853] was considered to be 6 – 36%. Up until quite recent times, a number of Bunsen burner-type fire tests (e.g., by the Federal Aviation Administration) used a mixture called *B-gas*. This was a standardized version of town gas, comprising 55% H_2, 18% CO, 24% methane, and 3% ethane.

Turpentine

Turpentine is hazardous because of its very low LFL, which is 0.7%[4] and its tendency towards self-heating when dispersed (e.g., when applied to rags). In an early study[1197] of various paints, varnishes, and oils, turpentine was found to have the highest iodine number (206), the second-highest heat of reaction (234 kJ kg^{-1}), and the greatest tendency to react with oxygen from the air.

Unsymmetrical dimethylhydrazine

UDMH, $C_2H_8N_2$, is a liquid fuel for rockets; its ignitability characteristics have been studied by the Bureau of Mines[1854]. Its LFL is 2.3% and the LTL is –15ºC. The UTL is nearly identical to its boiling point, 63ºC. For UDMH vapor, the LFL is 1.9% at 100ºC and 1.8% at 200ºC. The UFL at 100ºC is 92%, rising to 99% at 200ºC. The AIT is 250ºC at ambient pressure, dropping to 148ºC at 14.6 atm. According to the Bureau of Mines, UDMH is not prone to autodecomposition and is insensitive to initiation by shock. The main hazard is associated with the very wide flammability range.

Upholstered furniture and mattresses

NFPA estimates[1855] that ignition of upholstered furniture or mattresses comprises some 33% of the fire fatalities in the US. While US fire deaths have dropped dramatically in the last 25 years, the proportion of deaths attributed to upholstered furniture ignitions has additionally decreased. In 1976 it was estimated[1856] that this fraction was 54%. CPSC estimates[1857] that US fire deaths for upholstered furniture ignited by cigarettes, cigars and similar non-flaming sources dropped from 1150 during 1980 to 340 during 1998. Similarly, flaming-ignition fire deaths dropped from 110 to 80.

Upholstered furniture and mattresses (for purposes of examining the ignitability behavior, these two categories of goods are commonly treated as one category) ignite in practice from four main types of sources:

(1) smoldering cigarettes
(2) small flames (children playing with fire; electrical faults)
(3) radiant heat (too close to heaters; on-going room fire)
(4) burning brands (houses exposed to wildland fires; wartime activities; on-going room fire)

Regulatory concern has mostly focused on #1 and #2. Source #3 may be important in individual fire histories, but has not been seen as an important factor in overall loss statistics. There is a sizable amount of research data available on the radiant ignition of upholstered composites, however. Very little research is available on #4.

SMOLDERING AND IGNITION FROM CIGARETTES

Certain types of both fabrics and foams used in upholstery are susceptible to smoldering. Cigarettes are the primary smoldering ignition source for furniture materials, although other causes (e.g., glowing electrical connections) are possible. Ignitability from cigarettes is largely correlated to presence of cellulosic materials in the construction. As with most fire properties of upholstered furniture materials, it normally requires the testing of a realistic, composite as-

sembly. Individual testing of fabric or padding layers may not give predictive results, although several test methods are based on individual-component testing. The ignitability of upholstered items from cigarettes has been reviewed extensively by Babrauskas and Krasny[1858], Krasny[1859], and Krasny, Parker, and Babrauskas[1860].

Damant studied a large amount of data collected from composite mockup tests conducted on over 1200 commercial furniture samples in California[1861]. His salient conclusions were:

- Thermoplastic fabrics tested over untreated cotton battings showed a 15% probability of cigarette ignition.
- Cellulosic fabrics tested over untreated cotton battings showed a 94% probability of cigarette ignition.
- For thermoplastic fabrics tested over untreated cotton battings, the probability of cigarette ignition is inversely related to fabric weight. Fabrics over 400 g m^{-2} showed a 0% probability, while those under 300 g m^{-2} showed a 24% probability.
- Fabrics that are of mixed cellulosic/thermoplastic fibers tend to respond according to the fiber proportion. Fabrics having a 50/50 mix showed a 50% probability of ignition when tested over untreated cotton battings.
- When tested over a variety of paddings (market mix, but predominantly polyurethane foams), thermoplastic fabrics showed about a 5% probability of ignition. There was no significant effect of fabric weight. On this point, industry sources[1862] estimate that, for current-day materials, the probability is actually below 2%.
- When tested over a variety of paddings (market mix, but predominantly polyurethane foams), cellulosic fabrics showed results that depended on fabric weight. Fabrics over 440 g m^{-2} had an 86% probability of ignition, fabrics of 300 – 440 g m^{-2} had 57%, while those under 300 g m^{-2} had a 43% probability. Industry sources[1862], however, consider that other factors (e.g., the type of weave) can be controlling and that fabric weight alone is a poor predictor of ignitability.

In another study, Damant[1863] showed that the presence of a fabric is essential for a cigarette to induce smoldering in a smolderable polyurethane—no ignitions could be achieved without a fabric. Even in tests where a cigarette was placed directly on polyurethane foam blocks, then covered on top with fabric (as opposed to being placed on a fabric/foam composite) ignitions were very rare. Conversely, it is easy to get cellulosic fabrics smoldering even if the substrate (e.g., fiberglass) is noncombustible[1864]. For untreated cotton fabrics, smolder propensity is directly related to its basis weight, but the phenomenon is essentially go/no-go, and the maximum basis weight that can be used without leading to smoldering ignition is also dependent on the substrate. In one study[1865], it was found that fabric weights > 280 g m^{-2} led to smoldering when used over a fiberglass substrate, weights > 350 – 400 g m^{-2} led to smoldering over polyurethane foam, and weights > 400 g m^{-2} led to smoldering over FR treated cotton batting. When smoldering did occur, smolder rates of 150 – 300 mm h^{-1} were typically found.

The high ignition propensity of heavy-weight cellulosic fabrics have been identified to be almost entirely due to the presence of alkali metal ions in the material; well-washed cellulosic fabrics do not show a propensity to ignition from cigarettes, regardless of weight[1860].

Wool fabrics, which are neither cellulosic nor thermoplastic, show low probability of cigarette ignition. Paddings made from other natural fibers (hemp, coir, etc.) have similar smoldering tendencies as cotton batting. Resistance to cigarette ignition is typically imparted to cotton batting by treating with 8 to 12% boric acid crystals. Polyester padding is naturally resistant to smoldering; latex foam is highly smolder prone. Some grades of leather upholstery are resistant to cigarette ignition[1866], although this material has received only very limited study.

It is perhaps surprising that some polyurethane foams can smolder because smoldering requires the material to char and not to melt—otherwise melting would destroy the large pore area needed for a smolder front to propagate. It turns out that when presented with a low heat flux, some polyurethane foams can char. There is a narrow range of heating conditions over which this happens, with lower fluxes leading to extinction and higher fluxes leading to melting. The topic was studied to a limited extent by Rogers and Ohlemiller[1867,1868].

Most cigarette ignition testing is done under quiescent air flow conditions. Limited test results (discussed in Chapter 7) indicate that modest air flow velocities increase the propensity to smoldering ignition. Almost all testing for the cigarette ignitability has been done using actual cigarettes. Cerra and Ramsay proposed[1869] that statistical variations in the burning of cigarettes could be avoided by use of a Nichrome wire glowing igniter, and Ortiz-Molina et al.[1870] used exactly such an arrangement. Opposite to Damant's conclusion, they found that the most smolder-prone foam (of three tested) was able to smolder without any fabric covering. Their least smolder-prone foam required a heavy-weight cotton fabric to smolder. Another study[1871] also demonstrated that some polyurethane foams can be induced to smolder in the absence of a smolderable cover fabric, but in this case the heater had to be applied by a long time, 3000 s.

The transition from smoldering to flaming of upholstered furniture items has been studied statistically by Babrauskas[1872]. From a database of 102 full-scale tests on chairs, sofas, and mattresses, it was found that 32% burned up or went out without erupting in flaming, 64% transitioned to flaming, with 4% undetermined or manually extinguished. Of the items that did transition to flaming, the

mean time for flaming to erupt was 88 minutes, with the total experimental range being 22 to 306 min. These studies were all based on testing in an open laboratory environment. If furniture starts smoldering in a tightly closed space, it may smolder for a very long time.

Test results show that furniture composites which will not get ignited from a cigarette placed open on the surface, may get ignited if the cigarette is covered by a bedsheet[1873]. This is the reason that the standard test method for mattresses (see Chapter 7) involves use of a sheet over the cigarette. Bed sheets are rarely used on top of upholstered chairs or sofas, thus testing the latter is normally done without a bedsheet. However, pillows, 'throws,' and other accessories are sometimes used in a living room, and a cigarette slipping under one of these articles would create a condition not anticipated by standard test methods.

THE POSSIBILITY OF SAFER CIGARETTES

The ignition of upholstered furniture from cigarettes requires that the cigarette be ignition-capable, and that the upholstered furniture item be ignitable. The bulk of research and regulation, on a worldwide basis, has been addressed to second requirement. But since ignitions could also be avoided if cigarette characteristics were altered to make them no longer competent ignition sources, this alternative was explored in the US during two research projects. Both projects were specifically legislated by Congress, with the overall responsibility falling to CPSC and the technical research portion being organized by NIST. Both projects included economic studies, which are not within the scope here. Actual ignitability results obtained from research under the Cigarette Safety Act of 1984 were in the form of two technical reports[313,1874] and two papers[1875,1876]. The first study identified that there were negligible differences among commercial US cigarettes in regards to their ability to act as competent ignition sources. After this was found out, NIST turned to examining patented and specially-fabricated cigarettes. It was concluded that cigarette design aspects leading to a lowered propensity to ignite furnishings are:

- lower packing density of tobacco
- lower paper permeability
- a smaller diameter, e.g., 21 and not 25 mm
- avoidance of citrates in the paper wrappers
- use of a filter tip.

The type of tobacco was found not to have a significant effect. Some cigarettes having these design features were prone to self-extinguishing in air (which might be objectionable to smokers) but others were not. In addition, many of the patented designs were found to be promising.

The primary results from NIST studies done under the Fire Safe Cigarette Act of 1990 emerged as a report documenting the development of two test methods[1877], along with two papers[1878,1879]. The two methods developed in the study were:

(1) A Mock-up Ignition Test Method that uses three different weight standardized cotton-duck fabrics and a polyurethane foam padding. The least ignition-susceptible fabric also uses a layer of thermoplastic film underneath the fabric.
(2) A Cigarette Extinction Test Method that uses layers of cellulose filter paper as the smolderable substrate. The three levels of test comprise 3, 10, or 15 layers. The method is easier to conduct and to standardize than the one using simulated furniture constructions.

The study also identified 4 experimental cigarette types that rarely ignited the most-difficult-to-ignite composite and had tar, nicotine, and CO yields similar to best-selling commercial cigarettes. Hirschler conducted a follow-on study that demonstrated the relation between Mock-up Test results and results with an extensive collection of 500 fabrics[1880]. The US tobacco industry vigorously opposed the proposed test methods, generally on the grounds that they found imperfections in the procedures[1881-1885]; however, no alternative test methods have been put forth by the industry. Most regulatory fire safety tests are designed to eliminate the worst-performing products, not to guarantee a minimum level of performance. The latter is rarely possible, since there are too many end-user variables that are not under the control of the product maker. The tobacco industry position, summarized briefly, was that no test method should be promulgated since none can always correctly predict the in-use behavior. In 2002, the Cigarette Extinction Test Method was standardized as ASTM E 2187[1886].

The NIST Mock-up Ignition Test Method is based solely on using polyurethane foam as the padding material, since this is the most common padding used in the US. In the UK, however, latex and cotton batting paddings still see fairly common use, thus Paul[1887] conducted extensive tests with various cigarettes using the British BS 5852[1888] mockup rig and a variety of padding materials. He also reported on tests with beds. His 'improved' cigarettes were normal marketplace, slim types, so the improvements offered over ordinary cigarettes were found to be modest.

In early studies, it had often been tacitly assumed that if a cigarette is designed so that—in air—it would cease burning if not puffed, then such a 'self-extinguishing' cigarette would also not ignite furniture materials. Unfortunately, research proved otherwise, so actual testing by placing cigarettes on furniture remains necessary[1889].

In July 2000, the Philip Morris company started producing fire-improved Merit-brand cigarettes by using a patented cigarette paper, PaperSelect, that has rings to periodically slow down the burning rate. NIST tests[1890] indicated that the cigarette does indeed show a reduced ignition potential, but the probability of ignition was still 3 – 50%, depending on the test substrate.

Table 201 Performance of European furniture composites when subjected to various ignition sources

Construction	No. 2 butane flame	No. 3 butane flame	No. 5 crib	No. 7 crib	20 g paper pillow	100 g paper pillow
FR polyester fabric HR PUR foam	N	N	M	Y	M	Y
cotton fabric graphitic PUR foam	Y	Y	M	M	M	M
wool fabric graphitic PUR foam	N	N	N	N	N	M
acrylic fabric melamine PUR foam	N	N	N	Y	N	Y
FR PVC covering HR PUR foam	N	N	N	Y	N	Y
FR polyester fabric FR cotton interliner melamine PUR foam	N	N	M	Y	N	M

HR – high resilience
PUR – polyurethane
Y – generally ignited (flaming)
M – mixed results
N – generally did not ignite (flaming)

- FR but non-HR foams showed a mixed record of ignition/non-ignition. The foam densities were 19 – 45 kg m^{-3}.

Matches, hot wires, candles, and small cribs were found to readily ignite uncovered polyurethane foams of various densities, as well as latex foam[1893]. When PVC or wool fabrics were used to cover the foams, the probability of ignition decreased. For composites involving fabrics other than these two, match ignition nearly always occurred. When the foam was an FR-grade* and was covered with PVC or wool fabric, ignition probability further decreased; however, a substantial number of ignitions were still found. Generally similar observations were also made by Woolley et al.[1894], who saw less benefit in wool or PVC coverings, but found that if certain interliners (fiberglass or FR cotton) were used, then frequently only the fabric would become ignited and burn off, but the foam underneath would not undergo sustained combustion.

IGNITION FROM SMALL FLAMES

Very little of furniture available in 2003 to consumers in the US will resist a small flame, if the flame is applied for more than a few seconds. Considering fabrics alone, wool, FR cellulosic, and heavily PVC-coated fabrics tend to resist a 20-s application of a match-size flame[1860]. Polyester and nylon fabrics tend to shrink away from the heat source instead of igniting. Apart from the California TB 117 procedures (see below), paddings are normally not tested for ignitability from flames, since they are not directly exposed to external flames. Results on composites are discussed in several sections below.

When using a methenamine pill, one set of tests[1891] indicated that ordinary furniture-grade polyurethane foams not containing any FR agents did not ignite. But a more extensive study[1892] showed that:

- All conventional (non-FR, non-HR) foams ignited and burned up. The foam densities were 19 – 30 kg m^{-3}.
- No high-resilience (HR) foams ignited, even though some were FR and some non-FR. The foam densities were 32 – 48 kg m^{-3}.

Table 202 Supplemental radiant heat flux needed to cause ignition of upholstered furniture composites from a methenamine pill

Fabric	Heat flux needed (kW m^{-2})
none (bare foam)	0
cotton corduroy	0
polyester	< 2
rayon/nylon	< 2
FR cotton drill	6
wool	8

Prior to the introduction of British regulations requiring that furniture resist small flames, Raftery[1895] tested 10 full-scale furniture items for match flame and small burner flame ignitability. The furniture samples included convoluted styles with various crevices and re-entrant corners. Ignitions were invariably obtained, except for one item with a PVC covering and a polyurethane padding foam covered by a polyester batting 'topper' layer.

When upholstered furniture mockups were subjected to ignition from burning, balled-up newspaper, FR wool-covered composites were found to resist ignition, and 60% of non-FR wool composites resisted, but PVC-covered composites ignited[1896]. Wool-covered composites commonly, but not always, resist ignition from the smallest wood crib ignition source ('No. 4 crib') described in the British standard BS 5852, discussed below, but ignite from all larger cribs[1897]. Leather upholstery, when used in the thicker grades, generally resists ignition from match-sized flames[1866].

A roundrobin was organized in Europe which tested several composites, when exposed to a variety of ignition sources[1898]. The butane flames and the wood cribs followed the specifications given in the British standard BS 5852. The results are shown in Table 201. The foam types are common in the UK but not elsewhere. The results only refer to flaming ignitions. A number of specimens showed smoldering, but not flaming, ignitions. It often happens that fire exposure involves both a small flame and radiant heating. Moulen et al.[1899] ran tests using the smallest available flam-

* Results in the literature attributed to "FR foams" must be viewed with caution, since FR formulations of polyurethane foams can range all the way from ineffectual to highly effective.

ing ignition source, the methenamine pill, supplemented by a radiant heater. The criterion for ignition was visible flame propagation away from the ignition source. The fabrics were in all cases on top of 23 kg m^{-3} PUR foam. The results (Table 202) show that adding a radiant heat flux of 1 – 2 kW m^{-2} will lead to ignite of a numerous upholstered items that might not otherwise ignite from a tiny flame alone.

IGNITABILITY FROM RADIANT HEAT

Both the minimum heat flux for ignition and the time to ignite under a given irradiance have been used to determine ignitability of fabric/padding composites. This is relevant to the scenario in which an upholstered item is exposed to the radiant heat from other burning items or from the heated walls, ceiling, or upper hot gas layer. Radiant ignition can take place under piloted or unpiloted conditions, but few unpiloted tests have been run on furniture assemblies.

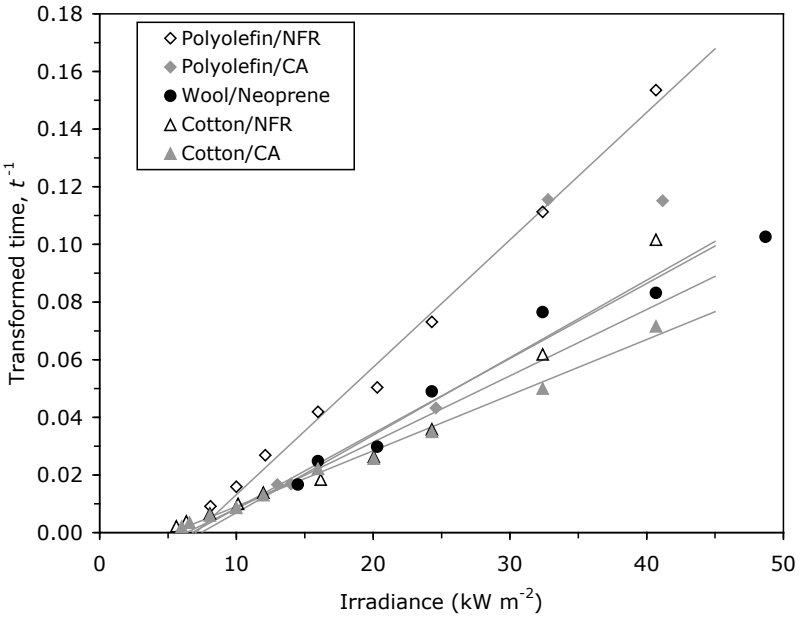

Figure 115 Cone Calorimeter ignition results for upholstered furniture specimens tested at NIST (first designation refers to fabric type, second to foam type: NFR = normal, CA = TB 117-compliant)

A number of researchers have reported radiant ignition data for furniture foams. This information is usually of limited value, since the contributions of foam and fabric cannot be integrated except by testing composites. Nonetheless, some typical data are the following. Palmer and Taylor[1893] tested the autoignition of uncovered polyurethane foams at a radiant heat exposure of 7.2 kW m^{-2}. Half of the tested specimens ignited at this flux and half did not. Of the ones that ignited, higher foam densities led to longer ignition times. The authors also found that the ignitability depended on the thickness of the foam, with around 200 mm needed for ignition at the 7.2 kW m^{-2}, but details of this thickness exploration were not furnished. The maximum time duration of the experiments was not specified, but in one case an ignition was recorded at 145 min. Smith[1609] tested the piloted ignition of an unspecified polyurethane foam by exposing it to tungsten lamp radiation. The specimen ignited in 220 s at a flux of 5.2 kW m^{-2}; lower fluxes were not tried. Foley and Drysdale[1900] conducted piloted ignition tests in the Cone Calorimeter and found that, for most furniture foams tested, the minimum flux for ignition was below 15 kW m^{-2}. But for two samples of mel-

amine-treated polyurethane foam, the values were ca. 17.5 and 25 kW m^{-2}.

Turning now to tests on composites, in a 1954 study[1901] FRS researchers found that upholstered chairs autoignited at a heat flux of 8.7 kW m^{-2} during a 25-minute exposure. The construction was not specified, but the study predates the use of foams in furniture. Hilado et al.[1902,1903] tested vertically-oriented foam/fabric composites in front of a radiant heater and obtained problematic results, since many fabrics melted out of the specimen holder prior to ignition. In general, they found no autoignitions at 25 kW m^{-2}, but most specimens autoignited at 58 kW m^{-2}.

A series of fabric/foam composites were tested at NIST in the Cone Calorimeter using spark ignition[1858]. Figure 115 shows the results when plotted as for thermally-thin materials. Some results produced a straight line, while others showed a fair bit of deviation. Four of the 5 specimens showed a slope which is probably identical to within experimental error. This implies that the differences in their effective thermal properties were insignificant. These properties are dominated by the behavior of the fabric and the basis weights of the fabrics were relatively similar. The densities of the paddings were grossly different (Neoprene 115 kg m^{-3}, polyurethanes 17 and 21 kg m^{-3}), but their effect is minimal. The reason for the unusual behavior of the polyolefin/NFR composite is not clear. The minimum heat flux for ignition varied from 5.6 kW m^{-2} (for cotton/NFR) to 14.5 kW m^{-2} (for wool/Neoprene). The two specimens with polyolefin fabrics required 8.1 and 13.0 kW m^{-2}.

A similar search for the minimum heat flux for ignition was undertaken as part of the CBUF study[1904], although only a portion of the total specimen collection was tested for ignitability. The results (Table 203) show the lowest flux was 6.5 kW m^{-2}, surprisingly for a construction using FR cotton fabric. The specimens showing values of $\dot{q}''_{\min} > 10$ kW m^{-2} were construction types uncommon in residential furniture, apart from leather which has been rising in popularity. The FR polyester was a polyester fabric with inherent FR qualities, not one with added FR agents. The results show that there is no discernable relation between $\dot{q}''_{\min}$ and the propensity of furniture presented with a 30 kW burner flame to propagate or not propagate fire. It also indicates that while protective interliners can be helpful in reducing the HRR of furniture, they do little to forestall ignition. This should not be surprising, since they are situated *underneath* the top (fabric) layer.

Chen[1905] tested the ignition of composites using a modified ISO 5657 test where ignition was with an electric spark, not a gas pilot. All tests were conducted over a single type of polyurethane foam. For 14 different fabrics used, values of $\dot{q}''_{\min}$ ranged from 6.5 kW m^{-2} to 17.5 kW m^{-2}, but the major fraction (57%) gave 7.5 kW m^{-2}. The unusually hard-to-ignite specimen was a nylon pile fabric. She also noted that for melting fabrics, at any given flux, if ignition occurred at all, it took place in 190 s or less. This was not true for charring fabrics and one such specimen took 778 s to ignite. Values of critical heat flux, using a thermally-thin fuel model were typically 1 kW m^{-2} lower than $\dot{q}''_{\min}$. She also determined that values of $L\rho C$ ranged from 0.89 to 2.17 kW m^{-2} K^{-1}, but with most values being around 1.3 kW m^{-2} K^{-1}. This grouping of constants in an effective fire property for a thermally thin material (see Chapter 7), with L = thickness (m), ρ = density (kg m^{-3}) and C = heat capacity (kJ kg^{-1} K^{-1}). For the specimens tested (which were mainly thermoplastic and did not include any FR grades), she recommended that ignition time t_{ig} (s), as a function of irradiance $\dot{q}''_e$ (kW m^{-2}) can be estimated as:

$$t_{ig} = \frac{338}{\dot{q}''_e - 7.8}$$

The effect of padding material on the radiant, piloted ignition of upholstery composites was specifically investigated by Moulen and Grubits[1906] and Table 204 shows that it is generally small-to-nil. In some cases, the composites using mineral fiber or wool batting showed somewhat longer times, but in other instances no effect could be seen. This question was further explored by Forsten[1907], who ran Cone

Table 205 Cone Calorimeter piloted ignition times (s) for school bus seat specimens

Covering	Padding	Heat flux (kW m^{-2})								
		2.5	3.5	5	7.5	10	15	35	50	75

Kevlar backed, 830 g m^{-2}	Rebonded PUR, 73 kg m^{-3}	--	--	--	--	99.0	42.5	8.2	4.3	2.1
UMTA, 770 g m^{-2}	Melamine treated PUR, 85 kg m^{-3}	NI	462	174	--	48.6	21.8	4.1	2.1	2.1
UMTA, 770 g m^{-2}	CMHR PUR, 49 kg m^{-3}	NI	736	260	--	50.4	21.8	4.1	2.0	1.7
UMTA, 770 g m^{-2}	Polychloroprene foam, 145 kg m^{-3}	NI	546	233	--	48.8	--	4.0	2.2	1.0
UMTA, 770 g m^{-2}	Rebonded FR PUR, 90 kg m^{-3}	NI	510	208	--	49.2	22.1	3.8	2.2	1.4

Standard – PVC backed with polyester scrim
Kevlar backed – same as 'Standard,' except nonwoven Kevlar interliner laminated to back.
UMTA – same as 'Standard,' except claimed to meet UMTA flammability guidelines
'--' – denotes not tested at this heat flux.
NI – no ignition.

Calorimeter tests on composites formed from 14 fabrics combined with polyurethane foams that were either TB 117-compliant or of the melamine type and an optional light-weight Kevlar interliner. Use of melamine foam increased the ignition time by an average of 20%, that of the interliner by about 10%.

Upholstered furniture composites of the type used on school buses were tested by Braun et al.[1908] using the Cone Calorimeter (Table 205). Note that the padding densities used in this application are much higher than for domestic furnishings, where they typically range from about 16 to 32 kg m^{-3}. It is interesting to note the very low values of minimum flux for ignition obtained in these tests. Four of the 6 constructions showed 3.0 kW m^{-2}. Braun also repeated the tests with the LIFT procedure and obtained values of $\dot{q}''_{\min}$ = 9.0 kW m^{-2} for the first assembly, 13.0 for the second, and 3.0 for the four remaining. Apart from the second value, these results show a good agreement with Cone Calorimeter data. Plots of the school bus seat results show that the data conform neither to thermally-thin nor to thermally-thick behavior. The explanation possibly lies in the fact that for a physically-thin substance such as a PVC fabric, when very long ignition times are involved, the material becomes sufficiently thermally degraded so that it cannot be represented by a single set of effective properties (T_{ig}, etc.).

The conclusion from the above studies is that the majority of upholstered furniture composites in common use for residential applications show minimum heat flux values in the range of 6 – 10 kW m^{-2}. The results from studies done on bare foams do not have much practical application to upholstered furniture problems, since (1) foam is never used in furniture uncovered; and (2) there does not exist any means whereby bare-foam ignitability could be correlated to some performance aspect of the actual composite. Despite a shortage of autoignition tests on furniture composites, experience indicates that, at flashover, upholstered furniture items not yet burning will normally ignite. This can be taken to mean that if a heat flux of roughly 20 kW m^{-2} is applied, then autoignition is in most cases assured. But it is not necessary for a room to reach flashover before significant flaming and high heat fluxes can be found in localized places. Thus, upholstered furniture may well ignite from radiant heating occurring prior to flashover. In addition, NIST and CBUF testing indicated that, if one arm of an upholstered chair or sofa is flaming, the other arm commonly ignites from radiant heating, not by surface flame spread.

IGNITION FROM BURNING BRANDS

An old study indicates that upholstered furniture of the 1960s was relatively resistant to being ignited by burning brands, although with cotton fabrics and large brands (38 mm size) some ignitions did occur[1049]. A study on this topic has not been performed with modern furniture. Furniture fires have been started in houses exposed to wildland fires, where window glass broke and brands entered the premises, but research has not been reported to quantify this ignition scenario.

IGNITABILITY MODE COMPARISONS

Ramsay and McArthur[1909] examined the effect of various ignition sources on four bean-bag chairs. The specimens were all filled with expanded polystyrene foam beads and the coverings were heavy, PVC-coated fabrics. The beads of two chairs were FR and were non-FR for the other two. Neither cigarettes nor methenamine pills could ignite any specimens. Wood safety matches, 43 mm long, were able to ignite the chairs only when buried into folds; limited burning occurred even in the worst case. Crumpled balls of newspaper (100 g) ignited all specimens. When a radiant electric room heater was placed directly up to the chair, somewhat buried into it, and energized for 195 s, ignition and full consumption occurred for all specimens.

Several studies have examined the ignitability differences between radiant heating and a wood crib. In one study[1910] using a variety of furniture composites, it was found that the BS 5852 Crib No. 5 was less severe than a radiant exposure of 25 kW m^{-2}. Relatively similar results were found in another study[1911].

In a NIST study, five different chairs were exposed to a variety of ignition sources[1912]. A TB 133 gas burner ignited all chairs; a 1.5 kW radiant heater directed at the front of

Table 206 Comparison of flaming ignition sources to Cone Calorimeter results

the chairs caused only slight pyrolysis in 30 min, but when it was then tipped forward, the pyrolysis gases ignited in presence of an electric spark; a focused quartz/halogen reading lamp used as the heater caused only ignition of the acrylic fabric covered chair; the BS 5852 Flame No.1 did not ignite the cotton covered and the expanded vinyl covered chairs; and the cigarette ignited only the cotton covered chair.

Krasny and Huang[1913] tested a series of upholstered furniture composites using four flame sources:
(1) methenamine pill. Specimens tested horizontally.
(2) 97 W burner flame, applied for 20 s. Specimens oriented vertically, with flame applied to face at 25 mm above the bottom.
(3) 210 W burner flame, applied for 20 s. Same specimen conditions as above.
(4) 210 W burner flame, applied for 40 s. Same specimen conditions as above.

Cone Calorimeter tests examining piloted radiant ignitability at two heat flux levels were also conducted on the same materials. Table 206 gives the results obtained. A qualitative relation between ignition resistance for the two types of ignition sources could be seen, but not firm enough to be quantitative.

EFFECT OF WEAR AND SOILING

Ignitability is rarely tested for other than virgin material. In one study where mechanical cycling was done to simulate in-use wear conditions[1914], it was found that 6 out of 7 specimens were no longer able to pass the BS 5852 small-flame test after cycling. CPSC conducted limited testing to examine a series of related issues. They found small or no effect on ignitability from spilled beverages[1915]; soiling with greasy material[1916]; and pounding (to simulate wear), professional cleaning, or home cleaning[1917]. In industry testing[1914], it was found that cigarette ashes, when used to soil a fabric which originally passed the cigarette ignition test, caused it to fail. Cigarette ashes also caused a TB 117-complying foam to no longer pass the TB 117 test. Similarly, a TB 117 complying-foam, when soaked in human urine and then dried out not longer passed the test.

UFAC AND BIFMA REQUIREMENTS FOR IGNITABILITY

From 1976 to 1981, the US Consumer Product Safety Commission (CPSC) considered the possibility of adopting a mandatory standard for the cigarette ignition resistance of upholstered furniture, much as it already had inherited (from the Department of Commerce) a mandatory standard for mattresses. CPSC asked NIST to develop a method, and NIST produced a long study and a proposed method[1918]. The work resulted in the publication of ASTM E 1352[1919], which involves placing lit cigarettes on a fairly large mockup of the intended construction. The industry was opposed to having a mandatory requirement and, in 1981, CPSC accepted the counter-proposal from industry that they will form an entity, the Upholstered Furniture Action Council (UFAC) which will vigorously promote a test on a voluntary-compliance basis. A special tag was developed to identify the complying furniture, with the notion that this would call the attention of the consumer to the benefits of improved fire performance. Since it was felt that testing all fabrics over all paddings would be onerous, a classification scheme was adopted, whereby fabrics are tested over a standard polyurethane foam and classified as Class I or

Class II. Class I fabrics do not permit ignition of the polyurethane foam during the test, while Class II fabrics do. However, Class II fabrics may be used to make furniture if a suitable barrier is used between the fabric and the polyurethane foam. Similarly, battings and other filling and padding materials are tested separately underneath a standard fabric. Some of the UFAC procedures have been standardized as ASTM E 1353[1920], but the ASTM version has not been much used. Further description of details has been published[1860]; actual UFAC requirements change on a periodic basis and are obtained from the organization itself[1921]. The UFAC requirements pertain only to cigarette ignitions; there is no testing from flaming sources. The Business and Institutional Furniture Manufacturer's Association (BIFMA) published a standard[1922] for furniture intended for the business and institutional markets which essentially represents the combination of ASTM E 1352 for cigarette resistance of composites and CS 191-53 for flaming performance of fabrics.

CALIFORNIA TB 117 STANDARD FOR IGNITABILITY

The Cal. TB 117 standard[1923], which came into effect in 1977 and is mandatory in the State of California, comprises separate test procedures for flaming ignition of fabrics, flaming ignition of paddings, and smolder-resistance of padding materials. There is no control over the cigarette-ignition propensity of fabrics, even though smolderable fabrics have been a larger problem than smolderable paddings. The State has published a separate method TB 116, which addresses the cigarette ignition resistance of as-built mockups, but this method is non-mandatory. The test procedure for the smolder-resistance of paddings is similar to that in ASTM E 1353. The Cal. TB 117 procedures concerning smolderability of paddings are, effectively, a subset of the UFAC requirements; thus, UFAC-complying furniture items would meet the California requirements in that regards.

For flaming ignition regulation, the California procedures do not examine the actual-use composite. Instead, foam and fabric are subjected to separate tests. The test for the fabric is the CS 191-53 (16 CFR 1610) test (see *Fabrics*). Almost any fabric that is suitable as an upholstery material can pass this very lenient test, although rare failures occur. The foam test is more demanding, and some FR agents have to be added in order to meet it. Since almost any fabric will pass the Cal. TB 117 test and since, in actual ignitions, the fabric is the material which is closest to the flame, common sense would indicate that the test method does nothing to reduce the potential of small-flame ignitions. Engineering tests confirm this. In tests using a 70 W ignition flame (corresponding approximately to the output of a cigarette lighter)[1924], it was found that real chairs made with Cal. TB 117 complying materials readily ignited. CPSC conducted extensive testing[1925] and concluded: "TB 117 component results were not predictive of full scale performance"; and "TB 117…would not, if federally mandated, ensure a substantial reduction in the risk of small open flame ignition of finished articles of furniture." CPSC also documented that small-flame ignitability of upholstered furniture is governed mostly by the performance of the fabric. Talley[1926] further demonstrated that furniture made to the Cal. TB 117 standard ignites readily from small ignition sources and shows ignitability behavior identical to regular commercial furniture not made to the Cal. TB 117 standard. His study is especially noteworthy since he used the very small methenamine pill ignition source.

The TB 117 test for flammability of foam exposes vertically-oriented specimens 76 mm wide × 304 mm tall × 13 mm thick to a 12 s burner flame applied at the bottom edge. Specimens pass if the maximum char length is not over 203 mm, the average char length for 5 specimens not over 152 mm, the maximum afterflame time not over 10 s, and the maximum afterglow time not over 15 s. Usually, a small amount of FR additives must be added to polyurethane foams to meet this requirement, but in some cases even ordinary furniture foams without any FR additives pass the test[1891].

In 1999 California Bureau of Home Furnishings and Thermal Insulation announced that the TB 117 standard will be substantively revised. It appears, at this point, that when the revised method is published (anticipated for 2003), it will retain the component-testing features and add a procedure for testing composites, roughly modeled on the British BS 5852 standard.

FLAMING-SOURCE IGNITION EXPERIMENTS AND PROPOSED TEST BY CPSC

In examining small-flame ignition hazards to upholstered furniture, CPSC concluded[1927] that nearly all products in the marketplace as of 1996 ignite when exposed for a short time of 5 – 20 s. In their study[1928] CPSC used a 96 W butane diffusion flame simulating a match to ignite full-scale chairs. A total of 27 different furniture specimens were tested: 9 made to the Cal. TB 117 standard, 9 made to UFAC requirements, and 9 to the British BS 5852 standard. Two locations were tested: at the seat/back juncture and at the seat/arm juncture. Of the 54 total specimen/location tests, ignition occurred in 100% of the specimens. Of these, 3 occurred in 5 s, 44 in 15 s, and 7 in 20 s (a 10 s exposure condition was not attempted). There is probably little actual difference between 15 s and 20 s ignitions. But two of the 5-s ignitions were for Cal. TB 117 specimens, one for a BS 5852 specimen, and none for the UFAC specimens. Since the UFAC procedures make no restrictions on open-flame ignition performance, while Cal. TB 117 test method has a requirement for open-flame testing of upholstery fabrics, it can be concluded that the California procedure is ineffectual. The tests were terminated once ignition was established and did not go on to examine further burning. CPSC also undertook to verify that the test conformance claimed was

met. Upon performing the pertinent tests, however, they found that several of the filling materials for chairs claimed to conform to Cal. TB 117 did not meet the test requirement. None of the chairs claimed to meet BS 5852 were found to meet it 100%, but this perhaps reflects the fact that the specimens were not of UK manufacture. In one *ad hoc* test, it was found that a glass cloth interliner, while having no effect on ignition of the fabric, was successful in preventing ignition of the underlying foam from a 96 W flame.

In preparation for regulatory action, in 2001 CPSC proposed[1929] that a test rig similar to the BS 5852 rig be used*, that composites be tested comprising that fabric, standard foam (although actual foam is permitted as an option), and optionally a barrier. A 96 W butane flame is applied for 20 s, since this time length is typical of the burning time of a match. Flames from cigarette lighters may, of course, be applied by a small child for longer than 20 s. They also proposed that a fabric passes if flaming self-extinguishes within 120 s and smoldering within 15 min, and the burned area does not extend to the edge of the mockup; no ignition time limits, per se, were proposed. A separate test is provided for dust covers, which are typically non-woven fabrics used to close in the bottom of the furniture item. An optional test is included for assemblies containing interliners or barrier fabrics; it is based on Crib No. 5 of BS 5852. Of 50 fabrics tested by CPSC, they found that 29 would pass the proposed test. All except two of these were either intrinsically-FR or FR-treated. They also then procured some commercial chairs actually manufactured in the UK and found that, of 27 specimens, 21 met the requirements of the proposed test and 16 showed no ignitions in full-scale testing.

CPSC received public comments in 2002 on its 2001 proposal and expects to make a revised proposal in 2003.

UK FURNITURE REGULATIONS

The current UK fire regulations concerning upholstered furniture were promulgated in 1988, with minor changes made subsequently[1930]. The requirements are roughly based on the British standard BS 5852[1888] but do not follow it in all respects. BS 5852 was originally published in two parts, but the 1990 edition consolidated all tests into a single document. The actual furniture composite is required to pass a cigarette-resistance test. For flaming-source performance, polyurethane foam is tested as a composite, over a standard FR-polyester fabric, and exposed to a No. 5 crib. Other filling materials are only tested with a small gas flame. It has especially been of serious concern that latex foam, which is typically more hazardous than polyurethane foam, is treated much more leniently. The small-flame ignition resistance of fabrics is tested using a composite with a standard polyurethane foam. Welt cords are not subjected to test, despite the fact that this is a preferred place for cigarettes to cause ignition.

MATTRESSES

The ignition characteristics of mattresses are generally nearly identical to those of upholstered seating. The two main differences are: (1) an absence of non-planar surfaces; (2) the universal use of sheets and bedding in connection with the product. Extraneous items, e.g., quilts, pillows, are also often used in conjunction with seating furniture, but this interaction has generally been ignored in testing and in regulations. Recent US statistics involving mattresses are shown in Table 207. These were obtained from a special study of four cities[1931] where more detailed information was elicited than normally reported; the data include fires where either the mattress or bedding was the first-ignited item. The open-flame ignitions (matches, lighters, candles) comprise 39.6% and exceed the 36.4% reported for cigarettes. By contrast, statistics[1932] published in 1972, prior to the 1973 introduction of the Federal standard mandating cigarette-ignition resistance for mattresses, showed that 65.9% of mattress ignitions were from cigarettes. This improvement is not all due to the standard, since during the 1970s cotton-batting was largely superceded by polyurethane foam for mattress padding. Mattresses made with untreated cotton batting will almost invariably ignite from a cigarette, while a large fraction of PUR-foam upholstery systems will not, so some of the improvement would have occurred solely to this marketplace change.

Technically, the same principles govern the ignitability of mattresses and upholstered furniture, so below we summarize only a selection of mattress-specific research. A cigarette placed on a mattress will typically burn about 20 min. It has been found that self-sustained ignition of the mattress tends to occur at about the time that the cigarette is nearly finished burning[1933]. Balls of crumpled up newspaper (100 g) placed in between two cotton sheets on top of a mattress were found to readily ignite four different types of cotton ticking/polyurethane foam mattresses[1934]. In a test series[1935] where mattress padding materials were tested alone, without a mattress ticking, it was found that:

- crumpled newspapers ignited all paddings

Table 207 Fires originating in mattresses or bedding, arranged by ignition source, as obtained in a study of four US cities during 1996-1997

Ignition source	Percent
cigarette	36.4
match	21.4
lighter	15.5
candle	2.7
heater	2.7
electric blanket	0.9
other	16.4
unknown	4.1

* Even though the proposed CPSC tests are based on a rig evolved from BS 5852, the proposal does not share much in common with the UK regulations.

- a paper match ignited latex foam paddings
- a paper match ignited non-FR polyurethane foam paddings, but 1 out of 4 self-extinguished
- a paper match only ignited 1 out of 8 FR-polyurethane foam paddings, and that specimen self-extinguished
- a paper match did not ignite a Neoprene foam padding
- a paper match did not ignite a boric-acid treated cotton batting padding.

In the same study, the resistance to crumpled newspaper ignition sources was also examined for several complete mattresses, with ticking. Using an FR-polyurethane foam, ignition was achieved when a nylon-reinforced PVC ticking was used, but not for an FR-cotton ticking. Also, the newspaper source was not able to ignite a mattress that had an FR-cotton ticking and an FR-cotton batting. Details of the FR treatments were not given. In another study on boric-acid treated cotton batting[454], it was found that neither paper nor wood matches produced sustained ignitions, with the fire dying out after leaving a small burned area.

Latex foam (an SBR elastomer) mattresses were found by Hilado to be readily ignitable in a smolder mode from cigarettes[1936], although earlier Swanson and Adolph[1937] were not able to achieve that. Palmer et al.[1938] subsequently clarified that latex foams are ignitable by cigarettes in a smolder mode if: (a) the foam is bare; or (b) the fabric itself smolders; or (c) the fabric melts away, shrinks away, or burns through under the cigarette. Ignitions were found not to occur when PVC or wool fabrics were used. Unpublished NIST work showed that latex foam is almost inextinguishable once ignited and continues to smolder even if surface flaming is extinguished with water. A methenamine pill may cause either a smoldering or a flaming ignition of latex foam mattresses[1936]. For polyurethane foam mattresses, whether or not a methenamine pill will cause a flaming ignition tends to depend on the ticking material[1936].

If furniture starts smoldering in a tightly closed space, it may smolder for a very long time. A case is documented[1939] where a victim was murdered in bed and the bed lit (in a flaming mode) by the perpetrator. After a time, the bed fire went to smoldering due a lack of oxygen and smoldered for "two or three days" before someone entered the house to investigate the foul smell coming from the victim. Upon opening the door, smoldering transitioned to flaming.

In the US, mattresses made since June 1973 have had to comply with a test method in the Federal regulations. Originally, the test method[1940] was developed by NIST, but after the establishment of CPSC it was taken over by CPSC. The pertinent test is still commonly known by its original designation as FF 4-72. The test is on a full-size article and involves placing 9 cigarettes on the bare mattress and 9 more sandwiched in between two sheets placed on the mattress. In late 2001, CPSC announced that it may institute another standard for mattresses, this one to require open-flame resistance. Also in 2001, the State of California passed a law which will require mattresses sold there to be resistant to open flames, starting in 2004. Their proposed TB 603 standard is expected to contain testing methods that are similar to a scheme developed at NIST[1941], whereby two T-shaped burners are used to expose the edge of the mattress to fairly large flames. The criteria are to be based on HRR and ignitability is not directly involved.

Since the Federal test only uses two bed sheets, it may be speculated that if a full set of winter bedding is present on the bed and a lighted cigarette is introduced atop the top sheet, the likelihood of ignition will be greater. CPSC conducted unpublished research in 1984 which explored this effect to a limited extent. They concluded that complying mattresses will not be ignited if the bedding is mainly thermoplastic, but may be ignited if it is primarily cotton. They also speculated that when ignition of complying mattresses occurs, this may be because it is easier to ignite rumpled beds than beds with flat and smooth bedding; however, this conjecture was not explored in the laboratory.

Mattress test requirements in the UK have a complex legislative history, but in practice testing is normally done under the 'low hazard' section of BS 7177[1942]. This standard contains both a cigarette ignition portion and a test using a small gas flame; the same standard also contains specifications for higher-performance contract furniture. The current version of the British tests follows the European standards EN 597-1[1943] and EN 597-2[1944]. Many other countries have mattress ignition standards, commonly only against cigarette ignition, and a number of those have been reviewed[1858,1945]. European countries, however, are now coming to use the EN standards.

The safety of bedding on ships is governed by IMO, which has a test standard that includes a smoldering and a flaming ignition source[1946]. The smoldering source is unique in that the cigarette is placed on the mattress (a mockup of 450 × 350 mm is used) and is covered, not by a sheet, but by a layer of cotton wool. As with most non-US standards, the IMO standard ignores the possibility that the welt cord may be the most smolder-prone component in the assembly. US Coast Guard testing showed that the cotton-wool scheme is much more stringent, since 9 of 9 test specimens passed the test requirements when covered by a sheet (a draft IMO requirement that was dropped), while only 3 out of 9 passed the cotton-wool-cover procedure[1947]. The test method also differs from US procedures, in that the failure criterion for smoldering is an ill-defined "progressive smoldering," rather than a more quantifiable length of char. The flame source is a small gas burner flame of about 80 W.

Vacuum cleaners

Sloan[1948] reports of an incident where an industrial-type 'wet-or-dry' vacuum cleaner ignited while stored inside a truck. There was a large buildup of dust and oil in the motor area, causing the motor to overheat. It was concluded that

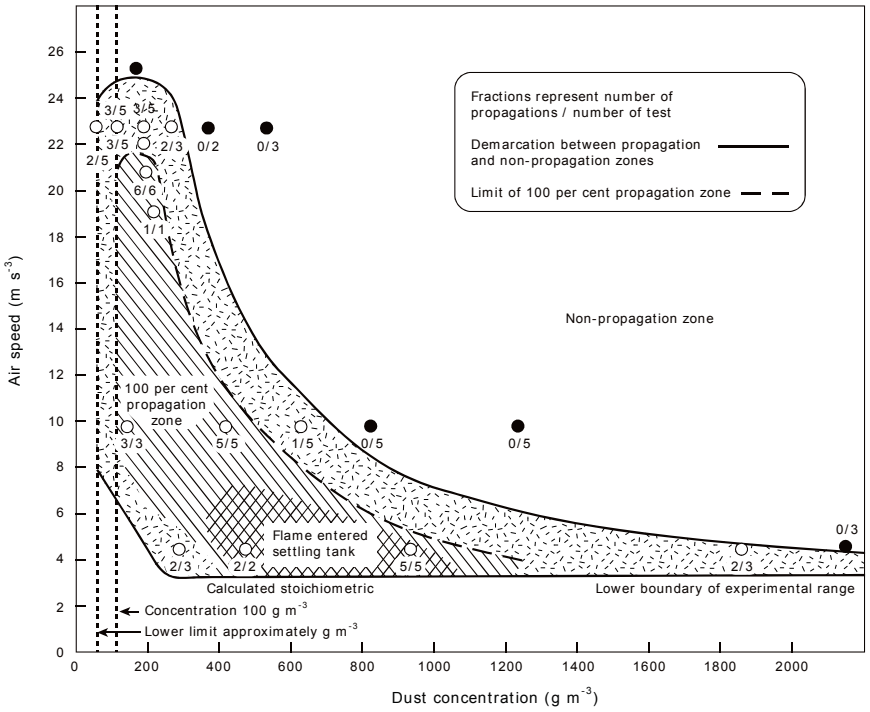

Figure 116 Conditions in vacuum cleaner suction hose for which an explosion of coal dust is possible
(Copyright HMSO, used by permission)

smoldering started in this material while the unit was still being used, but later erupted into flaming when no longer energized.

SMRE[1949] conducted a study where explosions in vacuum cleaner suction hoses were studied for coal dust being vacuumed. For a 50 mm diameter hose, the regime in which explosion is possible—given an ignition source—is delineated in Figure 116.

Wastes

The fire aspects of wastes have been studied by various researchers focusing on either issues arising in waste incineration, or else use of wastes as fuel. Cone Calorimeter ignitability studies have been reported by Hirunpraditkoon and coworkers[1950]. They studied dry wastes and wastes with 22% and 38% moisture. The effective heat of combustion of these fuels varied somewhat according to the test irradiance, but were approximately 17 MJ kg^{-1} for the dry material, 16 MJ kg^{-1} for the 22% moisture samples, and 8 MJ kg^{-1} for the 38% moisture samples. Using a data reduction method similar to Janssens' for thick fuels, their results are given in Table 208. Minimum flux values for ignition were not specified, however.

Table 208 Ignition of wastes, as a function of moisture content

MC (%)	Critical flux (kW m^{-2})	T_{ig} (°C)	$\lambda\rho C$ (kJ^2 m^{-4} K^{-2} s^{-1})
0	7±2	214±67	0.13±0.10
22	7±2	208±76	0.15±0.13
38	9±2	267±47	0.22±0.10

Water heaters

ELECTRIC WATER HEATERS

Despite the fact that electric water heaters are devices that can draw heavy power (typ. 3.5 to 11 kW), they are rarely a cause of ignition. Goodson[1951] has described the operation of electric water heaters and their possible failure modes. He investigated close to 40 fires which were considered to have possibly been caused by an electric water heater, but did not find a single incident where a detailed investigation supported this hypothesis. He concluded that the only significant probability of ignition involves faults in the branch-circuit wiring or in poor connections of the supply leads at the heater terminals.

GAS-FIRED WATER HEATERS

The most serious fire scenario involving water heaters is when the flame of the water heater serves to ignite gasoline vapors and a flash fire or explosion results. This scenario typically takes place in a garage, but on some occasions, flammable vapors are introduced into a basement, utility room, etc., where a water heater had been installed. According to CPSC estimates[1952], approximately 2000 fires each year result from ignition of flammable vapors by gas-fired water heaters. Gas-fired water heaters are the primary cause for ignition of gasoline vapors in dwellings[1953], accounting for 66% of such cases; the remaining 34% of cases are distributed among a wide variety of causes.

US building codes require that if a gas-fired water heater is placed in a garage, it must be raised 457 mm (18") off the floor. Gasoline tank leaks, fueling operations, and any number of thoughtless actions by occupants can result in gasoline vapors being introduced into the space. Gasoline vapors are heavier than air, and will normally accumulate at floor level. With sufficient stirring, heavy vapors can, of course, be mixed into the entire air space. But spills normally occur near floor level and it is reasonable to presume that significant stirring is not common in most situations. Thus, the building code requirement, while not offering absolute certainty, at least endeavors to minimize the risk. Unfortu-

nately, many home owners do not install water heaters at a code-complying height. Talbott and Beckham[1954] documented full-scale tests performed to determine the effectiveness of the 457 mm requirement. They spilled an unspecified quantity of gasoline from a 2-gallon container and observed that ignition of vapors took place for the unit without the raised legs, but not for the one located so that the burner was 457 mm above the floor. A combustible gas detector also indicated high concentrations at 152 mm and undetectable at 457 mm. Tests were conducted by CPSC[1955] where gasoline was spilled at 0.46 m away from the centerline of the heater and gas concentrations monitored at the location of the pilot flame. The results, shown in Table 209, while not extensive, suggest that even raising the heater as little as 0.15 m (6") improves the chances significantly of avoiding a vapor ignition.

Table 209 Results from CPSC test on gasoline spills close to gas-fired water heaters

Height of heater above floor (m)	Amount spilled (mL)	Results at location of pilot	Conditions
0	450	reached LFL in 2/4 trials	still air
0	2000	reached LFL in 1 trial	still air
0.15	2000	did not reach LFL in 5 trials	still air
0.15	2000	did not reach LFL in 2 trials	forced air ventilation, pilot cover off
0.30	1000	did not reach LFL in 1 trial	forced air ventilation

Following several years of study by CPSC and by industry groups, a standard (ANSI Z21.10.1-2001[1956]) was adopted in 2001 which will require designs that are resistant towards acting as an ignition source for flammable vapors[1957]. The provisions of this standard will be phased in during 2003 – 2005. The earliest such model was already produced in 1999 and comprised a combustion chamber that is sealed, except for a path for incoming combustion air that enters through flame arresters. The design also includes a non-resettable thermal sensor within the combustion chamber that shuts off the gas supply if abnormal temperatures are sensed. Designs that comply with the new standard will also have to make provisions against failure due to clogging from lint, dust, or oil deposits that may accumulate on flame arrester surfaces. Water heaters made to this new standard will generally not require to be installed on raised legs.

In a gas-fired water heater, the combustion system sits at the bottom of the unit. Without additional legs installed, the combustion chamber is raised from the floor by short legs of 70 – 100 mm. If the floor is made of wood particleboard and a leak occurs in the heater, the wood may rot out underneath and the heater drop down to the point that the combustion chamber is contacting the particleboard. Fires have been documented to occur under these conditions, since the bottom of the chamber runs at temperatures much higher than can safely be placed against wood[1958]. Another failure mode that sometimes occurs is when burner orifices become blocked and flames get directed downward instead of up.

Under some circumstances, water heater burner flames may 'roll out' and burn outside the combustion chamber, setting fire to surrounding combustibles[1959]. There are four possible causes of rollout:

(1) Excessive burning within the combustion chamber. This can happen if anything greatly increases the burning rate within the combustion chamber, such as a failure to maintain fuel gas at a suitable pressure. But case histories also are known of rollout due to product defects that cause soot to accumulate within the combustion chamber. When this happens, it is possible for the soot eventually to catch fire *en masse*.
(2) Inadequate air supply for combustion. Commonly, this will occur if the heater is improperly closed in within a small room that lacks door louvers or other means of obtaining combustion air. It can also occur due to blockage of the air ports into the burner. Running the heater in this way will cause serious soot buildup in the flue tube, which may eventually clog. If this happens, sooty yellow flames may roll out of the burner[1960].
(3) Faulty venting. If the burning fuel gas cannot properly move up a vent pipe, flames may leave the combustion chamber by other means.
(4) Negative pressure conditions in the house. A NIST study[1961] documented that negative pressure conditions can cause an absence of upward draft when the burner is first started up, leading to roll-out. A tightly-constructed house can achieve a negative pressure due to action of exhaust fans, furnaces, fireplaces, or similar devices.

A number of heaters have combustion chamber doors designed in such a way as to make it difficult to replace them, once they are removed. Leaving off the combustion chamber doors will not lead to roll-out of flames by itself. But if conditions occur that are conducive to flame roll-out, absence of doors will increase the chances of a roll-out and of possible external ignitions. The NIST study[1961] also documented that some water heater designs are much more prone to flame roll-out than others, although it did not try to identify the reasons for poor performance. Gas-fired water heaters are generally highly reliable appliances, but are sometimes chosen by arsonists desiring to stage an 'accidental' fire. Thus, the possibility of the appliance being deliberately sabotaged, or foreign objects introduced for them to get ignited, needs to be considered by fire investigators.

Excessive combustion, possibly leading to external fire, can be expected if a water heater designed for natural-gas service is hooked up to an LPG supply without making the necessary combustion system modifications. The same factor can of course come into play for any gas-fired appliance. The maximum combustion rate (kilowatts) of an appliance is fixed by its design, while the rate of fuel delivery, in simple domestic appliances, is controlled by an orifice. This flow then is determined by the orifice diameter and the supply pressure (back pressure upon the orifice). For an orifice diameter much smaller than the pipe diameter:

$$\dot{Q} = \Delta h_c \frac{AP}{RT}\sqrt{\frac{2P}{\rho}}$$

where $\dot{Q}$ = HRR (kW), Δh_c = heat of combustion (kJ mol^{-1}), A = orifice area (m^2), P = pressure (Pa), R = 8.314 Pa m^3 mol^{-1} K^{-1}, and ρ = density (kg m^{-3}). If the temperature is kept constant, then the scaling relation for different fuel gases is:

$$\frac{\dot{Q}_2}{\dot{Q}_1} = \frac{\Delta h_{c(2)}}{\Delta h_{c(1)}}\frac{A_2}{A_1}\left(\frac{P_2}{P_1}\right)^{3/2}\sqrt{\frac{M_1}{M_2}}$$

where M = molar mass (g mol^{-1}), and 1 and 2 denote the two fuel gases. Thus, if propane were substituted for methane without changing the orifice size or the supply pressure, the HRR would increase by a factor of 1.54. When expressed in Imperial units, this relation is sometimes called the Wobbe Index.

Welding*

Welding can cause fires by many ignition modes and in each welding incident the factors involved must be analyzed. There are two main heat sources used for welding—gas and electric. Welding can be further subdivided by the type of process, such as joining or cutting, and by material, such as aluminum or steel, and further by the type and size of spatter that is created during the process. Spatter is used here to include all of the material that is created during the welding process and includes incandescent particles of base material, the filler material, slag or other inert materials, and pieces that may be cut from the object. Each has its own specific hazards which will be generalized in this section. The discussion is based primarily on common gas torch and electric stick welding techniques and does not include specialized welding processes such as plasma arc, TIG, MIG, laser, explosive, friction, magnesium cutting bars, spot, or submerged arc.

Because the function of welding is to melt the parent material, all welding processes will be competent ignition sources to flammable mixtures at the point of welding since it generally involves open flame or an open arc. Numerous examples of explosions caused by cutting or welding on containers that had previously held flammable material can testify to this hazard. Sometimes welding is done in a mixture above the UFL, for example to repair natural gas leaks. The effect of an inert gas local atmosphere (cone) used in MIG or TIG welding has not been specifically tested but the presence of incandescent spatter that exits the gas cone would indicate that an ignition source is present.

Direct ignition of combustible materials in contact or proximity to the heated base material is common and is seen in shipboard fires. It is common to see steel glowing red on the back side of a bulkhead, indicating temperatures in excess of 600ºC. Procedures to minimize fires are specified in numerous standards and codes and include the removal of combustibles, direct observation of the materials including the opposite side and fire watches intended to suppress delayed ignition. Most fire watch requirements are for 30 minutes but situations involving thick materials with high heat input or materials that are prone to smoldering may require longer observation times. Investigation of these fires should include determination of the orientation, thickness and type of base materials, the type and size of the filler material (rod or wire) and the settings on the heat source such as amperage, range, polarity, voltage, speed, pressure, flow, and other factors specific to the welding equipment. In some cases the parent material, ignited materials and welder have been secured for laboratory or *in-situ* testing with instrumentation to determine the exact temperatures reached.

Spatter produced from the cutting process probably causes more fires. With gas cutting, commonly utilizing propane or acetylene in the US, steel is heated to a high temperature, at which time a high pressure stream of oxygen is directed onto the preheated metal. The resulting oxidation of the steel melts the adjacent material which is then blown away and also helps keeps the process continuing. The oxygen pressure is a function of the tip type and the material thickness and generally ranges from 1.3 to 10 atm gauge. The spatter that is produced can contain drops of molten steel as large as 8 mm. With electric arc cutting, several processes can be used. Electrodes with a special coating create a directional arc jet that will melt the material and blow it away from the electrode. Or, a carbon rod can be used with an air jet in a special holder in a process called air-arc. The arc is struck and the high pressure (5.4 – 6.8 atm gauge) air jet blows the molten material out of the arc. When cutting, pieces of base material can be produced that may weigh in excess of 500 g and be cherry red. Typical parts in the field include bolts, nuts and rivets and would be extremely competent ignition sources. Characteristics of welding slag are discussed in Chapter 11.

WHOLE WOOD

PROPERTIES OF WOOD AND ITS DEGRADATION AND COMBUSTION

The density of natural wood is highly dependent of the species, the growing conditions, the part of the tree from which the timber was taken, and the moisture content. Very roughly, density* ranges from 300 to 550 kg m^{-3} for common woods, but some rare tropical species exceed 1000 kg m^{-3}. Density is best determined by actually weighing a specimen, since there is a fair bit of variability within each species. Several sources exist[1962,1963] where densities are tabulated for a wide range of species. The thermal and diffusional properties of wood are highly anisotropic (different in different directions): the main permeability is through the end-grain and not through side/longitudinal grain.

The elemental composition of wood, by mass, is 47 – 53% C, 40 – 44% O, 6% H, 0.1 – 0.2% N, and 0.1 – 0.6% total for the trace amounts of various other elements[1964]. The heat capacity of wood can be represented by:

$$C = \frac{0.1031 + 0.003867\,T + 4.19M}{1+M} + \left(0.02355T - 1.32M - 6.191\right)M$$

where C = heat capacity (kJ kg^{-1} K^{-1}); M = moisture content (--), expressed as a fraction (not percent) of dry weight; and T = temperature (K). For charred wood, reported values[1965] range from a constant C = 1.0 to a much higher, temperature-dependent expression:

$$C = 1.39 + 0.00036\,T$$

The thermal conductivity of wood in the direction perpendicular to the grain (in either the radial or the tangential direction) can be expressed as:

$$\lambda = S\left(0.1941 + 0.4064M\right) + 0.01864$$

where λ = thermal conductivity (W m^{-1} K^{-1}) and S = specific gravity (--). The latter can be taken as roughly = ρ/1000, where ρ = oven-dry density (kg m^{-3}).

For room-conditioned wood, a good fit to experimental data is obtained by[1966]:

$$\lambda = (0.195\rho + 25.5)/1000$$

The thermal conductivity in the direction along the grain is about 1.8 times greater than in the perpendicular direction. For charred material,

$$\lambda = 0.67S - 0.071$$

The thermal diffusivity α is defined as:

$$\alpha = \lambda / \rho\, C$$

But since thermal conductivity is roughly proportional to density, the thermal diffusivity for woods is almost independent of species and density; values of 1.4 – 1.8 × 10^{-7} m^2 s^{-1} are typical[1981]. Some more detailed expressions than the above, including shrinkage and density changes, have been given by Janssens[1967] and by Yuen[1968].

The surface of wood is not opaque to thermal radiation, but, rather, a certain amount of radiation is absorbed in depth[1969]; the property of non-opaqueness is called 'diathermancy.' Gardon measured the diathermancy of two wood species across the visible spectrum[1970]. The values of the effective in-depth absorption coefficient were progressively smaller at longer wavelengths, dropping to 1.3 – 4.5 mm^{-1}, depending on the species, at a wavelength of 0.7 μm. For most accidental ignitions, the wavelengths in the infrared will be of primary importance, but infrared diathermancy of wood has been less studied. A single graph by Gardon shows values of ca. 1.0 mm^{-1} for 0.7 – 1.3 μm, and ca. 3.5 mm^{-1} for 1.4 – 1.9 μm. Russian researchers[1971] have reported a coefficient of 4.0 – 5.0 mm^{-1} for a radiant source at 4500ºC, and values of 2.5 – 4.5 mm^{-1} at a wavelength of 0.7 μm. The effects of diathermancy on the ignition properties of wood are generally ignorable, except perhaps in the case of ignitions from nuclear weapons[1972].

Timber is relatively light-colored and, consequently, the absorptivity is 0.3 – 0.4 in the visible spectrum[1970]. Accidental ignitions, however, commonly involve radiation that is primarily infrared, not visible. A typical value of the absorptivity of a virgin wood surface for infrared radiation is 0.76, but this reaches close to 1.0 at the moment of ignition; thus it is recommended that a value of 0.88 be used for modeling the ignition of wood[1252]. Because of the surface absorptivity changes with prolonged exposure, accurately separating the effects of absorptivity from in-depth absorption effects would not be easy.

Chemically, the main components of wood are cellulose, hemicellulose, and lignin. In addition, wood contains lesser amounts of extractives (substances in wood, not an integral part of the cellular structures, that can be removed by solution in hot or cold water, ether, benzene, or other solvents that do not react chemically with wood substances), mineral matter (reported as 'ash' in chemical analysis), and water. The chemistry of wood's thermal degradation (pyrolysis) and self-heating is surprisingly poorly known and controversial. A multitude of reactions occur, some of them competing or only occurring under certain conditions of heating rate or specimen temperature. The kinetics of the thermal degradation of wood has been studied by numerous re-

* The density of wood, of course, depends on its moisture content. In the wood industry, *specific gravity* is often reported instead of density using a peculiar definition: $S = \frac{\text{oven-dry mass}}{\text{actual volume}} \times \frac{1}{1000}$. Since wood shrinks when dried, the consequence is that S quoted at moist conditions is a slightly lower number than for oven-dry conditions. True density, on the other hand, increases with increasing moisture content. The wood industry also uses the equally peculiar 'basic density,' which is the same as S, but without the factor of 1000.

Table 210 The results of exposure of matchstick-sized wood samples to elevated temperatures for long periods

Temp.	Time (days)	Condition
107ºC	1050	light chocolate color
120ºC	1235	brittle, dark-chocolate color
140ºC	320	lost 45% of weight, became like charcoal
150ºC	165	lost 65% of weight, became like charcoal

searchers. It is quite clear that a single, global expression for reaction kinetics does not capture the rudiments of the chemistry. In an early study, Akita[1973] showed that an effective value of activation energy is determined as 105 kJ mol^{-1} if temperatures below 400ºC are studied, $E \approx 75$ kJ mol^{-1} at 400 – 470ºC, and $E \approx 54$ kJ mol^{-1} at 470 – 720ºC. Studied on the self-heating behavior of wood in finely divided form (see below) show $E \approx 100$ kJ mol^{-1}; but studies on the pyrolysis of whole wood[1974] generally show $E \approx 125$ kJ mol^{-1}. Apart from the basic oversimplification in representing the degradation by a single-step, global kinetics expression, possibly the higher E for whole-wood heating implies that is more difficult to pyrolyze wood when access to oxygen is poor, as it is in slab-form samples.

In a comprehensive review of wood degradation, Antal[1975] points out that there are several tiers of competing degradation mechanisms, which makes any engineering treatment very difficult without making gross, questionable simplifications. Vovelle et al.[198] proposed a simplification where there are two simultaneous reactions (essentially, one representing cellulose and the other the remaining wood components) and two mass loss regimes, the first from virgin material down to about 40% mass, with the second continuing to the end. The second mass loss regime, of course, is not relevant to ignition studies. For the first regime, cellulose is taken to show a first-order reaction, with $E = 250$ kJ mol^{-1}, and $A \approx 10^{19}$. The non-cellulose component reacts in a zero-order reaction, $E = 84$ kJ mol^{-1}, and $A \approx 10^{4}$. Even though such a two-reaction scheme is greatly simplified from reality, it still would not be trivial to make computations using it. Furthermore, even though more realistic than a representation using a single, one-step chemical reaction, the Vovelle model is grossly simplified, and it is not clear what its limits of validity might be. Russian researchers[1976] have concluded that the pyrolysis of wood and cellulose is an autocatalytic process and provided kinetic constants pertinent to a first-order autocatalytic reaction. Wichman and Oladipo[1977] reviewed several schemes and concluded that the 3-step kinetics of Broido[1978] offers a reasonable balance between simplicity and tractability.

When wood burns, there are two different mechanisms of oxidation. During initial combustion, volatiles are pyrolyzed out of the wood and burn in the gas phase, with a flame. Once this process is finished, a char still remains. The char then oxidizes heterogeneously, showing surface glowing, but not flame. There is an intermediate period of time when both processes occur. The gross heat of combustion of whole wood is around 19.3 to 21.6 MJ kg^{-1}; the heat of combustion of the volatiles is around 16.4 to 18.3 MJ kg^{-1}, while for the char[1979] it is around 30 MJ kg^{-1}. The gross heat of combustion is not realized in fire exposure, and is generally around 10 – 15 MJ kg^{-1} during early burning, approaching 30 MJ kg^{-1} when charring is nearly complete.

It is sometimes suggested[1980] that wood chars upon reaching a specified temperature, for example, 288ºC. But such a simplification will be valid only over limited circumstances—typically only high heat flux exposures, such as from a fire resistance test furnace, are considered. Even then, the demarcation between charred and non-charred material is often very gradual and indistinct[1981]. Long-exposure studies have shown that degradation first becomes visible when the wood (not the environment) reaches a temperature around 100ºC[1618]. McNaughton at the Forest Products Laboratory exposed small (3 × 6 × 76 mm) wood wedges to slightly elevated temperatures for long periods[1982]. His results are shown in Table 210. At the same institution, MacLean[1983] exposed woods of various types to high-humidity environments. He reports that specimens showed "very pronounced" charring after long heating periods at ca. 93ºC. Unlike McNaughton, however, he did not further specify the resulting color. Comparing the results of MacLean to those of McNaughton, the conclusion could be drawn that even lower temperatures suffice to cause charring in high-humidity environments than in normal ones. This was, in fact, a conclusion explicitly noted by MacLean, although without additional quantitative comparison.

In general, the relation between temperature, color, and state of degradation of wood is time-dependent. In short-term heating of white pine shavings, Vandaveer found the first color change at 170ºC, with the wood turning light brown at 190ºC and dark brown at 260ºC. White and Nordheim[1984] consider that wood has charred when it first attains a temperature of 288ºC. Kubler concluded[1619] that when exposed over many years, even moderate temperatures around 120ºC suffice for the decomposition of all wood components; on the other hand, wood heated rapidly under exclusion of oxygen reaches relatively high temperatures prior to disintegrating to the charcoal stage. Regardless of the time scale, if wood reaches temperatures above 300ºC, it is inevitably carbonized and black[1964]. It is important to realize that the above experimental results only deal with tiny samples for which any self-heating effects are limited. Thus, for such conditions, around 120ºC is expected to be the minimum temperature at which dark char would be found. If the size of the member is large enough so that self-heating cannot be ignored, the effective interior temperatures will rise to a higher value than is the externally imposed temperature. Thus, it will be possible to find dark char in larger members, even though externally they were heated to less than 120ºC.

Table 211 Summary of ignition temperature results for wood

Year	Investigator	Specimen size	Ignition temp. (ºC)		Comments
			Piloted	Auto-ignition	
1887	Hill[254]	0.5-15 g		**220–300**	measured air temperature near sample
1910	Bixel, Moore[263]	35 mm ?		200–250	measured oven temperature; scant details
1922	Banfield, Peck[1985]	50×50× 200 mm		302–308	measured surface temperature
1934	Brown[189]	1–5 g		**220–250**	measured oven temperature; tiny samples; unsound ignition criterion
1936	VanKleeck[1986]	chips		**235**	measured specimen temperature; unsound ignition criterion
1947	NIST[1987]	shavings		**228–264**	softwood shavings in test tube; criterion—glowing or flaming
1949	Graf[997]	7–13 g		**232–245**	measured oven temperature; tiny samples; unclear ignition criterion
1949	Angell[1988]	13×19v 51 mm		204	measured gas temperature close to specimen
1950	Fons[255]	2-9 mm cylinders		343	measured oven temperature; solved inverse problem
1958	Narayanamurti [1989]	?	228		measured oven temperature
1959	Thomas et. al. [1990] (based on 1915 data of Prince[1991])	32v32v 102 mm	210		measured oven temperature; solved inverse problem
1959	Akita[1973]	20×20× 1.8 mm	450	489	measured oven temperature; solved inverse problem
			< 350		measured oven temperature only
1960	Simms[1992]	8 mm ø		545	calculated from correlation; error found in calculations by Koohyar
1960	Moran[1993]	50×50× 6.4 mm		255	at flux = 25 kW m^{-2}; measured surface temperature
1961	Patten[1994]	3 g shavings	**260**	**260**	measured oven temperature (Setchkin test)
1961	Buschman[1995]	57×57× 8 mm	369		calculated from correlation; fluxes 14.3 to 37.2 kW m^{-2}
1964	Shoub, Bender[1626]	920×920 mm		254	measured surface temperature
1964	Tinney[1996]	≥6 mm ø		350	measured oven temperature
1967	Simms, Law[1997]	76×76× 19 mm	380		calculated from correlation
1967	Muir[1998]	80 × 160 mm	364-384		measured surface temperature; flux range 15 – 25 kW m^{-2}
1967	Koohyar[1981]	100×100 × 12-19 mm	361	402	measured surface temperature; flux range 18 – 35 kW m^{-2}
1969	Melinek[1999]	100×100 ×13 mm	353	382	calculated from correlation
1969	Jach[2000]	few grams		**260–290**	measured oven temperature
1970	Smith[1609]	75×75× 19 mm	350	413–714	temperatures measured by optical pyrometry; autoignition values dubious
1983	Atreya[2001]	64 mm ø × 19 mm	370		temperatures measured, but below surface; flux = 18 kW m^{-2}
			350		temperatures measured, but below surface; flux ⌑ 30 kW m^{-2}
1986	Atreya et al.[2002]	75×75 ×19 mm	330–405		temp. measured, but below surface

? – denotes unknown measurements

Table 211 - continued Summary of ignition temperature results for wood

Year	Investigator	Specimen size	Ignition temp. (ºC)		Comments
			Piloted	Auto-ignition	
1988	Abu-Zaid[2003]	150×75 ×37 mm	420		forced-air flow; temp. measured but below surface; flux = 18.5 kW m^{-2}
			350		forced-air flow; temp. measured but below surface; flux > 25 kW m^{-2}
				530	flux = 40 kW m^{-2}
1991	Janssens[1252]	100×100 ×17 mm	300–364		surface temp. measured; fluxes 25 to 35 kW m^{-2}
1992	Li, Drysdale[2004]	64×64 ×18 mm	411–497		temp. measured but below surface; flux < 20 kW m^{-2}
			353–397		temp. measured but below surface; flux > 20 kW m^{-2}
1993	Masařík[2005]	2.5 g	**220–240**		tested wood fiberboard; measured oven temperature (Setchkin test)
1996	Fangrat[2006]	100×100 mm	296–330		surface temp. measured; fluxes ¤ 25 kW m^{-2}
1997	Moghtaderi[2007]	100×100 ×19 mm	332		temp. measured but below surface; at 20 kW m^{-2}
			297		temp. measured but below surface; at 60 kW m^{-2}
2001	Boonmee[2008]	40×40 ×40 mm		650	measured w. infrared camera; at 40 kW m^{-2}
				400	measured w. infrared camera; at 75 kW m^{-2}
? – denotes unknown measurements					

In terms of radiative heating, if the heat flux is less than 4 kW m^{-2}, then lengthy exposure (hours) can occur without darkening of the surface[2009]. Conversely, at 12 kW m^{-2}, the surface becomes charred black in about 10 min.

The pyrolysis of wood is, to a certain extent, oxidative. Moghtaderi[2010] has provided data on the mass loss rate of wood specimens prior to ignition. An oxygen-concentration effect is seen, which implies an oxidative reaction of the solid.

IGNITION TEMPERATURE OF WOOD

The ignition temperature of wood was recently surveyed by Babrauskas[2011] and this section summarizes the review. The topic addressed here is ignition during short-term heating. Slow heating over protracted time periods (months, years) is treated separately below. As can be seen in Table 211, studies on the ignition temperature of wood go back well into the 19th century and have continued until the present time. The spread of data is clearly enormous. Excluding one value, the results in Table 211 span 210 – 497ºC for piloted ignition and 200 – 510ºC for autoignition. Babrauskas considered the following reasons that might account for the spread:

- the definition of ignition that is used
- piloted vs. autoignition conditions
- the design of the test apparatus and its operating conditions
- specimen conditions (e.g., size, moisture, orientation)
- species of wood.

The design of the test apparatus may have a significant influence. The majority of devices fall into one of two types: (1) a furnace into which a small specimen is bodily plunged; or (2) a specimen sitting in the open air and being radiatively heated, e.g., the Cone Calorimeter. But this basic division is confounded by the fact that there is a preferred specimen type for each test: specimens of only a few grams are normally put into a furnace that exposes the whole specimen bodily, while specimens placed in front of radiant heaters are typically on the order of 100 g and of sizeable dimensions in at least two directions. The results from Type 1 tests are indicated in **bold** in Table 211 while Type 2 are underlined.

An analysis of the results indicated that disparities arise because Type 1 tests are normally conducted at heat fluxes near the minimum flux for ignition, while Type 2 tests are normally conducted at higher fluxes. But essentially all of the data become consistent when it is realized that if a wood specimen is ignited under external heating barely sufficient to ignite it, it will ignite at ca. 250ºC regardless of the type of heating arrangement. The data also indicate the same 250ºC value is found irrespective of whether a pilot is used or not. The reason is because ignition at minimum-flux heating is always initially a glowing ignition, and only later, if at all, it may transition to flaming*.

By comparison, materials that are not susceptible to glowing ignition (e.g., thermoplastics), show a substantially

* This characteristic is also shared with other combustibles that are capable of glowing, but available data on this point for most other combustibles are sparse.

Table 212 Summary of ignition temperature results

	Flux		
	Minimum	**Low**	**Medium**
Ignition type	glowing	glowing or glowing/flaming	flaming
T_{ig} (ºC), piloted	250	350 – 400 peak, lower for fluxes close to minimum.	300 – 310 hardwoods 350 – 365 softwoods
T_{ig} (ºC), autoignition	250	no data	400 ??

lower T_{ig} in the Setchkin furnace for piloted than for autoignition conditions. The glowing ignition temperature must not be confused with the temperature of the glowing spot. In a glowing ignition, a glow begins at one spot and very quickly reaches red-hot conditions (over 600ºC). This high temperature is not the glowing ignition T_{ig}; instead the latter must be determined either by a thermocouple reading just before a steep jump takes place or by a thermocouple on the same surface but away from the spot of initial glow.

As the heat flux is raised above the minimum value, there is a certain flux range (whose limits have not been sufficiently well studied thus far) where the ignition temperature rapidly increases with only small increases in heat flux. Moran's data are instructive here. Although intermediate data were scattered, as the flux was raised from 25 kW m^{-2} to 29 kW m^{-2}, the ignition temperature rose from 255ºC to 301ºC while the ignition time dropped by 33%. The 300ºC value is significant, since wood pyrolysis involves competing mechanisms, with temperatures under 300ºC leading largely to charring, while over 300ºC gasification being favored[2012]. Thus, if heating conditions are such that the material does not exceed 300ºC, a glowing ignition is favored.

At higher heat fluxes, 2-stage (glowing, followed by flaming) ignitions are not found and specimens, instead, ignite directly in a flaming mode. For piloted ignition, $T_{ig} \approx 300$ – 350ºC adequately represents most of the results from most of the studies. Janssens[1252] noted that the range can be further shrunk by considering the slight but systematic effect of *wood type*. His results for oven-dried specimens were:

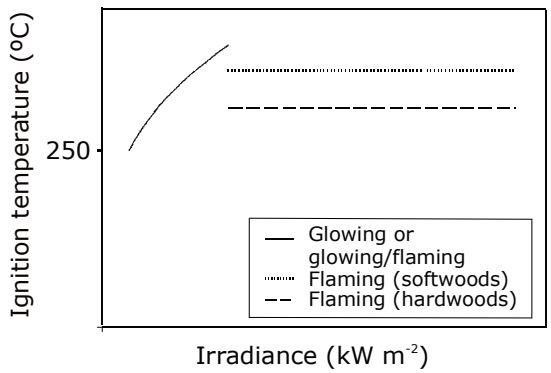

Figure 117 Summary of ignition temperature trends for piloted ignition of wood

hardwoods 300 – 311ºC; softwoods 349 – 364ºC. The effect is attributed to the differences in wood composition between hardwoods and softwoods. As indicated below, hemicellulose ignites at the lowest temperature, cellulose higher, and lignin higher yet. Compared to hardwoods, softwoods have a smaller fraction of hemicellulose and a higher fraction of lignin, thus accounting for their higher T_{ig}.

Concerning *moisture*, as would be expected, at the minimum flux condition Moran found no difference in T_{ig} between oven-dried and room conditioned specimens. In the medium flux regime under piloted conditions, Janssens[2013] concluded that T_{ig} rises by 2ºC for each percent of moisture content increase. This will normally be insignificant for practical moisture contents. *Grain orientation* (i.e., along-grain versus end-grain exposure) may also have an effect on T_{ig}, but good enough data are not available to explore the issue. Almost all existing experimental data deal with along-grain exposures, which are also common in accidental fires.

The basic ignition temperature conclusions are summarized in Table 212 and Figure 117. The data of Koohyar, Li, and Boonmee suggest that the dividing line between 'low' and 'medium' fluxes may be around 22 kW m^{-2} for piloted ignition and 33 – 40 kW m^{-2} for autoignition, but the scatter is quite large. The survey indicated that very few data are available for high fluxes (over 80 kW m^{-2}), thus no conclusions at all are drawn concerning ignition temperatures in that regime.

IGNITION FROM RADIANT HEAT FLUX

Experimental results on piloted ignition

In Chapter 7 Janssens' method for correlating results obtained from radiant-heating tests on thermally-thick substances was presented. It entails plotting the ignition time raised to the –0.55 power on the y-axis and the external imposed heat flux (irradiance) on the x-axis, and is illustrated with Janssens' own data in Figure 118. For the example wood species studied, the equation describing the data plot is:

$$t_{ig}^{-0.55} = \left[\dot{q}''_e - \dot{q}''_{cr}\right] / B_{ig}$$

where the two material constants are $\dot{q}''_{cr}$ = 9.3 kW m^{-2} and B_{ig} = 201 kW m^{-2} s$^{+0.55}$. An equation of this type is specific to a particular species of wood, tested under one set of conditions (e.g., orientation, moisture, etc.). The question then

becomes, is it possible to obtain an equation which would be generally predictive of the piloted ignition of wood, without having to have test results for a particular species? Koohyar[1981] studied this question as early as 1967, but this was prior to the availability of current-day equipment for making radiant-heating ignition tests. Babrauskas[2011] reviewed the question recently, and his results will be summarized here.

Since different wood species differ mostly in the values of density and thermal conductivity, it was considered that these are the primary factors to be treated. Density is easy to measure for any specimen, but thermal conductivity is not. Fortunately, within a given chemical family, thermal conductivity is generally a direct function of density. The other variable of significant importance is moisture. To make an accurate treatment of moisture, the extremes of green wood to oven-dried wood would have to be considered. Green wood can have MC > 100%, but there are no available ignition data on it, with the literature containing data only for oven-dried specimens and ones that are equilibrated to room conditions. For room-conditioned wood specimens, MC is commonly in the 9–12% range, which is actually close to zero, if the whole range of possible MC values were considered. Thus, correlations were sought on the basis of capturing density, moisture, and orientation (horizontal or vertical) effects, with data available on densities over the range 170 – 850 kg m^{-3}. A density effect was statistically identified, but moisture and orientation effects were swamped by data scatter. To eliminate systematic effects of test apparatus, only tests run in the Cone Calorimeter were analyzed. Based on 254 data points, a correlation was evolved:

$$t_{ig} = \frac{130\rho^{0.73}}{\left(\dot{q}''_e - 11.0\right)^{1.82}}$$

where ρ = density (kg m^{-3}), $\dot{q}''_e$ = heat flux (kW m^{-2}), and t_{ig} = ignition time (s). An 0.73 power for the density factor seems low from a theoretical viewpoint, but Kelley[2014] also found a low value, 0.9 in his case; Harada[2015] used 1.0, but with an offset, i.e., $t_{ig} \propto \left(\rho - 105\right)^{1.0}$. The goodness of fit is shown in Figure 119. The root-mean-square error of the predictions is 64%, which indicates that predicting times to ignition can only be done semi-quantitatively, but this must also be placed in the context that experimental data went from 2.5 to 4200 s, or a range of 1 : 1680. A close inspection of the figure also reveals that below about 15 kW m^{-2} the points deviate systematically above the straight line. This is as might be expected, since the theory is based on a thermally thick material, and wood specimens 12–25 mm thick no longer behave in a thermally thick manner when heated for a long time. Recently Harada[2016] offered another prediction method based on a similar concept of relating species effects solely to density. Using his method (and correcting for a missing factor of 10^6), however, the rms error is 77%.

The *minimum flux* for ignition is often a quantity of interest. In 1965, McGuire[2017] suggested that this value can be taken as ca. 12.5 kW m^{-2} for most wood materials apart from low-density fiberboard. A value of 12.5 kW m^{-2} has subsequently been used for design purposes in many countries. This is indeed the value that is customarily obtained in the Cone Calorimeter and in other test methods where the time allotted for observation of ignition is 10 – 20 minutes. But lower values have been found, although not widely publicized. Spearpoint[2018] recently conducted Cone Calorimeter tests of longer duration. For side-grain exposures, Spearpoint found $\dot{q}''_{\min}$ = 12.5 kW m^{-2} for redwood and somewhat less than 12 kW m^{-2} for maple (Figure 120). Ignition of maple at 12 kW m^{-2} required 4200 s. However, since the minimum flux needed for piloted ignition cannot be higher than that need-

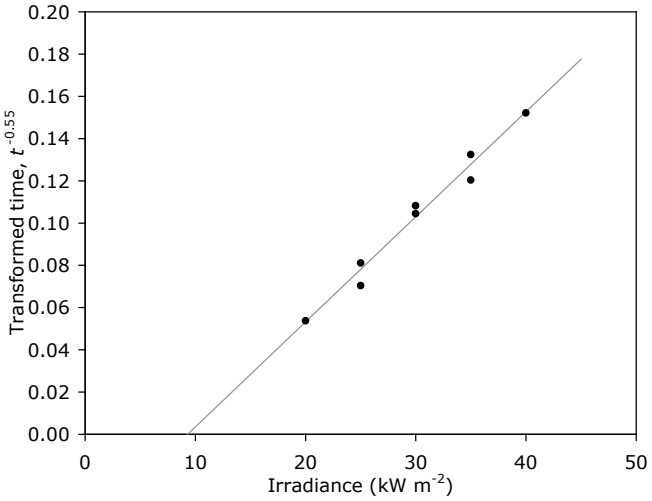

Figure 118 Janssens' piloted ignition results for Blackbutt, oven-dried, vertical orientation

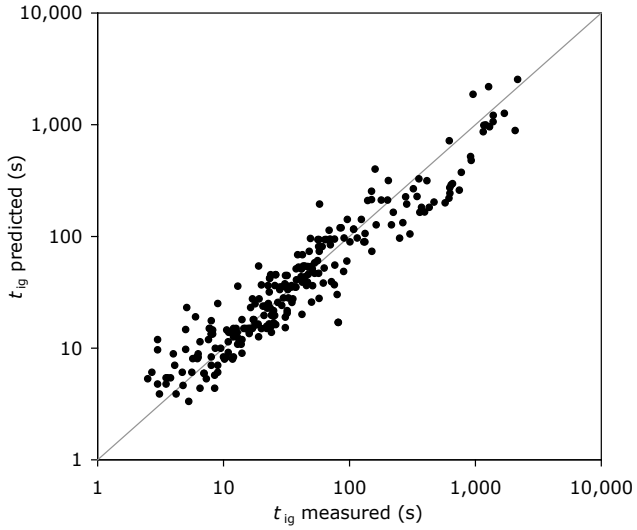

Figure 119 Goodness of fit for equation for estimating the piloted ignition time of wood

ed for autoignition, and the latter value (from Shoub and Bender, as discussed above and further discussed below) has been reported as 4.3 kW m^{-2}, the minimum flux for piloted ignition can also be taken as being approximately 4.3 kW m^{-2}.

Grain orientation has a strong effect on ignition. Ignition data for wood are normally presented with heating being in the perpendicular-to-the-grain ('side grain') direction, since end grains are not so commonly exposed to early ignition in building fires. However, as noted above, the thermal properties of wood are decidedly anisotropic, and this influences ignition. In his tests, Spearpoint also examined end-grain ignitions. At high fluxes, due to the greater thermal conductivity, the end-grain ignitions, not surprisingly, took longer (Figure 120); however, at low heat fluxes, the results were reversed. This is possibly connected in some way with the fact that end-grain surfaces tend to have an intrinsic irregularity, but the exact reason has not been elucidated; possibly, this could also be related to the nature of the specimens tested at the low fluxes, which was a sandwich laid up of four 12.5 mm layers. For end-grain ignition of maple, the lowest flux at which ignition occurred was 8 kW m^{-2}, with no ignition at 7 kW m^{-2}, making $\dot{q}''_{\min}$ = 7.5 kW m^{-2}. The minimum flux for end-grain ignition of redwood was not fully explored, but was found to be below 9 kW m^{-2}. For ignitions occurring at fluxes below 10 kW m^{-2}, a glowing spot was first seen to occur on the surface (Color Plate 141), with the glowing spot later catching flames. Unlike at higher fluxes, after this first flaming occurred, flames spread only slowly over the rest of the exposed surface. The above results would suggest that, for end-grain ignition, $\dot{q}''_{\min} \approx 7.5$ kW m^{-2}. However, the true value is presumably lower, since his finding was that a lower flux suffices for end-grain than for side-grain ignition, and 4.3 kW m^{-2} suffices for side-grain ignition of wood products (see below).

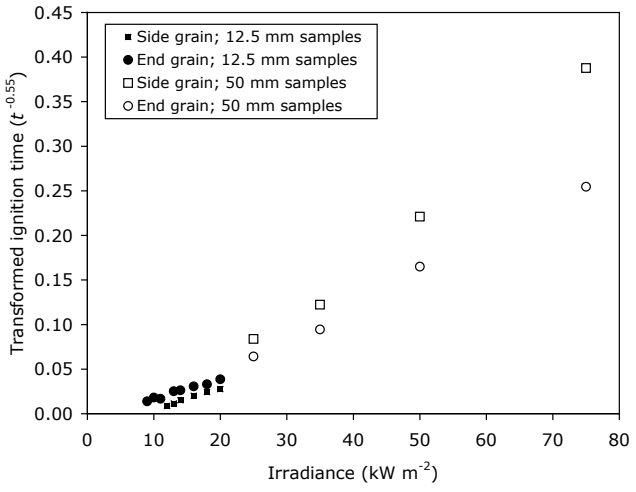

Figure 120 Grain-orientation effect on the piloted ignition of horizontal Douglas fir specimens

Earlier, Vyas[2019] studied the piloted ignition of wood, when exposed to the end grain. In his study, he determined that for fluxes in the range 37 – 109 kW m^{-2}, the ignition times in the end-grain orientation were 2× those found for side-grain exposure. He did not, however, investigate the value of the minimum flux for ignition.

Generally, 'piloted ignition' means the presence of a flame or a spark in the gas phase where pyrolysates accumulate. But it is also possible to apply a gas flame directly onto a surface as an *impinging pilot*, in which case much less radiant heating is needed to achieve ignition since a local heat flux concentration is created. An old FRS study[2020] showed $\dot{q}''_{\min}$ = 5 kW m^{-2} for Western red cedar and Douglas fir. No other published studies exist. Apart from surface-applied pilots, both the type of pilot and its location can affect ignition times. Several studies[2021,2022] produced limited data—more studies would be needed to quantify trends reliably. It is also possible to heat a wood surface by applying a relatively-uniform 'wall of flame' onto it, and this is discussed later.

Experimental results on autoignition

Unlike piloted ignition, autoignition of wood under radiant heating conditions has been studied by only a few researchers, most notably Simms, who conducted various experiments at FRS in the 1950s and '60s. In a 1952 study, he tested 6 different species of wood using 19 mm thick specimens[2023]. The results, including the correction for a 20% flux mis-calibration[2024], are shown in Table 213. In a 1961 study[2025], he reported an enormous value of up to 117 kW m^{-2} for autoignition of blackened oak and cedar specimens. In a 1967 study[1997], he reported minimum fluxes for piloted ignition that were similar to the corrected 1952 values, but autoignition values reported were quite a bit higher, being ca. 40–50 kW m^{-2}. In his 1961 study, Simms noted that a draft strong enough to be turbulent was helpful in reducing the $\dot{q}''_{\min}$. This was evidently a gas-phase effect, but even today there is no systematic knowledge on this topic. In another study[1992], Simms concluded that the quantitative effect of the rather small exposure size of 8 mm is nearly negligible, so presumably the enormous $\dot{q}''_{\min}$ values in the 1961 study were mainly due to insufficiently long test time. Moran[1993] examined the ignition of vertical panels of 6.4 mm thick ponderosa pine using an electric radiant panel and found $\dot{q}''_{\min}$ = 25 kW m^{-2}. Shields et al.[2021] examined the autoignition of Sitka spruce in the Cone Calorimeter and in the ISO 5657 apparatus. They exposed specimens in increments of 10 kW m^{-2}, so their results were only approximate. Since the heater arrangements have some similarity, it is not clear why the values obtained in the Cone Calorimeter and the ISO 5657 apparatus were not closer. Shields' data do illustrate that it is much more difficult to achieve autoignition in the vertical orientation than in the horizontal orientation. The above studies were all of less than 20 minutes duration. Boonmee[2008] tested vertically-oriented redwood

Table 213 Minimum flux for autoignition of wood, as reported by various researchers

Study	Orient.	MC (%)	Draft	Specimen size exposed	Max. time of test	$\dot{q}''_{min}$ (kW m^{-2})	Notes
Lawson, Simms (1952)	V	0	N	50 × 50 mm	20 min	29–33	
Simms (1961)	V	0	Y	8 mm ø	14 s	75–100	blackened surface
			N		18 s	117	
Simms, Law (1967)	V	0	N	76 × 76 mm	70 s	46	
				150 × 150 mm	79 s	42	
Moran	V	0	Y	50 × 50 mm	9 min	25	
Shields et al.	H	≈10	N	100 × 100 mm	96 s	30–40	
	V				59 s	40–50	
	H	≈10	N	165 × 165 mm	12 min	< 20	ISO 5657 test
Boonmee	V	6	N	100 × 100 mm	22 min	38	but lower for glowing-only ignition mode
Shoub, Bender	V	≈10	N	920 × 920 mm	3.9–5.2 h	4.3	

samples in the Cone Calorimeter and found a minimum flux of 34 kW m^{-2} for producing flaming ignition in the side-grain orientation and 38 kW m^{-2} for end-grain. Glowing-only ignitions were possible at lower fluxes, but he did not explore the limit. Only the study by Shoub and Bender[1626] involved exposures extending into hours. They used an electric radiant panel operating at an effective black-body face temperature of 273ºC and producing a heat flux of 4.3 kW m^{-2} at the center of the specimen, and lower heat fluxes at the edges. While they did not test any whole woods, they tested 13 mm plywood. It ignited at the 4.3 kW m^{-2} flux, but required waiting over 5 hours. In their tests, they also documented that the face temperatures of the specimens in some cases reached temperatures higher than that of the radiant source, indicating that self-heating of the material was important and that assuming an inert solid would not be appropriate. The conclusion is that wood will autoignite at about 4.3 kW m^{-2}, if exposed for hours, rather than minutes. For short-term exposures, a value of 20 kW m^{-2} perhaps best captures the research results. Experiments should be made to replicate Shoub and Bender's findings, but the value appears to be reasonable. If the autoignition temperature of wood at the minimum flux is taken to be 250ºC, then a simple estimate can be made by assuming that for the surface to be brought up to 250ºC, it must be irradiated by a heater which is at least at a temperature of 250ºC. The radiant heat flux coming from an infinitely large black body at 250ºC is $= 5.67 \times 10^{-11} (250 + 273)^4 = 4.2$ kW m^{-2}. Thus, an experimental value of 4.3 kW m^{-2} is plausible, since the simple estimate ignores the contribution of both self-heating (which will lower the needed flux) and convective cooling (which will raise it).

At any given irradiance, if ignition occurs under both autoignition and piloted ignition conditions, it is evident that ignition times for the latter will be shorter (unless the pilot is badly placed). A tractable theory, such as Janssens', models only the solid phase, so the presumed conclusion would be that ignition times do not change. A more refined point of view would be to assume that for autoignition, heating up the solid to the same temperature suffices as for the piloted case, but that afterwards a delay time must be added to account for gas-phase events. A theory of this sort has not been developed, however. Experimentally, even though there is a great deal of scatter the results of Shields et al. can be used to derive an equation:

$$t_{ig}\ (autoignition) = \left(2.86 - 0.0172\, \dot{q}_e'' \right) \times t_{ig}\ (spark)$$

Thus, for example, at a flux of 25 kW m^{-2}, under autoignition, ignition times can be expected to be 2.43× those for the spark-ignition case, while at 50 kW m^{-2} the factor drops down to 2.0×. Since the highest experimental flux was 70 kW m^{-2}, the rule should not be extrapolated to greatly higher fluxes. Also, due to the data scatter, the guidance is only semi-quantitative.

Other radiant ignition effects

The minimum heat flux needed for wood to stay ignited (*sustained flaming*) has been studied very little. Babrauskas[2026] examined the piloted ignition of 18.3 mm thick red oak specimens in the Cone Calorimeter. At an imposed heat flux of 20 kW m^{-2}, all specimens burned essentially to completion (> 90% mass lost) when tested in the horizontal orientation. But when tested vertically, two out of three specimens self-extinguished in the middle of the test. Mass loss values at the end of the test were 30%, 38%, and 78%. In a radiant test apparatus, the heat flux received by the specimen after ignition includes both the externally imposed flux and the flux from the flame. But the flame flux is higher in the horizontal orientation, leading to a higher heat release rate. A minimum heat release rate, in turn, can be viewed as the actual criterion that should determine whether burning continues. There is also a wood species effect: 19.1 mm thick white pine specimens burned to completion in both orientations at the 20 kW m^{-2} flux. The species effect can most likely be ascribed to density, the red oak being 660 – 860 kg m^{-3}, white pine 400 – 410 kg m^{-3}. Parker[2027] considers that for wood the question of sustained flaming is affected by cracking. After the initial peak in heat release from a wood specimen, flaming becomes no longer uniform and is localized, instead, to the places where there are fissures. Thus, the minimum heat for sustained

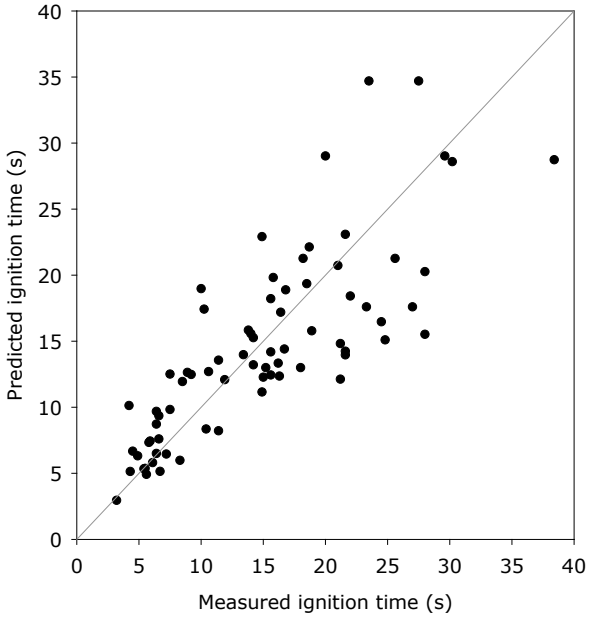

Figure 121 Prediction of ignition time from flame contact

flaming can be expected to depend on the grain orientation, among other factors.

Ignition with *laser radiation* produces very different results than radiation from flames or grey-body radiators. Kashiwagi[2028] exposed horizontally-oriented red oak specimens to laser radiation at 10.6 μm and found $\dot{q}''_{\min} \approx 80$ kW m^{-2} for autoignition and 55 kW m^{-2} for piloted ignition. These values are, of course, much higher than those obtained using normal radiant heaters.

IGNITION FROM FLAMES

When a thin piece of wood is lit at the bottom, burning may continue to completion. But a thick piece of wood will not undergo self-sustained combustion under the same circumstances. Bryan[2029] reported that the maximum thickness for self-sustained burning, given a flaming ignition at the bottom of a vertical piece, is about 19 mm. Tuyen et al.[2030] found that 14 × 14 mm or larger sticks would not continue burning, but smaller ones would. Ignitability of wood boards has been examined[2031] using the ISO 11925-2 small-burner test. Using a 30 s flame exposure to the surface, ignition rarely occurred and never spread to the 150 mm limit, even with specimens as thin as 2 mm. For 30 s bottom-edge impingement, specimens of 18 mm thickness or less commonly ignited, but only ones of 10 mm thickness or less generally reached the 150 mm mark. Using the methenamine pill test (a standard test for floor coverings), it was found[2032] that no ignition occurred for any of a wide variety of wood products tested in thicknesses of 10 – 21 mm. Friedman[2033] claimed (without explaining the basis) that a piece of wood must attain an average temperature of at least 320ºC for self-sustained flaming to continue. The latter criterion, even if correct, would not be easy to apply, since simple methods do not exist for estimating the average temperature of a specimen burning on all sides.

The earliest study where wood was ignited by direct exposure of flames to the entire specimen face was by Bamford et al. and is discussed in Chapter 7. Later data were collected at the University of Oklahoma by Ebeling[2034] who tested oak, white pine, redwood, and yellow pine. From his results it is possible to derive the correlation:

$$t_{ig} = 41.3\rho^{0.94}\left(\dot{q}''_e\right)^{-1.82}$$

where ρ = density (kg m^{-3}) and $\dot{q}''_e$ = irradiance (kW m^{-2}). The results of this predictive equation are shown in Figure 121. The equation captures the basic trends, but the fit is only fair. The above equation implies that the critical flux for ignition (the x-axis intercept if flux is plotted against $t_{ig}^{-0.55}$) is identically zero. This is somewhat different from the results obtained from non-flame radiant sources, where values substantially above zero are normally found. The flame used by Welker et al. was a liquid fuel/oxygen flame and this may make the results systematically different than from flames in normal building fires. In any case, their flame ignition times were a fair bit shorter than times found when applying the same heat flux in radiant heating tests. This is at least partly due to the fact that there is no convective cooling of the surface in a flame-ignition test.

GLOWING OR SMOLDERING IGNITION AND IGNITION BY FIREBRANDS

Glowing and smoldering are similar, but not identical mechanisms of ignition. Smoldering is, by definition, a self-sustained process. Ignition and consumption of a wood material by glowing, on the other hand, can occur if it is subject to sufficient radiant or convective heating, without a requirement that the process continue, should the external heat source be removed. Firebrands themselves may be flaming or glowing, and they may, in some cases, initially cause flaming in the target fuel, although a smoldering ignition is the usual concern.

Self-sustained smoldering occurs easily in various wood products which are highly porous or finely divided (fiberboard, wood shavings, rotted wood, etc.). Whole wood, however, is only slightly porous to the inflow of oxygen. Whole wood will not smolder as a single surface facing open air. Ohlemiller[2035] reports that by supplying external heating of ca. 10 kW m^{-2}, wood can be made to burn in a glowing mode; this of course is not smoldering, since it is not self-sustained. But by preheating the bulk of the wood sufficiently, self-sustained combustion can be obtained. This can be seen in a fireplace where individual pieces may continue glowing even after a 'three-log' effect no longer exists.

Only a limited number of experimental studies exist on the question of minimum conditions necessary to start wood

smoldering. Ohlemiller[2036] conducted experiments where smoldering was achieved by providing a 'three-log' arrangement (Figure 122). In these experiments, three pieces of wood were used to form a U-shaped channel with an air space of 51 mm. Even with this optimal geometry, to achieve smoldering required (a) applying an electrical igniter for 1.5 hours; and (b) blowing air through the channel, with the flow velocity being maintained over a narrow range. A minimum air flow of ca. 0.08 m s^{-1} was needed to sustain smoldering, while velocities over 0.22 m s^{-1} led to flaming, rather than smoldering. Increasing air velocities led to increasing temperatures of glowing wood, and the transition to flaming was found to occur when the glow-front temperature reached about 700ºC. The smolder front propagation rate along the interior surface of the channel was 20 – 70 mm h^{-1} for forward smoldering and 30 – 40 mm h^{-1} for reverse smoldering. In an earlier study, Ohlemiller and Rogers[2037] found that it is also possible to initiate smoldering in white pine arranged in a vertical-channel geometry with only one or two wood slabs. Again, ignition was by flat electric heaters, applied for a long but unspecified time. Smoldering ignition required that a temperature of 310 – 360ºC be reached, but the authors noted that the results were not well repeatable. Dependence on air flow rate was noted, but not quantified in these tests.

Solid wood is most commonly ignited by firebrands during wildland fires. Some statistical information on this topic is given in Chapter 13. It can be seen there that a wide variety of wood structural and trim items have been ignited by firebrands in actual fire incidents. Humidity plays a strong role in the process, and wildland fires often involve extremes of high temperature, low humidity, and strong wind gusts. Several laboratory studies also exist on the ignitability of solid wood by firebrands.

In Australia, there are numerous timber bridges and these often ignite in wildfires, leading CSIRO to study this particular ignition target. Dowling[2038] conducted both field and laboratory experiments on this ignition process. In laboratory experiments conducted at 20ºC and 65% RH and still-air conditions, mockup structures made up of weathered bridge beams removed from service were tested. Wood cribs of 200 g or greater showed a high probability of causing self-sustained ignitions, while 150 g cribs only showed limited charring. Cribs were placed over 5 – 10 mm gaps between two wood members, and when smoldering was produced, it started at the edges and corners of the gaps. In another series of laboratory tests, wood cribs were burned up until they produced a mass of embers, then the embers were poured into a 10 mm gap between wood bridge members; 7 g of embers produced from the burning of a 150 g crib sufficed to start self-sustained smoldering. In field experiments conducted at 16 – 19ºC, 52 – 87% RH and typical wind speeds of 0.5 m s^{-1}, ignitions were not obtained when gaps between wood members were smaller than 10 mm. But for gaps of 10 mm or greater, a 300 g crib, producing 20 g of

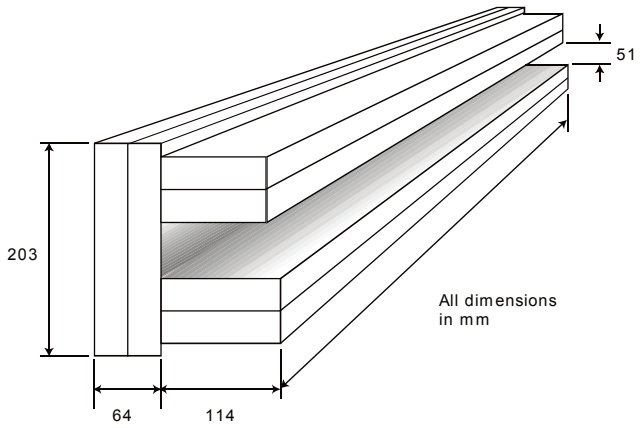

Figure 122 U-shaped arrangement used by Ohlemiller to create smoldering in wood

embers, was found sufficient to cause a smoldering ignition of a 40-year old deck. The differences between laboratory and field results were ascribed to weather conditions. Dowling also concluded that timbers that are rotted or heavily fissured are much more prone to ignition than sound timbers. He also found that flames from large (6 kg) wood cribs placed below the bridge structure and impinging flames up on it, simulating a wildfire below the deck, were sometimes able to cause a smoldering ignition of bridge timbers.

Even smaller ignition sources sufficed in another CSIRO study by McArthur and Lutton[2039] who tested the ignitability of wood siding from very small (0.8 – 12 g) wood cribs and piles of leaves and twigs under an elevated ambient temperature (40ºC) and extremely dry conditions (10% RH) that are commonly associated with wildland fires. Dry specimens (5% MC) generally showed flame spread over most of their 0.5 m height (Color Plate 142), while moist ones (MC ≥ 12%) showed only localized charring. Even cribs as small as 0.8 g were able to cause ignition and substantial charring height. An inside-corner ('re-entrant corner') geometry of the siding was especially conducive to ignition. The specimens were extinguished when maximum char zone extent was recorded, so continued burning was not examined. In both CSIRO test programs, the target woods were hardwoods (*Eucalyptus*) and it is not known if any significant differences would be seen for softwoods.

Hamada[2040] studied the effect of wind and RH on the ignitability of wood by incandescent-red firebrands. Under no-wind conditions, brands of about 5 mm diameter were needed, but for an 8 m s^{-1} wind, even brands of 2.5 mm were likely to cause ignition. Low RH values (20%) were needed for this to occur. At an RH of 80%, even with a high wind of 8 m s^{-1}, it required a brand size of about 8 mm. In Waterman's study[1049], larger brands were needed than those used by Hamada, but Waterman did not measure or control the RH in his experiments. In a reported incident[2041], welding slag that dropped down on wood scaffolding planks

resulted in a smoldering ignition of the wood, which subsequently turned to flaming. It is unlikely that such a piece of slag would be greater than a few millimeters.

The present author conducted unpublished experiments examining the ignitability of wood studs (nominal 2×4") by applying the flame from an acetylene/air plumber's torch directly onto studs for periods of 1 – 5 minutes. It was found that this produces transient flaming, but combustion dies out after the flame is removed and smoldering is not initiated. Even in a 'chimney' geometry of two, closely spaced studs and in a corner geometry of a stud meeting a sill plate, sustained combustion could not be initiated. This does not rule out ignition in geometries more unusual than those tried, but it would appear that fire incidents attributed to plumbers' torches most likely involve the additional presence of other materials that can sustain smoldering, e.g., fiberboard, sawdust, cellulosic insulation, etc.

Sufficient results are evidently not available from these studies to be able to derive quantitative guidance on the minimum conditions needed to ignite solid wood in a smoldering mode or by firebrands. In general, it appears that a hot solid object is necessary; applying small flames—even very hot ones—to wood is unlikely to result in sustained smoldering once the source is taken away. Some exceptionally small brands can ignite wood under ideal conditions: very low moisture, and a geometry where the surfaces 'view' each other. Air velocity has a strong effect, both on the probability of initiating smoldering and on transitioning from smoldering to flaming. Ignition by heating sources sustained for very long periods of time (months) is considered separately below. A *cigarette* has been shown[2042] not to be capable of igniting solid wood or plywood surfaces, at least in still air.

IGNITION FROM OTHER EXTERNAL HEATING SOURCES

Ignition from nuclear weapons was studied by the Naval Applied Science Laboratory[2043]. A radiant exposure from an arc-image furnace was applied over a circular area of approximately 17 mm. The results for the brief, high-intensity pulses were expressed in terms of energy fluence. Very weathered Douglas fir, 19 mm thick, showed no ignition at 385 kJ m^{-2}, (equivalent to 65 kt bomb*) and transient ignition for pulses of 500 kJ m^{-2} (equivalent to 115 kt) or higher. No sustained flaming was observed under any exposure. Punky (i.e., partly rotted) Douglas fir also showed no sustained flaming; transient flaming followed by smoldering required in the range of 385 to 540 kJ m^{-2}. By contrast, when testing 13 mm thick fresh Douglas fir, transient flaming was observed at 1090 kJ m^{-2} (480 kt) and sustained flaming at 1300 kJ m^{-2} (1180 kt) or higher. Yellow poplar of 1.6 mm thickness also showed sustained flaming at 1090 kJ m^{-2}, but no transient flaming regime. Excelsior showed no ignition up to 540 kJ m^{-2}, smoldering ignition starting at 750 kJ m^{-2}, and flaming ignition at 1210 kJ m^{-2}. Except for one trial, sawdust showed no flaming ignitions, but transient ignition followed by smoldering required as little as 270 kJ m^{-2}; the lower limit was not explored.

Hinkley et al.[196] conducted autoignition experiments on wood planks (13 mm thick, 520 kg m^{-3}) and wood fiberboard (25 mm thick, 260 kg m^{-3}) by impinging an air stream from a hot-air blower onto vertically-oriented specimens. Their results are given in Table 121. Air flow velocities were not measured.

Table 214 Autoignition of whole wood and wood fiberboard from a hot-air blower

EFFECTS OF VARIOUS FACTORS ON EXTERNAL IGNITION OF WOOD

Fire retardants

The efficacy of fire retardants is varied; likewise any given FR agent may be applied by various methods and at various loadings. Thus, it is hard to make any general statements about 'fire-retardant treated' wood. At the good end of the scale, Gardner and Thomson[2044] showed that FR pine (pressure-impregnated) can have a minimum flux for ignition > 60 kW m^{-2}, pertinent to a 10-min test. On the other hand, a pine that was surface-coated with an different FR agent had a minimum flux for ignition of < 20 kW m^{-2}. Richardson[2045] reported that Southern yellow pine boards ignited in 36 s at a flux of 50 kW m^{-2}, but when FR-treated the ignition took 217 s. Spruce boards treated with a commercial FR agent were found to be greatly improved in their ignition properties[2046]. A 16% loading of the retardant raised minimum flux for ignition to about 35 kW m^{-2}, as measured during 10-minute tests in the Cone Calorimeter. Increasing the loading to 21% raised the minimum flux value to over 50 kW m^{-2}. A review of available literature[2047] showed that the effects on T_{ig} are small or inconsistent, with some retardants raising the ignition temperature, while others serving to lower it. The inconsistent test results must be considered from the point of view that FR agents are generally added to wood in order to improve the flame spread, heat release rate, or fire endurance properties; any improvements in ignition performance are normally a by-product, not the primary function. The use of many common types of FR agents in wood products is complicated by the fact that

* For atomic weapons, yield is expressed in equivalents of TNT, using the US ton (2000 lb) as the measure of mass of TNT.

many of them cause a progressive hydrolysis of the wood, making it lose strength over time. This can limit the applicability of products with these treatments to uses where loadbearing strength requirements are modest.

In recent years, it has been proposed that certain fire retardants, some of them water-soluble, might be applied on an emergency basis onto wooden sidings of houses in imminent danger from wildland fires. Some ignitability tests[2048] on several systems showed that ignition times at a 25 kW m^{-2} irradiance could be prolonged by about 5 – 10 minutes, but that minimum heat flux for ignition was not affected. The latter is simply because these surface-applied treatments are consumed during the heat exposure period.

Treatment with preservatives

In an early study, Weiss[2049] determined the piloted ignition temperature of Eastern hemlock using a vertical tube furnace. For untreated wood, he established an ignition temperature of 320ºC. Various inorganic preservatives had an insignificant effect on the temperature, although for a number of them Weiss remarked "hard to ignite"—perhaps this referred to time needed for ignition, which was unspecified. Organic preservatives invariably lowered the ignition temperature, with various tars and creosotes giving 217 – 243ºC ignition temperatures.

Impurities

Limited studies have suggested that certain metallic ions present in wood can affect the ignition temperature. Hshieh and Richards[1611] concluded that the natural presence of large concentrations of calcium and potassium is important in determining the glowing or smoldering ignition of wood. When those ions were artificially removed, specimens proved to be much harder to ignite. Adding cobalt (present naturally only in minuscule concentrations) significantly enhanced ignitability. Older studies[1618,2134] indicated that iron also plays a catalytic role in enhancing ignitability. None of the above studies, however, were conducted under conditions representative of radiant heating in real fires, so quantitative conclusions cannot be drawn from them.

Charring

Wood and other materials capable of charring are irreversibly altered when subjected to elevated temperatures. Thus, a practical question arises: Will wood ignite more, or less, readily if it is first pre-charred by exposing it to temperatures sufficient to cause degradation, but not enough for ignition? There are two competing effects when pre-charring occurs: (1) density and thermal conductivity are lowered; and (2) flammable volatiles are driven off. Lowering the density and conductivity lower the thermal inertia which, in turn, makes it easier for a given heat source to raise the face temperature of the material[292,2050]. But driving off volatiles makes it harder to cause ignition, since it becomes more difficult to generate enough volatiles to sustain a flame. Experimentally, it has been demonstrated that the latter effect dominates over the former and pre-charring makes it harder, not easier, to reach ignition. The Bureau of Mines[2051] conducted flame spread tests which showed reduced flame spread of pre-charred specimens. These results can be interpreted as pertaining to ignition since flame spread can be viewed as a succession of ignitions. More direct studies were done at the Fire Research Station[2052] where 50 × 50 × 12 mm thick oak specimens were baked at 120ºC for up to 72 days, at 150ºC for up to 36 days, and at 180ºC for up to 12 days. Autoignition tests on these samples indicated no change of ignition time for a given heat flux. The minimum ignition flux was raised, however, and the increase was linearly proportional to the fraction of mass that was lost in the pre-charring, up to 30% mass loss (Figure 123). The absolute values of $\dot{q}''_{\min}$ are systematically high in many series of FRS tests, as discussed above. However, a relative relation can usefully be derived as:

$$\dot{q}''_{\min}(\text{charred}) = \dot{q}''_{\min}(1 + 0.018ML)$$

where ML = mass lost (%). Thus, if ML = 30%, the minimum flux will increase by a factor of 1.54. Ignition time was raised in piloted Cone Calorimeter tests run at 50 kW m^{-2} by Akizuki et al.[2053] For 27 mm thick red cedar, they found an ignition time of 15 s for virgin material and 23 – 32 s for pre-charred material. When painted wood surfaces are subjected to pre-charring, however, the results are variable[2054].

The above findings must not be applied to situations where self-heating dominates. If ignition requires days-to-years, rather than minutes or hours, then self-heating—rather than external heating—is the dominant source of heat. This is discussed in the *Self-heating* section, below.

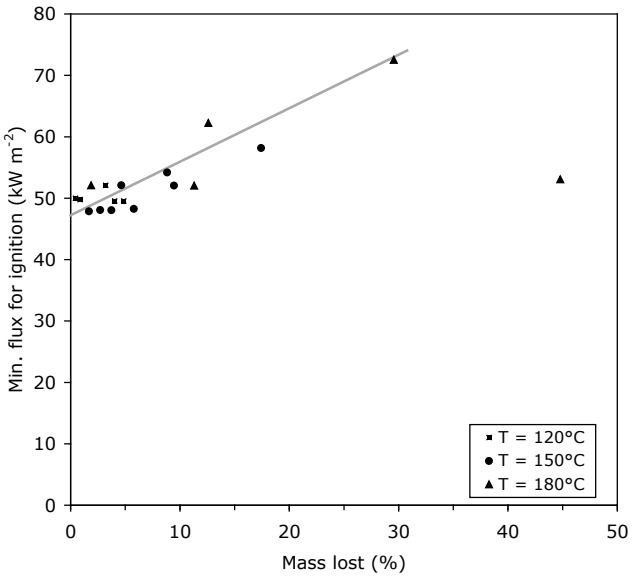

Figure 123 Effect of pre-charring oak on the minimum flux for ignition

Table 215 Autoignition temperatures determined by Hill

Wood	Autoignition temp. (ºC)	
	Sound wood	Decayed wood
hemlock–heartwood	255	208 – 285
hemlock–sapwood	220 – 235	223
pine–heartwood	238 – 300	NA
pine–sapwood	239	218 – 230

Table 216 Hill's results on the effect of specimen size on the ignition of decayed wood

Mass (g)	Autoignition temp. (ºC)
0.5	204
3.0	181
9.0	175
15.8	158

Weathering, aging, decay, and rot

The effect of weathering on cedar samples was examined by Muir[1998]. Using piloted ignition in a radiant panel apparatus, he found that unweathered cedar ignited in 126 s at 20 kW m^{-2}, but cedar weathered in 3 months of outdoor exposure took 328 s. At lower fluxes, however, the effect became progressively smaller; for example, at 16 kW m^{-2}, the results were 802 and 1097 s, respectively. He did not investigate the effect further, but it would appear that it may be related to a loss of potentially flammable volatiles from the outer layer of wood. The most noticeable effect which occurs when wood weathers is that the color darkens, but if the effect were mainly a raising of the surface absorptivity, the ignition times would fall, not rise. In any case, the absorptivity changes primarily in the visible part of the spectrum, and for realistic ignition sources the infrared part of the spectrum is important, not the visible.

It is sometimes claimed that *old wood* is more readily ignited than fresh wood. Kawasaki[2058] considers that the mechanism for this is the preferential decomposition of cellulose, with more of the wood now comprising the more-readily ignitable lignin. The only available data on this point[346] are shown in Table 217 and they do not indicate that there is any significant effect. The specimens listed as 'oven-dried' were dried for 83 days at 105ºC. Note also the results of Muir (above), where he found that weathered wood became *harder* to ignite.

Table 217 Effect of age and drying on the AIT of wood

Specimen	AIT (ºC)
white pine drillings (fresh)	285
wood, oven-dried	270
wood, 3 years old	240 – 264
wood, 20 years old	252 – 261

Hill[254] compared the autoignition temperatures of sound and decayed wood, using a convective heating arrangement and measuring temperatures in the air space near the specimen surface. His results are summarized in Table 215. It appears that decayed wood ignites at a slightly lower temperature than sound wood, but the difference is only about 10ºC. In an interesting further exploration, Hill then examined the specimen mass effect on a decayed hemlock heartwood sample that he recorded as igniting initially (for an unspecified mass) at 220ºC. These results are shown in Table 216. The decrease in the required air or furnace temperature with increasing specimen mass is due to a modest self-heating effect; note, however that the actual values reported in Table 216 are implausibly low.

Rotted wood was later studied by Angell et al.[1988] They exposed small (13 × 19 × 51 mm) specimens to convective, short-term heating. In comparing fresh and rotted southern yellow pine, they found an ignition temperature (as measured in the air near the specimen) to be 204ºC for sound wood, but only 149ºC for rotted wood. The test paradigm used temperature steps of 14ºC, thus the 149ºC reported value indicates that ignition occurred at 149ºC, but did not occur at 135ºC. Thus, their data suggest that rotted wood has an ignition temperature of about 50ºC lower than fresh wood. The ignition times were 427 s for the sound wood and 105 s for the rotted. Again, the very low values reported should be viewed as reflecting inaccuracies in measurement.

Stockstad studied the ignitability of several types of rotted wood in a horizontal tube furnace, but without a comparative study on sound samples[2055]. Specimen size was 2.5 × 2.5 × 25 mm, with a maximum test time of 3 min (this seems very short, but the small specimen size has to be taken into account). Table 218 shows the main results. The temperatures reported are those of the furnace. In a few cases, Stockstad also measured temperatures in the gas space close to the specimen; these averaged 18ºC lower than the furnace temperatures. The effect of moisture content was also examined, but with anomalous results—increasing moisture content over the range of 5 – 23% increased ignition times for autoignition, but not for piloted ignition.

The ignitability of rotted wood (unspecified species) by glowing, non-flaming juniper brands was studied by Bunting and Wright[504]. Using cylindrical-shaped brands, for the largest size used, 5 × 20 mm, they found that ignition re-

Table 218 Stockstad's tube-furnace ignition results for rotted wood specimens

Wood	Density (kg m^{-3})	T_{ig} (ºC) autoignition	T_{ig} (ºC) piloted
Douglas fir	247 – 332	260	250
ponderosa pine	234 – 457	270	260
subalpine fir	NA	300	NA

Table 219 Low-temperature, long-term ignitions of wood studied by the Swedish Fire Protection Association

Hot object	Ignited	Estimated peak temp.	Estimated time
insulated steam boiler return pipe	25 mm thick floor board	90 – 100ºC, rarely up to 120ºC	unknown
steam boiler return pipe	sawdust & shavings	70 – 100ºC	unknown
condensate water	insulation comprising cardboard + 12 mm wood	90ºC	unknown
high pressure steam pipe*	wood scaffolding	200ºC	2 h
pickling tank	floor under tank	112ºC	1 yr
low pressure steam pipe	cardboard + mineral wool	106ºC	< 1 yr

* This incident does not comprise low-temperature, long-term heating but is included here to present the entire table published by the original authors.

quired a minimum air temperature of 0ºC but that there were few ignitions until 4ºC was reached. Also, fuel moisture content of < 15% was found to be a prerequisite for ignition. Unlike for ignitions of fine-size fuels by brands, wind velocity and RH did not affect the results significantly. When brand size was varied, ignitions were found to regularly occur even for the smallest brands used, 2 × 10 mm.

Rosenhain and Gemmell[264] conducted experiments in 1913 which were a cruder version of the FRS oven-basket testing method. Using 0.305 m cubes of solid, but 'somewhat decayed' wood, they found that an oven temperature of 178 – 180ºC was needed for thermal runaway.

Rotting also removes mass and thus lowers the density and presumably the thermal conductivity. Thermal inertia of rotted woods have not been characterized, however. Rudge[1201] speculated that inorganic constituents in soil, especially calcium, play a strong role in lowering the ignition temperature of rotted wood.

SELF-HEATING, 'PYROPHORIC CARBON,' AND IGNITIONS FROM HOT PIPES

As already discussed at the start of this Section, wood is a very complex substance. Certain aspects of its chemistry have been studied at some length, but these studies normally do not help in solving practical ignition problems. Most of the problems of self-heating of wood arise in connection with porous forms of it, for example, wood fiberboard or wood sawdust. The chemical reactions leading to exothermic phenomena are, of course, the same, irrespective of the physical form of the substance. But when, as in the case of wood, self-heating involves an oxidation reaction (oxygen from the air reacts with the substance) then access of air to the interior of the material is necessary. This is readily feasible for porous forms and more difficult in the case of 'solid' wood. Yet already in 1902 Schwartz[2056] wrote: "Beams of timber may become capable of spontaneous ignition when exposed to prolonged influence of moderate warmth, even below 100ºC." A century later, this issue remains controversial and not fully resolved, as will be explored in this section. The controversies have centered around two related issues: (1) are ignitions possible from heat sources, such as low-pressure steam pipes* (which operate in the region of 100 – 120ºC); and (2) the character and role of char formation and char oxidation in this process. The controversies arise because, unlike piles of sawdust or wood fiberboard, structural members will commonly be no more than 150 to 300 mm thick in their thinnest dimension and, as discussed in Chapter 9, self-heating shows a very strong size dependence. An additional issue of controversy has been whether whole wood is sufficiently permeable to oxygen that a process of continued oxidation could be sustained.

Ever since about 1900, case reports have been published of wood members igniting after a long period of heating by steam pipes, hot water pipes, and other hot surfaces that have temperatures of 100 – 150ºC or, in some cases, lower yet. Since the autoignition temperature of wood, as discussed above, is 250ºC or higher, such cases are not just external ignitions—self-heating has to play a dominant role. In 1910, Bixel and Moore[263] reported details of more than 40 fires where the origin was identified to be a wood beam igniting from an uninsulated steam pipe which had been drilled through it. For most, the time required for ignition was unknown, but the two known cases involved 3 months and 3 years of steam heating prior to the occurrence of fire. Additional cases were collected by Matson et al.[2057]; of special interest is a case where it took 15 years for the condition to lead to a fire. In 1967, Kinbara[2058], a professor at Tokyo's Sophia University, studied two cases in Japan, one where the steam pipe temperature was just over 100ºC, the second estimated to be 140 – 150ºC. The question of the steam pipe temperature is, of course, very important. Low-pressure steam lines will run below 120ºC, while high-pressure steam lines might typically run at 170ºC. In some cases, the hot-surface temperature has been lower. Matson reports a fire where wood members in contact with a water tank ignited, and the latter could not have exceeded 100ºC and another where a steam return pipe could not have exceeded 100ºC. A fire in joists adjacent to a hot-water radia-

* Low-pressure steam is customarily defined as being below 2 atm absolute; steam at the latter pressure is at 120ºC temperature.

tor running at ca. 82ºC has been reported in relatively recent times[2059]. In this case, it was clear that the thickness of wood was greater than just one beam's worth. The actual arrangement involved 50 × 300 mm beams, along the bottom of which was clamped a radiator; below the radiator was a makeshift enclosure. One important practical observation in Matson's study was that in a number of the incidents where the fire was promptly discovered and extinguished, other wood members exposed to similar conditions were cut apart as part of the investigation. These commonly showed that the wood members had become charred black and charcoal-like near the places where they abutted the steam pipes.

In 1960, the Swedish Fire Protection Association published an assessment of the problem[2060]. The case histories surveyed are summarized in Table 219. The last case listed is especially interesting, since the author notes: "The fire [started] when the charring reached a gap with access to air." A recent case history was documented in an apartment house fire in Winnipeg, Canada in 2001. Fire investigation revealed the point of origin at an 1-¼" hot water supply pipe (left pipe in Color Plate 143 and Color Plate 144; the right pipe is an 1-½" return pipe), where it passed from one storey to the next within a wall cavity[2061]. The furnace was producing water at 88 – 93ºC and was checked out to be in proper operational order. The pipe was mostly insulated by 25 mm thickness of fiberglass insulation, but the insulation was omitted at the area of floor penetration. The pipe penetrated an assembly which consisted of 15.9 mm thick OSB sub-floor, on top of which was a 38.1 mm thick wall plate. The investigation was carefully done and all alternative fire causes were ruled out. In this situation, the heating conditions would not be conceptualized as a single hot surface on a body otherwise at ambient temperature. The floor-ceiling space was a small, closed volume and the trapped air space heated up to a temperature higher than ambient.

The fire incident with the lowest measured temperature known to the author involved a fire that occurred on 4 February 1972 in Van Nuys, California[2062]. The fire was found to have originated at a header in a wall cavity (of 2×4" timber construction) where a hot-water pipe passed through. To reduce the potential for vibrations, the plumber had forced a red cedar wedge into the aperture surrounding the pipe, so that good contact was made between the wood and the pipe. The fire broke out some time after numerous individuals of a large family had finished taking showers. During the investigation of the fire, the investigator measured the temperature of the hot water pipe as 77ºC, which is much higher than common for domestic hot water, but in this case was set to enable a large family to not run out of hot water.

Some reported cases should not be considered as solid-wood ignitions, since other substances, such as sawdust or oils, were also present. Other cases need to be excluded since investigation revealed that some heating malfunction had occurred and substantially higher temperatures were reached than are found in normally operating low-pressure steam pipes. In a rare quantitatively documented example[2063] it was noted that fire broke out where steam pipes penetrated walls, but it broke out at 10 places simultaneously. Molten lead in the flanges of the pipe system indicated that steam temperatures had surpassed 320ºC, and the investigators correctly determined the cause to be the failure of a pump in the steam system. It is possible that some fraction of incidents where the fire origin was attributed to normally-operating, low-pressure steam pipes, in fact, involved excessively high temperatures due to gross malfunction. However, it does not seem credible that *all* fires ascribed to low-temperature, long-term ignition of wood involved incompetent fire investigation.

If it is taken that low-temperature, long-term ignitions can occur, then of course there is an interest in explaining the phenomenon. In 1873 the German pharmacologist H. von Ranke[1173] proposed a theory of self-heating of haystacks where he concluded that *pyrophoric carbon* gets formed by self-heating, then this highly-reactive carbon is the substance which subsequently ignites. The term was selected because Ranke believed that the carbonized matter was particularly easy to ignite. The actual sequence of spontaneous combustion of haystacks was more successfully quantified later, and has been discussed above under *Forest materials, vegetation, and hay*. In his 1902 book, Schwartz applied the term and idea of 'pyrophoric carbon' to low-temperature, long-term ignitions of wood[2056]. The term 'pyrophoric carbon' (or 'pyrophoric char') has since been used widely in the fire investigation community. Fire investigators, however, have tended to use the term simply as a synonym for 'low-temperature, long-term ignition of wood,' not necessarily ascribing a particular chemical explanation to the phenomenon.

In 1908 Brooks and McCreary[2064], two students at Case School of Applied Science, conducted the first experiments to examine the potential for steam pipes to ignite wood. They constructed a test rig which surrounded a steam pipe with several boxes into which were placed various test materials. The experiment was conducted for 35 days, during which time steam heating was provided only about 11.5 h per day, with pipe temperatures being about 150 – 160ºC while steam was being provided. In the course of a single day, they obtained ignition in one box, which was packed with charcoal. But they got no ignition during the entire 35 day period in a second charcoal-packed box, nor in boxes filled with sawdust, pine chips, 'wastes' coated in machine oil, wood shavings coated in machine oil, or solid blocks of pine. They concluded that their testing was insufficiently long, and that future researchers should (a) conduct experiments for a whole year, and (b) examine more closely the issue of temperature cycling.

Table 220 Self-heating properties for wood products

Substance	ρ kg m^{-3}	E kJ mol^{-1}	P ln(K^2 m^{-2})	QA W kg^{-1}	QA/C K s^{-1}
various solid woods[2069]		104.6 – 123.4			
Douglas fir, solid[2070]		126			
solid wood[2058]		149			
Douglas fir chips, virgin[2050]		68.60	37.51		5.89×10^{5}
Douglas fir chips, pre-charred[2050]		80.45	39.98		5.93×10^{6}
wood sawdust[2071]	140			6.11×10^{13}	
hardwood chips[1768]	145	102	46.26		
Monterey pine sawdust[2072]	222	90		3.19×10^{11}	1.88×10^{8}
wood sawdust[445]	260	108.33	48.77		
wood sawdust[2073]	210	100		2.7×10^{12}	
wood fiberboard[445]	270	100.97	48.37		1.10×10^{10}
charcoal briquettes (high wood char)[275]		98.94	46.3		
charcoal briquettes (high wood char, in polyethylene bag)[275]		83.14	42.32		
activated charcoal[445]	370	97.02	49.72		

The first theoretically-based study of the problem was presented in 1967 by Kinbara[2058], who assumed wood sawdust behaves identically to whole wood, tested spheres of sawdust for self-heating, then applied simple F-K theory (Chapter 9) and concluded that a temperature of 130ºC would be needed to cause thermal runaway. Shortly thereafter, Handa et al.[2065] conducted tests and modeled a sphere of whole wood, as opposed to sawdust. Their study, however, does not have much generality since to represent certain features of a fire they wanted to reconstruct, they coated the test spheres with plaster or with fiberglass insulation. Later, Handa et al.[2066] conducted 300 h furnace tests on wood blocks and used the data to validate a two-dimensional theoretical model. Their experimental data showed 50 mm thick blocks igniting at a furnace temperature of 190ºC, decreasing to 155ºC for 200 mm thick blocks; the actual ignition times were not stated. A value of E = 149 kJ mol^{-1} was derived from the experimental results.

In more recent years, two researchers—Bowes and Cuzzillo—studied the problem and attempted to disprove either the possibility of low-temperature, long-term ignitions, or some aspects thereof. Bowes[445] started by reviewing data obtained from heating of whole-wood specimens in the kinds of experiments that are discussed in Chapter 9. There had not been many studies, but Bowes found two examples. Topf[2067] examined the effect of percent lignin content on the critical temperature for self-heating of wood using cylindrical specimens of 67 mm dia. and 90 mm height. His test condition was peculiar, however, in that the specimens were insulated with a 50 mm layer of mineral wool before being placed in a constant-temperature oven. As lignin content increased from 20% to 37%, Topf found that the critical temperature dropped from 155ºC to 136ºC. For the same tests repeated in a pure oxygen atmosphere, the critical temperature dropped from 149ºC to 130ºC. Heinrich and Kaesche-Krischer[2068] also used a very similar arrangement, with 60 mm specimen cubes, covered with a 60 mm outer layer of mineral wool. For solid-wood cubes, the lowest critical temperature value was 130ºC, for a highly-resinous Scotch pine sample; a comparable sample of normal Scotch pine gave 180ºC. In cube-tests on shavings of Scotch pine, the temperatures were 180ºC for normal and 100ºC for highly-resinous. The lowest temperature for normal solid wood was 160ºC for Norway pine. Criticality was reached in these tests in 11 – 23 h. Heinrich then ran self-heating tests on resins extracted from the woods, mixed with an inert substrate, and placed in 40 mm diameter cylinders. Critical temperatures as low as 70ºC were found in those tests. The authors also conducted unique tests where they tested beech specimens at 190ºC in a nitrogen atmosphere and found no evidence of exothermicity. Under the same conditions, but in air, thermal runaway was reached in 11 h. In a further test, they kept a specimen in nitrogen for 15 h, then admitted air into the oven, at which point thermal runaway took place.

Bowes analyzed in some detail both of these studies and estimated that about 30ºC needed to be added to Topf's values in order to represent the self-heating of uninsulated specimens. With this correction, he considered that cubes or short cylinders of 60 – 70 mm size are to be viewed as showing critical temperatures of 165 – 185ºC. Bowes also compared these results to studies which examined wood sawdust and observed that such critical temperature values are essentially identical to those found for wood cubes of the same dimensions. He concluded that, at least for cubes of 60 – 70 mm, this was indirect evidence that oxygen is able to diffuse through solid wood and become available for reaction in essentially an indistinguishable manner from

what occurs in wood sawdust. But the geometry of a steam pipe passing through a wood beam is different from any of the standard geometries considered in self-heating theory. Thus, Bowes performed specific calculations for the hole-in-slab geometry. Based on those results, he concluded that a pipe temperature of approximately 200ºC is required to cause thermal runaway.

More recently, Cuzzillo reported the results of several lab studies[2050,2074]. He placed an 89 mm cube of solid Douglas fir in an oven; it reached thermal runaway after being held at 200ºC for around 250 min. A 200 mm cube held at the same temperature for around 12 h was close to the runaway condition. When he sealed the end grain surfaces, however, a 200 mm cube then took some 9.2 days to reach criticality. Earlier, Kubler[2075] had argued that oxygen access into the interior of pieces of whole wood is essentially nil. But Cuzzillo's results indicated that oxygen *can* enter into the interior, primarily through the end grain, but also sufficiently through the side grain so that slow oxidation can take place. Furthermore, it is evident that extended exposure of wood to elevated temperatures *creates* porosity. Thus, the self-heating process of whole wood includes a secondary positive-feedback mechanism—the creating of porosity due to self-heating, with porosity then further promoting self-heating. In another series of tests, Cuzzillo conducted experiments where the self-heating properties of virgin wood chips (as expressed by F-K theory constants) were compared to wood chips which had been pre-charred for 8 days at 198ºC. His results, along with those from several other studies, are compared in Table 220.

Cuzzillo's results showed that, in his tests, the pre-charred chips had a slightly lower, not a higher, self-heating propensity. According to these results, for thermal runaway, a pre-charred 150 mm thick slab would require a temperature about 20ºC higher than a virgin layer. It should be noted that, despite sizeable differences in the individual data constants, many of the results in Table 220 are broadly consistent. As Cuzzillo pointed out, when a limited, realistic range is considered for the problem variables, agreement is good since pairs of different E and P values can lead to the same prediction of critical temperature versus size.

Kubler also argued that, for solid wood, because of the poor access of oxygen into the interior, hydrolysis and pyrolysis reactions, rather than oxidation, dominate. If the governing reactions, then, are chemically different, it would also be expected that the self-heating constants for whole wood would be different than for porous wood products, where oxygen is readily available and oxidation reactions dominate. Cuzzillo did not test enough cubes of solid wood, so his work did not prove or disprove Kubler's claim. But the values of E in Table 220 are rather higher for solid wood than for wood in more porous configurations.

Since his experimental results indicated that pre-charred chips show a slightly smaller, not larger, self-heating propensity in oven-basket testing, Cuzzillo concluded that he thereby disproved the theory of 'pyrophoric carbon.' While Cuzzillo did not specifically perform these calculations, it is also clear from either one of his results—virgin or pre-charred—that, if self-heating calculations were performed using the simple F-K theory, a broadly similar conclusion to Bowes' would follow: it would be 'proved' to be impossible to ignite wood members with low-temperature, long-term heating. But unlike Bowes, Cuzzillo did not specifically draw that conclusion. Instead, he concluded that low-temperature ignitions of wood members may occur, but would occur since the thermal inertia of charred wood is much lower than that of virgin wood. The latter claim, while true, is irrelevant for self-heating, because thermal inertia is a variable that only governs ignition from external heating, not from self-heating.

Neither Bowes nor Cuzzillo (1) conducted any chemistry studies on the reactions of wood, nor (2) conducted tests where a wood member would be subjected to conditions reasonably simulating the ones that have been involved in fires. Thus, neither of these studies have been directly helpful towards quantifying the conditions needed for low-temperature, long-term ignition of wood. It might be observed, furthermore, that use of the F-K theory is clearly inappropriate, in view of the time frames involved. Laboratory tests of the various researchers on small cubes and other similar samples showed that thermal runaway, if it happens, happens in a matter of hours or days. For example, in his test of longest duration, Cuzzillo obtained a thermal runaway time of 9 days for a 200 mm cube. Thus, it should be clear that the physicochemical mechanisms which are operating in incidents where it takes months-to-years for fire to break out are not ones within the scope of the simple F-K theory.

Turning now to other investigations and theories, Cuzzillo's experiments showing that pre-charring creates a less self-heating-prone situation is the opposite of what was found by Palmer earlier[2076] in tests of virgin and pre-charred sawdust. Palmer tested layers of sawdust on a hotplate, determining the minimum hotplate temperature needed for the ignition of a layer of a given depth. His results are shown in Table 221. The temperature needed for the ignition of the carbonized material was found to be 30ºC lower than for the virgin wood sawdust. Thus, the effect found by Palmer was about of the same magnitude, but in the opposite direction, as found by Cuzzillo. Palmer's trends were confirmed during recent testing by Fitz[2077], who conducted hotplate tests on pre-charred sawdust and obtained results nearly identical to Palmer's. Since the self-heating process involves a solid-state oxidation and not combustion of volatiles, it can be concluded that removing some of the volatiles by pre-charring aids, not hinders, the self-heating process. But in any case, neither sawdust nor wood-chip exper-

iments have direct applicability to ignitions of solid wood members.

McGuire[2017] reported on a study where temperatures of ca. 121ºC were maintained for 4 years on both whole wood and wood fiberboard specimens. Charring was found, but not a flaming ignition; however, the paper provided no details on experiments conducted.

There are a number of hints in the literature that the self-heating ignitions of wood members which take months-to-years are highly dependent on oxygen conditions, specifically, that ignitions of this type are promoted when oxygen is excluded from the wood member by a physical barrier such as a sheet-metal or a tile cover over wood. Already in 1922, Wedger[2078] wrote that "pyrophoric carbon" is preferentially formed "where there is no circulation of air." In current times, this has been illustrated by DeHaan[322] and others[2079]. It is not rare to find low-temperature, long-term ignitions under boilers where the unit has a solid-metal base in contact with wood flooring[2080]. Even without such overt devices restricting the availability of oxygen from the wood member, when a steam pipe or similar metallic member at an elevated temperature is located adjacent to a wood member, oxygen delivery into the interface will be restricted. Progressive charring causes shrinkage, so the exclusion effect would appear to diminish with time, but actual gas concentrations in these environments have never been studied.

To unravel details relating to the role of oxygen, it would be helpful if the chemistry of the pyrolysis and charring of wood were understood. The late Prof. Fred Shafizadeh, who was considered to be the foremost expert on the subject of pyrolysis of cellulosic materials, made an effort to do exactly that. He produced cellulose chars at various temperatures in an anaerobic process[2081]. Then, he conducted thermal

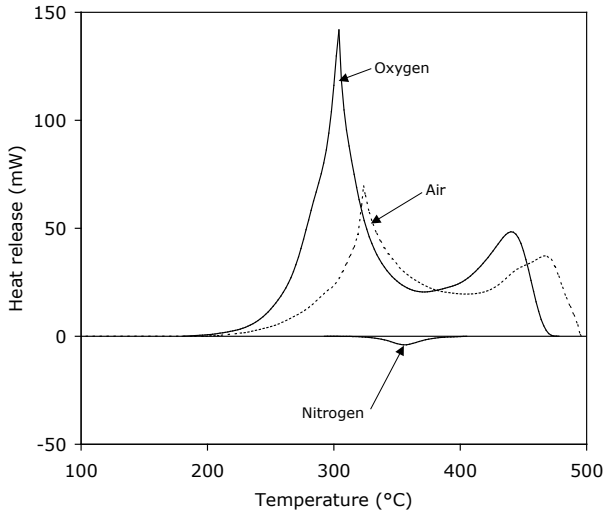

Figure 124 DSC curves for oven-dried Douglas fir
(Courtesy Frank C. Beall)

Table 221 Palmer's hotplate ignition tests on wood sawdust

Specimen	Density kg m^{-3}	Min. hotplate temperature needed for ignition (ºC)	
		Depth 25 mm	Depth 50 mm
wood sawdust	200	270	240
carbonized wood sawdust	200	240	210

analysis tests on these specimens and found that the chars produced at lower temperatures showed a pronounced exothermic peak occurring at a low temperature value; this exothermic peak was not present for chars produced at temperatures over 375ºC. This implied that chars produced at low temperatures are substantially more reactive than those produced under higher temperatures. The reactivity manifests itself as an exothermic chemisorption of oxygen onto the freshly-formed char. The chemisorption was found[2082] to produce up to 460 kJ per mole of O_2 and led Shafizadeh to refer to write that: "This gives credibility to Ranke's theory of pyrophoric char and his explanation of spontaneous ignition"[2083]. In 1989, Shafizadeh's student, Hsieh[2084] attempted to repeat these experiments at lower temperatures, but obtained negative results. No further investigations in this area have been reported since then.

As the review of McNaughton's work in the preceding Section has shown, the charring of wood already takes place at 107ºC and is full-fledged at 120ºC. Kollmann and Topf[2085] summarized several German DTA studies and found that the lowest temperature at which an exothermic behavior was detected ranged from 105ºC to 208ºC. The lower values from this study are quite consistent with McNaughton's results. The higher values would seem to reflect limitations in measuring technology. Even today, the ability to measure chemical activity at low temperatures is limited. Differential scanning calorimetry (DSC) plots for oven-dried Douglas fir taken on a modern instrument are shown in Figure 124. No detectable response is seen below about 180ºC. Thus, the paucity of chemistry studies is not surprising, in view of the fundamental difficulty of measuring reaction rates at low temperatures.

Considering Shafizadeh's and DeHaan's findings, plus the plethora of case histories, it is possible to speculate about the nature of the ignition mechanism. It appears that char is initially formed under conditions of very limited access to oxygen. It is well known that char shrinks and cracks under extended heating. Both of these factors will play some role in the chemistry, but the details are not known. It is possible that ultimate flaming ignition follows a time period when larger cracking took place. Cyclic aspects of the flow of heat, moisture, and oxygen may play a role. In many cases, low-temperature ignitions involved a heat source which is cyclic. This aspect has largely been ignored in recent inves-

tigations. However, early in the 20th century, Prof. Ira Woolson (considered to be America's first fire scientist), felt that low-temperature ignitions of wood are particularly liable to occur when steam pipes are in a heat/cool cycle[2086]. Much more recently, chemists at the National Research Council of Canada[2087] published a study giving an essentially identical opinion. It has often been noted that low-temperature wood ignition fires can occur after wetting of wood. But Woolson suggested that a water/air mechanism may apply to steam pipes. When steam heating is cyclic, ambient moisture may condense on pipes during periods of non-use. This will contribute to the exothermic heat of wetting to the self-heating process. When heating is restarted, a drying cycle occurs, in which there is an endothermic contribution from drying moisture, but an exothermic contribution from oxygen being made again available to char pores which were previously moisture-laden. Moore[262] speculated there may be a further mechanism involved, an interaction between wood and iron. For a variety of reactions, iron oxide acts as a catalyst, and he thought this should also be explored in connection with steam pipe ignitions.

As discussed earlier in this Chapter, wood is an extraordinarily complex substance, possibly the most complex substance which tends to get involved in accidental fires. Its enormously complicated degradation chemistry is known today only in its roughest outline. The standard self-heating theory (F-K theory), on the other hand, assumes that the substance is the simplest substance conceivable, not showing two-step reactions, parallel reactions, or effects of oxygen or moisture flow, and certainly no effects of thermomechanical phenomena such as cracking. Thus, it should be no surprise that the theory does not cope with the low-temperature, long-term ignition phenomenon. What has been missing—and is very much needed—is an experimental study where the low-temperature, long-term ignition of wood would be examined in a realistic environment. This should include a pipe which is cycled in temperature between, say, ambient and 120ºC. Experiments where oven samples are uniformly heated do not constitute a realistic representation of the fire cases that are of practical interest. In 1960 Östlin[2060] observed that, in practice, wood members have ignited at temperatures down to ca. 100ºC and pointed out: "That ignition did not occur in the laboratory attempts can be assumed to depend on the fact that these did not contain all the necessary conditions for ignition." This observation remains true today.

A more complex problem is *flue-pipe* ignitions. Here, it is generally difficult to estimate what the temperature of the pipe was. In addition, the heat transfer situation is normally complicated, since even in imprudent installation, flue pipes are not necessarily butted up to a wood member, but may be located some distance away. Thus, the boundary conditions at the high-temperature surface involve radiation and convection, not a fixed temperature surface. Even though the radiant/convective transfer situation entails a thermal resistance, which is zero in the fixed-temperature boundary-condition case, flue pipes are likely to be heated to significantly higher temperatures than steam pipes. The same questions of long-term, low-temperature ignitions exist, however. Handa et al.[2088] attempted to elucidate the mechanism of ignition whereby a fire in a Japanese hotel originated at a wood pillar that was located close to a flue pipe. The actual system was complex, including layers of plaster, metal, and two different woods, and the authors did not succeed in replicating the ignition by laboratory testing.

Self-heating of *porous wood products* (sawdust, wood fiberboard, etc.) where there is good access of oxygen into the entire volume of the product is a different problem. For sawdust surrounding hot pipes or vessels, a temperature as low as 65ºC was found to suffice[1197]. If ignition occurs within a short time of creating the pile, then use of F-K theory, along with the constants given in Table 220, should be sufficient to enable calculations to be made. This would not apply, of course, to situations where long-term heating took place, but there do not exist sufficient case histories nor experimental data to enable such possibilities to be considered. Further aspects of self-heating for porous materials are discussed below.

IGNITION BY ARC TRACKING

When an electric current is made to flow across a tree or a wood member, an arc tracking process can take place under some circumstances. Wood first dries out at the electrodes, then a carbonized channel starts to form. Given enough time and voltage, sufficient heating of the carbonized track takes place that the electric current passing through the track heats up the wood to ignition. The presence of contaminants in the water greatly lowers the voltage necessary to initiate arc tracking (Figure 125). Because of the anisotropic nature of wood, the carbonized tracks can appear in the interior of the material, not necessarily on the surface. Kinbara et al.[2089,2090] documented that wet wood is more easily ignited by the electric carbonization process than is dry wood, and also that ignition is more likely to occur if

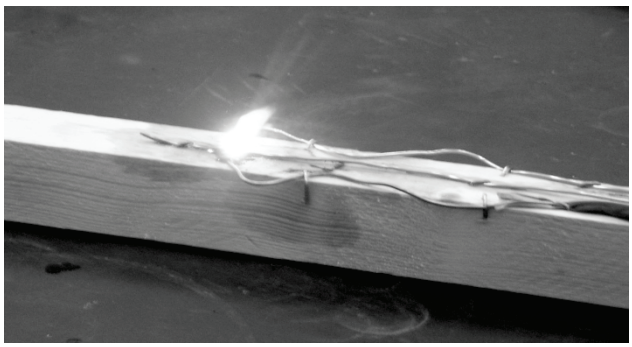

Figure 125 Arc tracking-induced ignition upon contact with wood by bare conductors carrying 120 VAC and wetting the surface with contaminated water.
(Courtesy Michael M. Fitz, MDE Engineers)

point electrodes are used instead of plate electrodes, since a higher current density is created with the former. Sanderson[2091] has reproduced some of these main findings. Fires due to wet arc tracking are common in the case of faulty installations of neon signs where high-voltage leads can contact wood.

In the case of high voltage power distribution lines, much higher voltages and currents are possible than with neon transformers. Ross[2092] studied the ignition of wood crossarms in power distribution systems. He found that the conditions most conducive to ignition involve a dry member that then receives moisture from a drizzle or fog. Under these conditions, patches of dry surface exist, and high electric potentials are then impressed upon these small areas. Leakage currents flowing through the dry patches then cause charring or ignition. Laboratory tests indicated that surprisingly little leakage current (10 mA at 12 kV) suffices to cause flaming ignition. Both testing and field experience, however, indicate that, because of the large wood member sizes, once ignited, the fires usually self-extinguish and the members are only partially burned.

Living or green trees have a much lower resistivity and are semiconductors, while dry trees are reasonably good insulators. Thus, Blackburn and Pau[2093] conducted tests with freshly-cut Eucalyptus trees to simulate a tree creating a high-impedance fault across a power distribution line. Cylindrical wood samples of various diameters and 0.4 m length were placed across a bare-conductor line and voltage was slowly raised across the line. Current flow was limited by a series resistor. It was found that ignition occurred in all cases below 0.5 A; a typical experimental result is shown in Figure 126. If a current limiting resistor was not used, they found that eventually the faults escalated to a short-circuit condition, which would have possibly tripped a circuit protection device. The high-impedance faults, however, clearly could not trip protection devices when currents were below 0.5 A. Blackburn and Pau also determined that the resistivity of undamaged (that is, without significant current flow) wood was 10 – 14 kΩ-m, and was independent of impressed voltage over the range 500 – 5000 V. As charring starts to develop, the resistivity drops rapidly until runaway conditions are reached. In the course of their experiments, they also noted that hot embers were dropped to the ground for a considerable period before short-circuit conditions were ultimately reached. Since the peak voltage across the specimens in their tests was measured at around 1700 V, it was concluded that the hazard is clearly demonstrated for voltage over 1700 V. But the authors considered it likely that, for long duration exposures, ignitions and short-circuit conditions could be experienced for voltages as low as 415 V. The pattern of charring was found to be initially concentrated near the two contacts, at which highest electric field values were recorded. Later in the test, the pattern of charring became more uniform along the length as did the electric field.

Both trees and wood poles are at high risk of ignition[1244] if the potential drop across the tree, induced from a high-voltage transmission line, exceeds about 100 kV, but of course the other results cited above indicate that ignition may occur at vastly lower voltages. Some additional studies on ignition of wood poles and crossarms were reviewed by Darveniza et al.[2094]

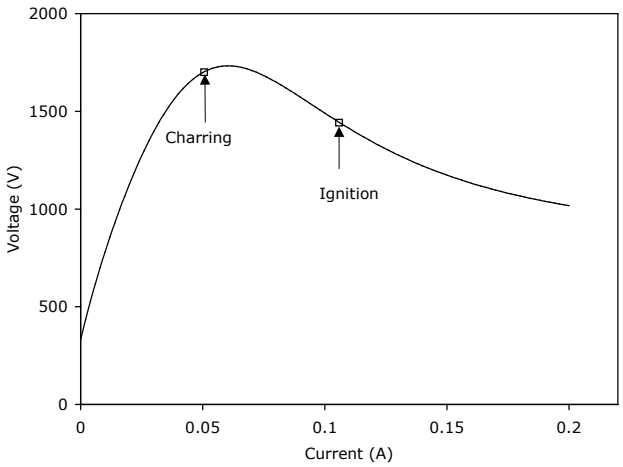

Figure 126 Voltage-current characteristic for Eucalyptus tree specimen bridged across a power line

WOOD COMPONENTS

A limited number of studies of the oxidation or ignition of wood components have been reported. Handa and coworkers[2095] conducted experiments to quantify the relative contributions of the three main constituents of wood: cellulose, hemicellulose, and lignin. They found that at 200ºC, if the HRR developed in the oxidation of cellulose is normalized to 1.0, then the HRR of hemicellulose is 2, the HRR of lignin is 12, while the HRR of wood (birch) is 4. Softwoods have a higher percentage of cellulose than do hardwoods, thus the implication is that they oxidize less readily. The results in this type of study, however, depend both on the temperature used and on experimental details. Roberts[2096] reviewed some other studies and these showed that hemicellulose invariably has a higher HRR than cellulose, but in most other studies the HRR of lignin was found to be much lower than what was determined by Handa, in some cases being lower than the HRR of cellulose. More extensive studies are available in the literature on pure cellulose, but since its oxidation is not the dominant factor in the self-heating of wood, extrapolations should not be made from studies on cellulose to the behavior of wood. Using their oxygen consumption technique, Handa et al. were able to measure the HRR of wood at temperatures as low as 150ºC, but found that up to 180ºC the HRR was quite small. From 180 to 210ºC there was a large jump in the HRR, with a subsequent tapering off (perhaps due to depletion of reactants). Using thermal analysis, they also demonstrated that, in the absence of oxygen, pyrolysis of wood is endothermic over its entire temperature range. They also observed that

even small amounts of moisture (1 – 3% MC) had very strong effects on the reactivity of char, tending to interfere with the consumption of oxygen and promote a closing down of opened-up pore structures. Similar studies were also made by Smith[2097], who studied fibers from numerous woods and found that the reaction rate was strongly affected by the percent of extractives in the fiber (the fraction extractable with an alcohol/benzene solution). For example, as extractives increased from 2.56% (cottonwood) to 7.03% (Ponderosa pine), the reaction rate increased 7-fold.

Buchanan[2098] studied the autoignition of wood components. Hemicellulose was found to ignite at 170 – 180ºC, lignin at 180 – 185ºC, and cellulose at 260ºC. DTA[2099,2100] and TGA[2101] studies conducted in an air atmosphere confirm that exothermicity is initially shown by hemicellulose at the lowest temperature, followed by lignin, followed by cellulose at the highest temperature. The phenol groups in lignin are considered to act as antioxidants[2102], but this fact alone does not give it an especially high ignition temperature. However, Kuriyama[2103] heated wood components in an aluminum retort and concluded that, under his test conditions, lignin had to be heated to a higher temperature in order to produce flammable decomposition products than did hemicellulose. As mentioned in the self-heating section above, limited studies indicate that resinous woods are much more prone to self-heating than non-resinous species. But data do not exist on this point for external-heating ignitions.

PAINTED WOOD

FRS studied the radiant ignition of wood surfaces painted with ordinary house paints[2104]. They found that there were two distinctly different ignition events—first the paint layer ignited, then substantially later the wood itself ignited. They also examined the effectiveness of various fire-retardant paints applied to low-density fiberboard, where they found that for untreated samples the critical flux for piloted ignition was 6.3 kW m^{-2} but that it was 8.4 – 41 kW m^{-2} for samples coated with various FR coating systems. Muir[1998] conducted piloted ignition tests on painted and unpainted cedar and found that oil-base paints slightly increased ignition times, but latex paint or spar varnish showed the opposite effect. In all cases the effect was quite small. The most extensive study so far has been by Staggs et al.[2105], who primed plywood and particleboard surfaces with a water-based primer then coated them with coats of alkyd enamel. Piloted ignition tests with the Cone Calorimeter at a 35 kW m^{-2} irradiance showed that one coat of enamel greatly increased the ignition time, two coats slightly increased the ignition time, while applying a larger number of coats caused a drastic decrease in ignition time (about 7-fold, compared to uncoated wood). A theoretical model was offered which can explain the basic trends. The authors consider that the increase in ignition time comes from a decrease in the surface absorptivity due to paint, while the increase is simply associated with volatile materials being pyrolyzed from the paint.

HARDBOARD

Hallman[440] examined the piloted, radiant ignition of hardboard (Masonite) samples of 1203 kg m^{-3} density and 3.2 mm thickness. His data show $\dot{q}''_{cr}$ = 9.7 kW m^{-2}, B_{ig} = 323. den Braven[1101] tested 6 mm thick hardboard and found $\dot{q}''_{min}$ = 11 kW m^{-2}. In a series of long-exposure experiments, Shoub and Bender[1626] exposed a 6 mm hardboard sample to a very low heat flux of 4.3 kW m^{-2}; autoignition occurred in 3.93 h. Test details are discussed in Chapter 7. Using the LIFT test[2113], $\dot{q}''_{min}$ was found to be 10 kW m^{-2} for 6.4 mm thick specimens and 14 kW m^{-2} for 3.2 mm thick ones. Painted specimens[1779,2113] showed slightly higher $\dot{q}''_{min}$ values of 14.7 – 17.0 kW m^{-2}. This included even a specimen painted with nitrocellulose paint (17.0 kW m^{-2}).

Tran et al.[2106] conducted large-scale mockup tests on wood siding made from hardboard. By placing 40 or 160 kW diffusion-flame burners adjacent to the siding, ignition was obtained in about 1 min. But ignition was not self-sustained and the fire went out when the igniting burner was shut off.

FIBERBOARD

Wood fiberboard (also called cellulose insulation board, even though it does not comprise pure cellulose) is made by interfelting wood fibers. The fibers do not have to come from trees, and a significant fraction is made from bagasse, which remains after sugar cane is processed. Although binders may be added, the felting process is mechanical, augmented by the ability of the lignin component to rebond when heated. The density range for wood fiberboard is 20 to 500 kg m^{-3}, although commercially densities of 180 to 300 kg m^{-3} are the most common. Even though wood fiberboard of 240 kg m^{-3} has half the density of whole wood, which might be 480 kg m^{-3}, its perpendicular-to-the-grain thermal conductivity (ca. 0.035 W m^{-1} K^{-1}) is only about 30% of whole wood's. Fiberboard is commonly used as sheathing board, for insulation of roofs, and as ceiling tiles.

Zicherman and Allard[2107] tested the ignition of fiberboard in the Setchkin furnace (Table 222). Their value for glowing-ignition temperature is essentially identical to the 250ºC recommended above for whole wood. They also measured the thermal conductivity of the FR specimens to be 0.053 W m^{-1} K^{-1} at 28ºC and 0.052 W m^{-1} K^{-1} at 93ºC. The FR treatment was boric acid, present in the specimen at a level of 7%. Much earlier (1947), the AIT of wood fiberboard[443] was reported by NIST as being 216 – 229ºC, but this does not appear to be a reliable value.

Ignition of wood fiberboard does not occur from very small flames such as the methenamine pill test[2032], but commonly occurs from plumbers' torches. Often the smoldering initiation is not observed until flaming breaks out, which can be from a half hour to several hours after initial ignition[2108]. It has been experimentally demonstrated[2109] that an ordinary Bunsen burner is also sufficient for ignition. The investigators found that, using a laboratory pre-burning procedure, only 2 out of 4 types of wood fiberboard tested could be ignited so that, after extinguishing visible flames, progressive smoldering would continue. Both asphalt-coated and uncoated specimens smoldered. However, the specimens which smoldered had densities of 240 and 245 kg m^{-3}, while the ones which did not had densities of 325 and 433 kg m^{-3}. This implies that the probability of initiation of smoldering is inversely related to density. Specimens that did smolder had a smoldering velocity of 66 – 71 mm h^{-1} in still air. These values are very close to the 57 – 79 mm h^{-1} velocities earlier measured by Palmer[2110]. When wind-blown, velocities can increase several-fold over the above values.

Ignitability of wood fiberboard from small-burner flames of the ISO 11925-2 test has been studied[2031]. Except for a very dense grade (443 kg m^{-3}) of fiberboard, ignition always occurred using a 15 s application of flame either to the surface or to the bottom edge, with flame always spreading farther than the 150 mm mark. The ignition temperature of medium-density (exact density unspecified) fiberboard was measured to be 330ºC in Cone Calorimeter testing[2111]. Using the LIFT test, the ignition temperature was measured to be 290ºC on fiberboard of unspecified density[2112].

In Cone Calorimeter tests, the minimum flux for piloted radiant ignition of low-density (270 kg m^{-3}) wood fiberboard was found to be 8 kW m^{-2} (see the example in Chapter 7). In one NIST study[1770] using the LIFT apparatus, the minimum flux for piloted radiant ignition of high-density (900 kg m^{-3}) wood fiberboard, was found to be 9.7 kW m^{-2} using the LIFT apparatus. In another study[2113] a minimum flux of 12 kW m^{-2} was reported for a low-density fiberboard. In a study by Shoub and Bender[1626] where long exposure times were used, it was found that 13 mm thick, 290 kg m^{-3} bagasse-fiber fiberboard autoignited in 0.92 h when exposed to a heat flux of 4.3 kW m^{-2}. Its face temperature was 260ºC at the time of ignition. Test details are discussed in Chapter 7.

Wood fiberboard can self-heat, however, it needs to be stacked into imprudently huge piles to self-heat at ambient temperature conditions. Although the initial temperature of the pile is not known, Mitchell[156] reports of an incident where a fire resulted when a pile of 680 m^3 was created. More numerous are incidents[445] where ignition takes place because the product was not allowed to cool down after manufacture before being stacked. Under such improper cooling conditions, truck-load quantities can ignite. A rough recommendation[1618] is that the product must be cooled down below 80ºC before stacking. Oven-dry fiberboard will adsorb moisture from the air. This is an exothermic process and contributes to self-heating of the material. Moisture effects cannot be included in simple F-K theory, and existing studies on moisture effects with fiberboard are mainly exploratory in nature, but they indicate that the effect can be serious[2115,2114]. Thus, a safety precaution in addition to cooling is to moisten the manufactured product to 8 – 9% moisture before stacking it[2115].

Table 222 Wood fiberboard results tested in the Setchkin furnace.

Specimen	Ignition temperature (ºC)		
	Glow	Flaming piloted	Flaming autoignition
untreated	249	310	377
FR-treated	318	310	427
FR-treated, painted	248	343	438

Thomas and Bowes[2116] re-analyzed the data of Mitchell[156] and Gross and Robertson[109] using a more refined formulation of self-heating theory. Their results (presented as a calculational example in Chapter 9) showed that ignition data of oven samples can be readily correlated in straight lines, just as the theory would predict. However, they then went on to compare the temperature rise predicted in the center of the sample under *subcritical* conditions to the theoretically computed value. The experimental value was about 10× the theoretical value (Figure 127). Thus, they concluded that at least two different exothermic reactions must be taken into account. The first reaction was consid-

ered to be short-lasting, but with a high peak HRR, while the 'main' reaction was much slower. Their conclusion was that the total heat of reaction for either reactions was about 335 kJ kg^{-1}, but disagreement on this value among investigators has been vast. By using the simplest assumption of there being only one exothermic reaction, they assigned an activation energy of about 106 kJ mol^{-1}. Other wood materials results are tabulated in Table 220. Walker et al.[2117] reviewed the Thomas and Bowes findings and concluded: "It is unlikely that any natural organic solid material would oxidize by one single oxidation mechanism."

Walker and Harrison[2122] determined that there is some species effect on the self-heating propensity of wood fiberboard, with Monterey pine being less prone to self-heating than slash pine or European black pine (*pinus nigra*). Oxidation studies showed that there is no significant difference during later periods of thermal exposure, but that at the early stages there is more HRR from slash pine than from Monterey pine. They concluded that the differences can be attributed to the extractives content, which is higher for slash pine.

PLYWOOD

The thermal and ignition properties of plywood are roughly similar to that of whole wood. Thermal conductivity is generally found to be lower for plywood than for whole wood.

Janssens[1252] reported a minimum flux of 15.1 kW m^{-2} for 11 – 12 mm Douglas fir and Southern pine plywood specimens, both at 9% moisture content; the measured ignition temperature was 368ºC. He also found $\dot{q}''_{\min}$ = 24 kW m^{-2} for FR Southern pine plywood. Ignition times of plywood measured in the Cone Calorimeter by various investigators are given in Table 223. Note that ignition times for FR plywood are typically either similar to non-FR specimens, or shorter. Yet, full-scale tests indicate that room fire hazard development is much slower with FR plywood[2118], where its lower HRR plays the key role.

In a series of long-exposure experiments, Shoub and Bender[1626] exposed 13 mm thick, 630 kg m^{-3} plywood to a heat flux of 4.3 kW m^{-2} and found autoignition in 5.17 h. A T_{ig} of 254ºC was measured. The test details are described in Chapter 7.

Loftus conducted measurements self-heating measurements on two grades of plywood using an adiabatic calorimeter[1728]. From his results (Table 224), the computed critical thickness for a slab at 100ºC is 72 mm for plain plywood, while for FR plywood it is 68 mm. Loftus' measurements would imply that the self-heating propensity of plywood is higher than for wood sawdust and chips

Table 224 Self-heating parameters for plywood

Material	ρ (kg m^{-3})	C (J kg^{-1} K^{-1})	λ (W m^{-1} K^{-1})	E (kJ mol^{-1})	QA (W kg^{-1})
plywood	470	2300	0.107	87.9	4.18×10^{12}
FR plywood	590	2300	0.107	96.2	4.85×10^{13}

but this has not been compared under identical conditions of test.

PARTICLEBOARD AND ORIENTED STRAND BOARD

A value of $\dot{q}''_{min}$ = 19.7 kW m^{-2} was determined in the LIFT test[1252] for particleboard of 7% moisture content, and 13 mm thickness; the measured ignition temperature was 422ºC. Other values reported for this material[2113,2123] were $\dot{q}''_{min}$ = 15.5 – 16 kW m^{-2}. It was found the FR particle board required 25 kW m^{-2} for ignition in the Cone Calorimeter[2124]. Using the ICAL test, Urbas and Parker[2125] measured a piloted-ignition temperature for 13 mm Douglas fir particleboard of 270ºC at a flux of 15 kW m^{-2}. For heat fluxes of 30 – 50 kW m^{-2}, T_{ig} rose to 300 – 330ºC.

A value of $\dot{q}''_{min}$ = 14.8 kW m^{-2} was determined in the LIFT test[1252] for oriented strand board of 7% moisture content, 585 kg m^{-3} density, and 11.4 mm thickness; the measured ignition temperature was 364ºC.

WOOD SAWDUST, CHIPS, AND WASTES

Typical thermal properties for wood sawdust are: ρ = 70 – 260 kg m^{-3} (but normally at the low end of this range if the material is not tightly packed); λ = 0.035 – 0.064 W m^{-1} K^{-1}; C = 1700 – 1840 J kg^{-1} K^{-1}. Piloted Cone Calorimeter testing[2126] of wood chips (particle density = 650 kg m^{-3}; bulk density = 200 kg m^{-3}) gave an ignition time of 27 s at 35 kW m^{-2} irradiance and 20 s at 50 kW m^{-2}; these values are not too different from results obtained on very light weight solid wood samples. The Bureau of Mines[346] obtained AIT values of 270ºC for oak sawdust, 279ºC for red cedar sawdust, and 225ºC for bark removed from a 3-year old wood post. Bowes[2127] tested the autoignition of shavings from 6 species of woods in a tube furnace and found T_{ig} values of 238 – 248ºC. For a heated metal bar to ignite pine sawdust, a temperature of 648ºC was found to be needed[1613]. Pryce and Cole[2128] reported on a wide variety of ignition tests with large-scale wood chip piles. Generally, ignition was difficult to achieve since relative humidity was typically 70 – 80% during their tests.

Table 225 Effect of wood species on the self-heating of sawdust

Species	T_o (ºC)*	ρ kg m^{-3}	α (m^2 s^{-1})	E kJ mol^{-1}
Zelkova	118	279	2.3×10^{-7}	99

Sitka spruce	142	131	2.8×10^{-7}	142

* - critical ambient temperature for an 0.61 m thick slab

Kotoyori[2129] conducted adiabatic furnace self-heating experiments on 15 different species of wood sawdusts and found distinct species differences, as shown in Table 225. There is a substantial difference between the least-safe and most-safe species, and this difference is not accounted for solely by density or E, but includes also the effect of QA, values of which were not tabulated by the author.

Sawdust and wood chip piles are known to show tendencies to self-heat. An experimental pile 7 m high reached spontaneous combustion in 9 months[2130]. However, standard recommendations for maximum safe storage heights of wood chip piles[1618] range from 8 to 18 m, depending on the type of wood. Self-heating in wood chips occurs through direct respiration of living cells, microbial action and fungal growth, and direct chemical oxidation of unsaturated fatty acids and other organic components. Fungal growth tends to be seen only after prolonged storage outdoors. A number of case histories of self-heating wood dust and chips have been collected[42]. It is reported[347] that a 30 m high pile of Douglas fir sawdust is likely to "ignite in a few months." Three piles of approximately 19 m high ignited in Sweden after rainy weather; presumably rain aided microbial growth[2131]. A detailed case history of a self-heating fire which occurred in a 250,000 m^3 pile of wood chips has been reported[2132]. The cause was assigned to an unusually high fraction of *resin* and to a presence of some very *fine-size* material. The former has been identified as a factor which tends to lower wood's ignition temperature. The contributing role of the fines was felt to be because they formed a blanketing layer near the outside of the pile, thereby decreasing the availability of convective cooling. Whether this is true is unclear, since if convective cooling is disrupted, so will the flow of oxygen to the center, and reducing oxygen inflow serves to reduce, not increase, the tendency to self-heating. It has also been stated[2133], somewhat more generally, that piles which contain material of varying sizes are found to self-heat more readily than piles of only coarse or only fine material, but a reason is not given. Rain promotes self-heating in wood chip piles, as does tramp metal, due to a catalytic action of iron[1618,2134]. Sawdust from seasoned lumber is less likely to self-heat than sawdust from green trees[2135]; this is presumably due to higher levels of microorganisms in freshly-cut timber.

A qualitative study[2136] has shown that whole-wood chips have a much more pronounced tendency toward self-

heating than do debarked chips. A ranking was established for self-heating as:

debarked chips < whole-wood chips < bark < foliage.

A case history was also reported for a production facility that monitored self-heating in a large pile of about 11 m high. The pile contained 30% whole-wood chips and 70% debarked chips. At 10 days after pile completion, a peak temperature of 97ºC was recorded. The temperature then dropped and leveled off at 57ºC. But one month later, a second rise began, reaching 102ºC. After a brief plateau, the temperature finally rose to 115ºC on the 49th day, at which the experiment was stopped. These results indicate that moisture appears to play a very strong role and that simple Frank-Kamenetskii theory is not appropriate. This was noted by Walker and Manssen[2137], who cited a case of a wood-chip pile where the interior temperature reached 90ºC, but actual fire did not break out until close to 1 year later. They concluded that a sizable moisture effect on the thermal conductivity of the material makes F-K theory inapplicable, and that a pile of sawdust or chips must dry out to below about 98% RH before thermal runaway becomes possible. They also stated that 75ºC is a critical temperature: most piles of sawdust, wood chips or wastes only self-heat to or below this value, with the exothermicity in this regime being due to microorganisms. But if rising temperatures over 75ºC are found, this indicates that chemical self-heating has taken over. There is no natural stopping temperature for chemical self-heating, in the way that bacterial growth stops at ca. 75ºC. Thus, if 75ºC is surpassed, the likelihood becomes significant that thermal runaway has started.

A case has been reported[1197] where filling material comprising sawdust and wood chips ignited from a steam pipe which was at 100ºC. The dimensions of the space occupied by the filling material was not specified, but clearly it was of modest size. In another case, the same authors investigated a fire around a condensate water tank, which was surrounded by wood boards and then with wood shavings. The case is of interest since the temperature of the tank could not have exceeded 100ºC. In another case, the authors describe the ignition of the wood shavings that formed a ceiling insulation around a vent pipe which did not exceed 65ºC. Not involving any elevated temperatures was a series of fires in the 1920s that occurred in icehouses insulated with wood sawdust and shavings[2138]. The wall cavity thicknesses were only 0.3 m, so presumably some contamination played a role.

Springer et al.[2139] conducted laboratory studies on chips of aspen and Douglas fir. For samples that were steam sterilized, killing both bacteria and living cells, no oxygen consumption or CO_2 release could be found below 35 – 40ºC. By contrast, samples free of microorganisms but with living cells not destroyed, showed strong oxidation from room temperature to ca 40ºC, then tapering off to zero as high temperatures killed cell activity when ca. 55ºC was reached. Beyond this temperature, chemical oxidation was seen as the only mechanism available for self-heating. Walker and Harrison[2134] studied the self-heating of wet sawdust and found a large catalytic effect of iron—in the presence of iron compounds, reaction rates approximately doubled. They considered it a relevant factor in spontaneous combustion of wood-wastes, where materials such as lengths of broken wire rope, may often be found.

Bowes and Thomas[2140] reported some self-heating properties of wood sawdust, obtained from a combination of testing, theory, and estimation. They assigned an activation energy E of 96 kJ mol^{-1} for the reaction. The order of the reaction was determined to be n = 2/3. Other results on wood sawdust are listed in Table 220 above. Sopping-wet sawdust cannot smolder. In bench-scale tests, it was found that at 40% MC, sawdust would no longer smolder. At 5% MC, a smolder velocity of 0.55 mm min^{-1} was found, dropping to 0.23 mm min^{-1} at 35% MC.

OILED SAWDUST

The self-heating tendency is exacerbated when the wood material is mixed or contaminated with vegetable or animal oils, nitric acid, and certain glues and organic dyes. Ettling and Adams made a study of sawdust mixed with boiled linseed oil[2141]. In one set of experiments, they found that an 80 g pile of sawdust+oil, mixed in a 1:1 weight ratio, was the minimum weight needed to lead to runaway at an ambient temperature of 22ºC. The time to reach critical conditions was ca. 28 h. At 30ºC, the time dropped to 9 h. A 1:1 mixture was close to the worst condition and increasing the proportion of oil beyond that decreased the amount of self-heating. The 1:1 mixture was also about the maximum amount of oil that will be readily absorbed by sawdust without dripping of excess; the amount of oil which can be absorbed, however, decreases with increasing pile sizes of sawdust. In another series of experiments, where the material was arranged differently, 24 g sufficed to lead to runaway. Moisture in the sawdust was found to reduce the self-heating, but the effect of contaminants, such as metal and floor sweepings was insignificant.

Sawdust mixed with raw linseed oil was studied by Napier and Vlatis[2142]. In their work, they ran both oven-cube tests and hotplate tests on sawdust+oil layers. They found that an oil content of 35 – 40% led to the greatest self-heating, which is not too different from the 50% seen in Ettling's study. They also found that very thin layers (5 mm) tend to crack when self-heating, which affects the heat transfer of the layer. In attempting to reduce their data according to standard self-heating theory, they found that the activation energy depended greatly on the moisture content of the mixture. For predictive applications, data would be needed in a form which accounts for both the loading percent of oil and the moisture content, but the work was not carried to that stage.

It has been suggested that propionic acid could be used to retard the self-heating effects in oiled sawdust, however, this is unlikely to be an economical solution.

WOOD PULP

Buchanan[2098] reported values of 210 – 265ºC for the AIT of various types of wood pulp.

SHINGLES AND SHAKES

Roofing shingles (produced by sawing) and shakes (produced by splitting) that are not fire-retardant treated are ignitable by 38 mm fire brands, but with a probability of significantly less than 100%[1049]. When shingles/shakes are weathered, they become more readily ignitable.

Wood-burning appliances

Wood-burning appliances include fireplaces, wood-burning stoves, wood-burning fireplace inserts, and similar devices. Pellet stoves, which burn small pellets compressed from wood sawdust, are a specialized form of wood-burning appliance. US statistics[289] on fires from these appliances are shown in Table 226 and Table 227.

An early study by Voigt [2143] showed that flue pipe temperatures typically ranged up to 450 – 480ºC. Temperatures on the metal base of stoves went up to 500 – 600ºC. Based on his test results, Voigt recommended that clearances of 300 mm be observed from wood ceilings or joists. For single-wall flue pipes passing through combustible walls, he recommended that either a ventilated air space of 100 mm be provided, or else that the annulus size could be reduced to 50 mm if it was packed with thermal insulation. Peacock[296] examined the results from a number of laboratory studies and concluded that peak external surface temperatures of wood-burning appliances may reach up to 300 – 450ºC, with flue gas temperatures reaching to about 700ºC. However, under improper use conditions, i.e., overfiring, the temperatures can be higher. Figure 128 shows the consequence of overfiring a fireplace with too much wood—a structural wood member inside the wall was ignited right above the fireplace.

Table 226 Equipment involved in wood-burning appliance fires

Source of fire	Percent
appliance	55
chimney	35
chimney connector	10

Table 227 Causes of wood-burning appliance fires

Cause	Percent
improper maintenance	27.5
combustibles (occupant goods) too close	18.1
improper equipment design	10.0
exterior fire from sparks	9.2
improper operation	7.5
ignition of structure	6.7
improper fueling technique	5.5
equipment malfunction	4.4
improper installation	2.4
improper chimney	1.3
use of flammable liquids	1.2
chimney fire	0.2
other	0.3

Figure 128 Ignition of wood wall-framing member from an overfired fireplace
(Courtesy Tim Bradley)

The process of burning wood pellets creates small burning embers which go up the chimney. Roof fires have occurred when such embers leaving the chimney landed on a wood-shake roof[2144].

Wool

The AIT of wool blankets[443] was reported by NIST in 1947 as being 205ºC. The method used, however, appears to give anomalously low values with other materials. Lawson[2145] reported that the minimum flux for ignition of wool fabrics is about 33 kW m^{-2} for piloted ignition and 84 kW m^{-2} for autoignition, but it is not clear what measurements were made to obtain the values.

Self-heating fires are known to occur in bales of greasy wool[1710]. Walker and coworkers examined the problem in a series of very extensive studies[2146-2149]. Self-heating problems do not occur with wool that is sheared—only with wool removed by chemical means or by a rotting process. For the latter, again no problems have been found for grease-free and completely dry wool; however wet (with water in excess of that needed to saturate the interstitial atmosphere) or moist (water content below that needed for saturation) wool will self-heat. The amount of water required to cause interstitial saturation is about 33%, dry basis ('re-gain'), but 'wet' wool can easily contain 100% moisture. Bales of wool at around 400 kg m^{-3} density may show significant, albeit sub-critical, self-heating if they have as little as 18% moisture and are thus substantially below the moisture needed for saturation. Significantly accelerated

self-heating starts for wool under conditions of RH > 85%, with an 85% RH corresponding to about 18% regain. Under most circumstances, self-heating stops at a temperature of around 76ºC, which is indicative of the death of microorganisms. Two types of bacteria are involved in the process—mesophilic ones dominating at lower temperatures and thermophilic ones at higher. Both are aerobic, since no self-heating is found under inert atmospheres. In a few laboratory tests, self-heating up to the vicinity of 100ºC was observed. The exothermicity at such higher temperatures is presumed to be of chemical, rather than biological, nature, but details have not been understood yet. It is also suggested that molds may contribute to the heating process. The balance between biological and chemical reactions is also not fully understood. In terms of moisture, the requirements are opposite: high moisture contents are conducive to bacterial heating, but deleterious to chemical oxidation, since water saturation reduces the supply of oxygen to the interior of the bale. The main chemical effect is considered to be the oxidation of unsaturated fatty acids. Trace amounts of iron and manganese may also act as catalysts. The self-heating of bales of wool is due to the subcutaneous fats that are mixed in, rather than the fibers themselves. Thus, self-heating problems can generally be eliminated by adoption of processing methods which are designed to minimize contamination of the wool with the fats[2150]. A small amount of grease in wool (about 1%) does not contribute to self heating—such wool exhibits self-heating characteristics that are essentially identical to Soxhlet extracted samples[2151].

Self-heating may also occur for bales of wool that are not greasy due to moisture of sorption effects, and Back noted that bales of wool coming from a dry climate have ignited when transported to a humid harbor area[2115]. Karim and Mehta[1418] found that clean wool samples start to smolder at about 200ºC. Jones reported results on standard oven-cube tests on greasy-fleece Merino wool specimens[2152]. For wool at 114 kg m^{-3} density, his data gives E = 91.5 kJ mol^{-1} and P = 42.5. While bulk density, of course, is one of the major variables governing self-heating, it was shown that for wool the fiber diameter does not affect self-heating results[2153]. It has been shown that the energy of compressing wool for shipping has a negligible effect on self-heating. There do not appear to be problems of wool textiles undergoing self-heating except in commercial cleaners' drying facilities, where higher ambient temperatures are attained[2154].

Further readings

Two NFPA publications contain extensive tabulated data. Hazardous Chemicals Data (NFPA 49) is essentially a compilation of brief-form MSDS information; flash points, flammability limits, and AIT values are given where available. Guide to Fire Hazard Properties of Flammable Liquids, Gases, and Volatile Solids (NFPA 325) presents similar information as does NFPA 49, but arranged in tabular format, without narratives. A larger number of chemicals are collected here than in NFPA 49.

P. G. Urben, ed., **Bretherick's Handbook of Reactive Chemical Hazards: An Indexed Guide to Published Data**, 2 vol. set, 5th edition, Butterworth-Heinemann, Oxford (1995). Bretherick's compilation of hazards of reactive chemicals is the most comprehensive collection on this topic. It is especially useful because references are given to primary literature sources for each material discussed. A chemical explanation is generally provided *why* a hazardous reaction occurs, a feature absent in most other hazardous materials handbooks. Of additional interest is Louis Médard's **Accidental Explosions**, 2 vols., Ellis Horwood, Chichester, England (1989). The second volume of this monograph is a handbook of reactive substances; the number of compounds covered is much smaller than in Urben's work, but extensive narrative information is provided for each.

Recommendations on the Transport of Dangerous Goods: Model Regulations, United Nations, New York. The periodically-revised UN compilation is the basis for regulations established in the US by the Dept. of Transportation governing shipping requirements, test methods, and prohibitions. Most common chemicals which are reactive, unstable, etc. are included in the compilation. The listing gives transportation restrictions, but does not provide a chemical description of the hazard.

T. E. Daubert, **Physical and Thermodynamic Properties of Pure Chemicals**, 4 loose-leaf vols. plus annual supplements. Taylor & Francis, Bristol PA (1995). This compilation of thermochemical data is based on the results from an AIChE research project and is an excellent reference for heats of formation of a wide array of pure chemical substances. From the heats of formation, heats of combustion can be computed.

Fire Test Standards, 5th ed., ASTM (1999). Most—but not all—of the ASTM standards that deal with fire performance are collected in this massive, but reasonably priced tome. Apart from the ASTM tests discussed in the present work, this tome contains the full texts of many other test methods dealing with ignition properties in specialized applications.

Chapter 15. Tables

Introduction **1022**
Pure chemical substances **1024**
Mixtures and commercial products **1056**
Aviation hydraulic fluids and lubricating oils **1059**
Refrigerants **1060**
NEC Groups according to chemical families **1061**
Dusts **1062**
Ignition temperatures of solids **1066**
Radiant ignition of plastics and elastomers **1070**
Miscellaneous thermophysical properties of solids **1072**
Further readings **1077**
References **1077**

Introduction

A number of tables are provided in this Chapter to serve as a convenient reference. The user must strongly keep in mind that many industrial ignition hazards occur at elevated pressures or in atmospheres substantially different from ambient. Thus, in assessing specific hazards, recourse should preferably be had to original research literature where hazards of a particular compound or reaction have been studied in detail. Even at a given ambient condition, measurements are notably dependent on test apparatus vagaries. Thus, above all, the reader is cautioned to keep the words of Magison[1] in mind: "*There are few absolute numbers in combustion and ignition studies*."

For the data given in Tables 1 and 2, the following explanation notes are pertinent. The data have been compiled primarily from BM[2,3,4] and NIST[5,6] publications. AIT values in air[*] are mostly from NFPA 325[7]. AIT values in oxygen are mostly from Mullins[8]. Data were also used from Pedley[9], Budaveri[10], Lide[11], Dean[12], Helwig[13], Britton[14],

[*] The values in NFPA 325 generally represent a compilation of the lowest values found in the literature. Thus, these values are best viewed as conservative bounds, not as best-estimate values. In some cases, the values given in NFPA 325 may be in serious error. For instance, the value for methane, reported for many years as 537ºC is actually 640ºC, according to latest and most reliable study (see Chapter 14).

Yaws[15], NACA[16], CPIA[17], Hertzberg[18], Burgoyne[19], Jones[20], Lambourne[21], Lewis[22], Dillon[23], and Snyder[24]. Notation: **g** - the substance is a gas at 25ºC, **s** - the substance is a solid at 25ºC, **e** - estimated value, **pyr** - pyrophoric, **exp** - explodes. Flammability limits in *italics* denote that the substance is flammable only at temperatures higher than ambient, consequently the data were obtained at a temperature higher than 25ºC; the original BM references can be consulted for details of test conditions. NEC Group information is from NFPA 497M[25]. The suffix '**t**' designates a value obtained by test, '**c**' by committee action without testing. Some substances have a dual designation, e.g., B/C. This denotes that the substance is in Group C, as determined by its MESG value, but in Group B, as determined by maximum pressure rise. Vapor pressures at the flash point are from Kueffer and Donaldson[26]. The values cited as 'Calcote' are from Calcote et al.[27] The flanged electrode data (rather than plain) are normally used, since these correspond more closely to the experimental arrangement subsequently used by the Bureau of Mines. Quenching diameters are listed from Grove[28]. The IEC MESG values are as tested by PTB[29]; where unavailable, values from HSE[30] were used. The values cited by NFPA 497 (not shown) are typically similar to the IEC values. The UL MESG values are from UL Bull. 58[31]. UK MIC values are from Slack and Woodhead[32] or from Magison[1] and refer to a circuit with an inductance of 95 mH. None of the values are available as *evaluated* or *best-estimate* constants, that is, having undergone a systematic review process wherein values obtained with poor experimental techniques are rejected in preference to values obtained from experiments judged to be of higher accuracy.

The reader will note that, in a number of cases, lower values are reported for AIT in air than in oxygen. This, of course, does *not* mean that these substances are less readily ignitable in pure oxygen than in air. The anomaly arises because data from different workers or different test rigs have been presented. If experiments are conducted in a single apparatus, the ignition temperatures measured will be lower in oxygen (or, in some cases, equal) than in air.

CAS (Chemical Abstracts Service) registry numbers are provided, since they are a unique identifier for chemical substances. A pure substance may be known by many different names, but it will not have multiple CAS numbers. Conversely, each CAS number denotes a unique chemical substance (there are limited exceptions, primarily for mixtures of isomers that are normally not available individually). The UN (United Nations) designation numbers are also provided, where they are relatively unique. In the UN system, many compounds are not assigned a unique number, but fall into broad categories, for example, "UN 3180: Flammable solid, corrosive, inorganic, n.o.s." These lumped categories have not been listed in Table 1.

Table headings are as follows:
CAS No. – Chemical Abstracts Service registry number
UN No. – United Nations designation
Formula – chemical formula of substance
MW – molecular mass
Δh_f – heat of formation
Δh_c – heat of combustion
C_{st} – stoichiometric volume concentration of fuel
LFL – lower flammability limit
UFL – upper flammability limit
AIT – autoignition temperature
NEC group – National Electrical Code Group
LTL – lower temperature limit
BP – boiling point
P_{vap} – vapor pressure at flash point
MIE – minimum ignition energy
Quench dist. – quenching distance
MESG – maximum experimental safe gap
MIC – minimum igniting current
T_{ad} at LFL – adiabatic flame temperature at the LFL
T_{ad} at stoich – adiabatic flame temperature at stoichiometry

For additional details on these variables, the reader should consult Chapters 3 and 4.

Pure chemical substances

Table 1A Pure chemical substances

Substance	CAS No.	UN No.	Formula	MW	Δh_f kJ mol^{-1}	Δh_c (upper) kJ mol^{-1}	Δh_c (lower) kJ mol^{-1}	Δh_c (lower) MJ kg^{-1}
acetal (1,1-diethoxyethane)	105-57-7	1088	$C_6H_{14}O_2$	118.18	-420.6	3941.3	3633.2	30.74

Versilube F-50 (silicone)	480	288	338

Refrigerants

The flammability of various refrigerants, as measured in the ASTM E 681 apparatus, was reported by Richard and Shankland[34]. They explored many ignition sources for use within the apparatus; their results using a match are listed in Table 4. In most cases, the differences in the flammability limits due to different ignition sources were very slight, but in one case, R-161, there was a major difference, which was not explained by the authors: LFL = 3.0% (match), and = 14.2% (spark). UFL = 18.0% (match), and = 43.7% (spark).

Table 4 Flammability limits for some refrigerants

Formula	Compound	ASHRAE No.	LFL (vol%)	ULF (vol%)
C_4F_8	octafluorocyclobutane	C-318	none	none

NEC Groups according to chemical families

The classification of compounds into Groups by the NEC can be roughly predicted according to chemical families. Table 5 shows the proposal according to NMAB 353-1[35].

Table 5 NEC Groups: prediction according to chemical families

Group	Classes of compounds
B	ethers w. 3-membered ring
C	acetylenes, higher alcohols, small unsaturated aldehydes amines, secondary and tertiary ethers containing $–CH_2$ or $–CH_3$ ethers, cyclic, larger than 3-membered ring glycol ethers mercaptans nitro compounds, aliphatic nitrogen compounds, aliphatic heterocyclic organo lead compounds sulfides (except CS_2)
D	aliphatic hydrocarbons alicyclic hydrocarbons alcohols (exc. those in Group C) amides amines, primary aromatic hydrazines aromatic hydrocarbons chlorinated hydrocarbons esters ethers not containing $–CH_2$ or $–CH_3$ glycols and glycol esters ketones nitro compounds, aromatic nitrogen compounds: cyanides, isocyanates nitrogen compounds: aromatic heterocyclic olefins, higher (most) organic acids organo phosphates organo sulfates and sulfones phenols

Dusts

Dusts of numerous substances have been studied by the Bureau of Mines[36- 45]. Illustrative data from these studies are given in the tables below. The ignition temperatures were determined in the Godbert-Greenwald vertical tube furnace. For dust cloud tests, 0.1 g was dispersed into the furnace. For layer ignition tests, wire baskets 12.7 mm deep and 25.4 mm diameter were used. The LFL values were determined in the 1.23 L Hartmann tube using a 23.5 mA inductive spark. Note that all of these data are highly dependent of the test apparatus and test conditions used. Especially, the discussion in Chapter 5 needs to be considered, where it is pointed out that reported LFL values below 30 g m^{-3} are suspect. Thus, the tabulated results should only be used as relative indications, not as absolute values. The layer ignition temperature testing method used by the Bureau of Mines was roughly similar to performing an oven-cube test for self-heating *at one specimen size*. The limitations of a strategy of this kind must be considered in the context of the principles developed in Chapter 9.

Much more recently, the Bureau of Mines[46] conducted a series of tests on dusts of metals and other pure elements using their 20 L test apparatus. The test apparatus uses extremely powerful pyrotechnic igniters, so the data should be viewed only as relative indications—actual ignition sources may not be so powerful. These results are given in Table 12.

The characteristics of dust clouds for a series of explosives was examined by the Bureau of Mines[47] using their 20 L chamber and a 2500 J pyrotechnic igniter. The results are shown in Table 6. For the loadings examined, all of the dusts produced only deflagrations and not detonations; although the authors considered it likely that if very high concentrations had been tested, detonations would have been seen. The size effect for the dusts of explosives is notably different from that for most other dusts (see Chapter 5): the smallest diameters show a higher, not a lower, LFL value compared to mid-range diameters. In general, the most explosible diameter for these substances is in the range of 10 – 50 μm. As far as actual LFL values are concerned, it is striking to note that these are not particularly low. The authors' analysis indicates that the data become highly consistent with that of common organic molecules if it is assumed that the $–NO_2$ groups in these molecules make *no* contribution to the explosibility and merely act as an inert fraction. The effective volatile fuel fraction is then only 22 – 46% for the explosives examined. Additional testing showed that HMX and RDX dusts, but not the other compounds shown in Table 6, were also explosible in a nitrogen atmosphere. In those cases, the $–NO_2$ groups do play a role, since they provide the only oxidizer available.

Field[48] evaluated a great deal of test data obtained at the Fire Research Station in the UK and considers that, under most circumstances, the dusts listed in Table 14 are non-explosible. A slightly different list has been published by the Bureau of Mines[44].

Table 6 Flammability limits for dusts of explosives

Explosive	Solid density (kg m^{-3})	Diameter (μm)	LFL (g m^{-3})
HMX	1900	7	240

acetamide	copper (foundry dust)	nickel permalloy
alizarine (yellow G)	cupric oxide	oxalic acid
alumina	3,5-diacetylamine 2,4,6-tri-iodo benzoic acid	plumbago
aluminum dichromate	diaminostilbene disulfonic acid	polytetrafluoroethylene
aluminum silicate	dicyandiamide	polyvinylidene chloride
amaranth lake (food red 9)	digitalis lanata leaf	potassium perchlorate
ammonium carbonate	era chrome brown	Prussian blue
ammonium nitrate	era chrome green	seaweed
ammonium perchlorate	erythrosine lake (food red 14)	selenium
bismuth salicylate	ferrous sulfate	sewage sludge, dried
bone charcoal	foundry blacking	shoddy
boron carbide	fuel ash, pulverized	silica
brass dross	graphite	sodium dihydroxy naphthalene-disulfonic acid
bronze	hammerscale	sodium di-isobutyl sulfosuccinate
cadmium red	herring meal	sodium perborate
cadmium sulfide	indigo carmine lake (food blue 1)	sodium trichloro ethyl phosphate
cadmium sulfoselenide	ivory and mineral black	sunset yellow lake (food yellow 3)
cadmium zinc sulfide	lampblack	talc
calcium borate	lead phosphate, basic	tartrazine lake (food yellow 4)
calcium carbonate	lead zirconate titanate	thiourea dioxide
calcium citrate	magnesium oxide	tomato base, spray dried
calcium gluconate	manganese dioxide	trichloro isocyanuric acid
carbon, activated (some)	molybdenum disulfide	tungsten
carbon black (some)	myrobalan and valonia nuts	urea
castor oil meal	naphthionic acid, crude	zinc oxide
coke		

Ignition temperatures of solids

For solids, the ignition temperatures compiled have been determined mainly with the Setchkin furnace (ASTM D 1929) or similar arrangements (Table 15). The reported ignition temperature in that test is the minimum temperature of the *air* near the specimen that is necessary for ignition to occur. A small number of ignition temperatures of solids have also been measured in the ASTM D 2155 test (see Chapter 6); that test was developed for liquids, but solids can also be tested. Available values are given in Table 16; it is evident that the AIT values are substantially higher than those found in the ASTM D 1929 test.

Table 15 Ignition temperatures for a number of solid substances, determined in the ASTM D 1929 test or similar test environments.

Radiant ignition of plastics and elastomers

Radiant ignition properties for a number of plastics are given in Chapters 7 and 14. Here, data from two major studies are provided, those of Hallman[78] (Table 17) and Scudamore et al.[79] (Table 18). Hallman's tests were using radiation from a specially-built flame source, while Scudamore used the Cone Calorimeter.

Table 17 Hallman's results on the radiant ignition of plastics and elastomers

Miscellaneous thermophysical properties of solids

Miscellaneous computed ignition properties for various solids are presented in Table 19. They have typically been obtained by running either Cone Calorimeter or LIFT tests. The properties obtained are 'effective' and were obtained by calculations according to a simplified ignition model and not by direct measurement (except for measured T_{ig} values, where given). The notation used is as follows: MC = moisture content; Thick = thickness of sample (mm); ρ = density (kg m^{-3}); λ = thermal conductivity (kW m^{-1} K^{-1}); C = heat capacity (kJ kg^{-1} K^{-1}); Eff. $\lambda\rho C$ = effective thermal inertia (kJ^2 m^{-4} s^{-1} K^{-2}) ; B_{ig} = ignition parameter, see Chapter 7; α = thermal diffusivity (m^2 s^{-1}); ε_s = radiant absorptivity (--); h_{ig} = effective convective heat transfer coefficient for ignition (W m^{-2} K^{-1}); T_{ig} meas = measured ignition temperature (ºC); T_{ig} comp = computed ignition temperature (ºC); q_{cr} = critical heat flux for ignition (kW m^{-2}); q_{min} = minimum heat flux for ignition (kW m^{-2}).

Further readings

Guide to Fire Hazard Properties of Flammable Liquids, Gases, and Volatile Solids (NFPA 325), NFPA, Quincy MA. This compilation gives listings for close to 2000 pure or commercial (but not trademarked) products. Flash points are included for most listed compounds, with AIT values and flammability limits provided for a fraction of those.

Flash Point Index of Trade Name Liquids, 9th ed., NFPA, Boston (1978). This valuable compilation of over 8800 products is no longer published and the ninth was the final edition.

Alizarine 1066
Alkali-metal carbides 452
Alkanes ... 54-55, 76, 109, 110, 185, 196, 683, 696, 856, 865
Alkyd paints 896-897, 962
Alkylation 6, 451
Alkyl-metal compounds 452
Allene 686, 1048-1050
Alloying 480, 667, **793**, 849, 875
Allyl alcohol 1024-1026
Allyl amine 1024-1026
Allyl bromide 1024-1026
Allyl carbinol 1024-1026
Allyl chloride 1024-1026
Allyl glycidyl ether 1024-1026
Alternators 738
Alumina 308, 314, 750, 751, 829, 1066
Aluminum 59, 72, 83, 86, 89, 149, 151, 161, 163, 165, 168, 211, 307, 319, 328, 353, 355-356, 358, 359, 393, 409, 419, 432, 454-455, 469, 472, 474-475, 480-482, 487-488, 508-517, 526, 534, 549, 552, 561, 572, 593-594, 601, 626-628, 690, 695, 703-704, 706, 719, 733, 753, 759, 769, 772-773, 780, 782, 784, 793, 795, 809, 822, 830, 844, 849-850, 856, 858, 862, **870-872**, 874-875, 878, 890, 896, 901-902, 912, 915-917, 923, 941, 962, 1063, 1065
Aluminum alkyl compounds 452
Aluminum bronze 513
Aluminum chloride 807
Aluminum dichromate 1066
Aluminum electrodes 546
Aluminum facings 307-08
Aluminum hydride 870
Aluminum oxide 357, 511, 517, 550, 750-751, 763, 871-872
Aluminum paints 510, 898
Aluminum particles 74, 500, 510, 514, 517, 553, 843, 872
Aluminum siding 666, 782
Aluminum silicate 1066
Aluminum tanks 624
Aluminum wiring 660, 662, 761, **762-765**, 796
Alva Cape (tanker) 719
Amalgam 870
Amaranth lake 1066
Ammonia 28, 31, 44, 82, 100, 121-122, 452, 476, 620, 623, **691**, 717, 826, 862, 1024-1026, 1060
Ammoniated polyphosphoric acid 706
Ammonium carbonate 1066
Ammonium nitrate 454, 471-472, 474-475, **691-694**, 808, 826-827, 885, 915, 917, 1024-1026, 1065-1066
Ammonium perchlorate 304, 475, 477, 479, 480-482, 484, **694-695**, 808, 858, 872, 885, 914, 1024-1026, 1065-1066
Ammonium perchromate 468
Ammonium phosphate 319, 562
Ammonium picrate 808, 811-812
Ammonium sulfate 562, 692-693, 706, 827
Ampacity 18, 549, 780-781, 794
Ampacity derating 781
n-Amyl acetate 1024-1026
sec-Amyl acetate 1024-1026
Amyl alcohol 1024-1026
sec-Amyl alcohol 1048-1050
tert-Amyl alcohol 1024-1026
n-Amyl amine 1024-1026
n-Amyl bromide 1024-1026
n-Amyl chloride 1024-1026
tert-Amyl chloride 1024-1026
n-Amylene 1024-1026
n-Amyl ether 1024-1026
n-Amyl nitrate 1024-1026
n-Amyl nitrite 1024-1026
Amyl propionate 1024-1026
ANFO 446, 453, 455, 459, 474, 490, **691-694**, 815, 827
Aniline 891, 1024-1026
Animal glue 868
Animal oils 886, 888, 966
Anisole 1024-1026
Anode 313, 466, 534, 539-540, 543, 546, 805, 864
ANSI Z21.10.1 940
Antennas, adventitious 572-573
Anthracene 480, 1024-1026
Anthraquinone 170, 526
Anti-caking agents 692
Antifreeze 226, **695**, 807
Antimony 319, 353, **872**, 1063
Antimony sulfide 472, 868, 915, 917
Antioxidants **400**, 404, 414, 723, 888, 903-904, 962
Antoine equation 185, 192, 199
Ants 667, 787
Apparatus dependence 9, 311
Apparel 321, 559-560, 703, 815, 823, 825
Appliance cords 655-656, 666, 773, **793-794**
APTAC Test 426
Aquariums 663, 758, 775
Arachlor 1059
Arc beads 795-804
Arc fault circuit interrupters 604
Arc flash 545, 642, 665
Arcing across a carbonized path 20, 237, **312-315**, 333-334, 663-664, 671, 673, 725, 732, 753, 756, 758-759, 769, 773-775, 786-787, 790, 804-805, 841, 855, 885, 925, 960
Arcing fault (*see* Electric arcs)
Arcing short 746, 774-779
Arc power (*see* Electric arcs: arc power)
Arc pressure 548
ARC Test (*see* Accelerating Rate Calorimeter)
Arc tracking 20, 237, **312-315**, 333-334, 663-664, 671, 673, 725, 732, 753, 756, 758-759, 769, 773-775, 786-787, 790, 804-806, 841, 855, 885, 925, 960

Arc welding 499, 506-507, 824, 864
Armchairs (*see* Upholstered furniture)
Aromatic hydrocarbons 865
Arrhenius kinetics 47, 60, 120, 247, 252-253, 281-284, 377, 391, 393-394, 405, 419, 426, 451, 458, 469, 488, 705, 723, 813
Arsenic compounds 695
Arsine 1024-1026
Arsonists 575, 725, 747, 765, 829, 864, 940
Aryl-metals compounds 452
AS1241 hydraulic fluid 1057
Asbestos 312, 501, 630, 685, 786, 832, 891, 904, 907
Asbestos-cement 630
Ashes 5, **695**, 711-712, 824, 860, 905, 935
Ashes (*see also* Embers)
Aspen 842, 966
Asphalt 328, 371, 475, 502, 515, 629-630, **696**, 754, 780, 827, 865, 884, 895, 898, 914, 919, 924, 930, 963, 1056, 1075
Asphalt shingles 499, 501, 1073
Aspirin 1065

Bubbles 207, 460-461, 518, 554, 565, 567, 594, 620, 622-624, 627, 694
Buchholz relays 768
Bulking discharge 556, 561-562
Bulldozers 918
Bullets, armor-piercing 621
Bullets, tracer 686
Buna-N rubber 627
Bunsen burner 35, 37, 286, 290, 322-323, 327-328, 433, 435, 507, **518-519**, 778, 820-821, 838, 928, 963
Buoyancy 64, 107, 116, 117, 403, 504, 525, 538, 539, 541, 544, 567, 610
Bureau of Mines 13, 21, 37, 45, 56-57, 60-62, 69, 76, 83, 116-117, 124-128, 146-148, 151, 156, 159-160, 170-174, 204, 221-223, 230, 322, 334-335, 401, 420, 435, 474-475, 484-486, 488-490, 495, 511-512, 514, 538-539, 596, 604, 619, 634, 688-689, 692-693, 717, 719-721, 723, 748, 806-807, 812, 862-863, 867, 870, 880, 928, 953, 986, 1023, 1062, 1065, 1086
Bureau of Mines 1.2 L furnace 171
Bureau of Mines flammability tube 124-125
Burlap 502, 730, 824, 826
Burning buildings 527-531
Burning forests and vegetation 531
Burning particles 74
Burning vehicles 532
Burning velocity 17, 35, 74, 79, 108, 121, 144, 731
Burn injury potential, from fabrics 819-821
Busbars 545, 769-772
1,3-Butadiene 620, 1027-1029
2,3-Butadione 1027-1029
Butanal 1027-1029
1-Butanamine 1027-1029
Butane 28, 31, 55, 56, 60, 62, 64, 89-90, 111, 119, 122, 216, 321, 447, 519-520, 524-525, 566, 594, 612-613, 619-620, 623, 686, 717, 818-819, 856, 866, 869, 882, 931, 936-937, 1027-1029
n-Butanol 194, 196, 199, 209, 1027-1029
2-Butanol 194, 1027-1029
sec-Butanol 194, 1027-1029
tert-Butanol 1027-1029
2-Butanone 1045-1047
2-Butenal 1030-1032
1-Butene 31, 119, 1027-1029
2-Butene 1027-1029
Butter 889
n-Butyl acetate 200, 1027-1029
sec-Butyl acetate 1027-1029
tert-Butyl acetate 903, 1027-1029
n-Butyl acrylate 1027-1029
Butyl amine 1027-1029
tert-Butyl amine 1027-1029
n-Butyl benzene 1027-1029
sec-Butyl benzene 1027-1029
tert-Butyl benzene 1027-1029
n-Butyl bromide 1027-1029
Butyl cellosolve 1027-1029
n-Butyl chloride 1027-1029
Butylene 119, 151, 717, 866, 1027-1029
Butyl ether 1027-1029
Butyl formate 1027-1029
n-Butyl glycidyl ether 1027-1029
Butyl glycol acetate 1036-1038
Butyl glycolate 1027-1029
tert-Butyl hydroperoxide 903
Butyllithium 869
Butyl mercaptan 1027-1029
Butyl methacrylate 1027-1029
tert-Butylperoxybenzoate 451
Butyl rubber 307, 628, 1071
Butyl stearate 1027-1029
p-tert-Butyltoluene 1027-1029
1-Butyne 1036-1038
2-Butyne 1033-1035
2-Butynedinitrile 1027-1029
Butyraldehyde 691, 1027-1029
Butyric acid 1027-1029
Butyrolactone 1027-1029
C4 explosive 55, 684, 810, 849, 986
Cacodyl 695
Cadmium 72-73, 83, 86, 168, 353, 512, 546, 550, 572, 602, **872**, 1063
Cadmium red 1066
Cadmium sulfide 1066
Cadmium sulfoselenide 1066
Cadmium zinc sulfide 1066
Calcined coke 713

Cone Calorimeter..... 217, 249, 252-253, 260-262, 265, 268, 272-273, 290-291, 293-299, 304, 306, 309-311, 317, 326, **330-331**, 333, 338, 344, 725-726, 729, 731, 785, 787, 821-823, 830-832, 842, 854, 861, 883, 890, 896, 899, 906-909, 932-935, 939, 945, 947-949, 952-953, 962-965, 1070, 1072
Cone discharge.....556
Connections 314, 336, 549-553, 600, 731-732, 734, 738-739, 741-743, **755-765**, 766-767, 769, 772, 774, 782, 790-791, 885, 925-926, 928, 939
Contact arcs..... 546-548
Contact discharge.....467, 540
Contacts (*see* Electric contacts)
Contaminants or impurities..... 57, 102, 308, 312-315, 318-319, 361, 374, **400-401**, 472, 481-482, 548, 563-565, 625, 627, 684, 694, 701, 704, 714, 723, 758, 775, 791, 810, 816, 824, 863-864, 873, 876, 886, 891-892, 895, 902, 912, 920, 953, 960, 966
Continuously-stirred tank reactors.....449
Convective heating **277-281**, 288, 297-298, 320, 477, 520, 710, 823, 950, 954
Conveyor belts.....557, 558, **727**, 912, 919
Cooking appliances..... 727-729, 905
Cooking fats..... 886-887
Cooking pans 519, 886-887
Cookoff (explosives)..... 464-465, 474, 487, 917-918
Cool flames.....8, 14, 44, **45**, 54, 57-59, 64, 93, 105, 114, 222, 250, 300, 460, 806-807
Coolite.....481
COPALUM connectors.....765
Copper.... 59, 70, 72, 84, 86, 94-96, 209, 221, 313-314, 319, 334-336, 393, 400, 402, 409, 417, 472, 474-475, 487, 508, 510-514, 534, 536, 540-543, 545-552, 569, 593, 602, 625-626, 670, 695, 703, 744, 759, 760-767, 772-773, 775, 778-781, 787, 789-790, 793, 795-803, 805, 824, 827, 849-850, 855-856, 863, **873**, 879, 884-885, 888, 895, 901, 912, 917, 923, 1063, 1065-1066
Copper acetylide.....468, 684-685, 810
Copper azide.....700
Copper-beryllium alloys.....510, 513, 850
Copper particles.....843-844
Copra 687
Cord reels.....781, 794
Cordelan 816
Cordite 810
Cork 161, 164, 307, 318, 401-403, 407, **729**, 826, 830-831, 896, 1064
Corn 144, 516, 526, 687, 688, 728, 734, 735, 836, 886, 888-889, 1056
Corn dust 508, 515-516
Corn oil..... 728, 734, 886, 889, 1056
Cornstarch.....144-145, 147, 149, 152, 156, 161-163, 165, 168, 448, 826, 1064
Corona discharge.....82, 312, 553-555, 560, 562, 565-566, 569-570, 592, 625, 644, 699-700
Corrugated iron.....630
Corundum.....511, 825
Cosmic radiation.....534, 571
Cosmic rays 534, 571
Cotton...8, 227, 268-269, 289, 301, 304, 311, 314, 316-319, 321, 324-327, 335, 370, 372-373, 401, 410, 433-434, 452, 505-507, 560, 574-575, 614, 619, 708, 716, 718-719, **729-731**, 734, 736, 749, 764, 765, 779, 787-788, 795, 816-829, 842, 844, 856, 861, 868-869, 891, 903-904, 919, 926, 929-938, 1064, 1067, 1073
Cotton, absorbent.....729, 779, 819
Cotton batting 335, 729-730, 929-930, 933, 935, 937, 938
Cotton gins.....507, 688
Cotton linters 1064
Cottonseed meal 826
Cottonseed oil.....828, 886, 889, 1056
CPAI 84.....926
Crankcase explosions 730-731
Crazing 404
Creamer, non-dairy.....515
Creep 549, 756, 763, 789-790, 843, 855
Creepage distance.....314
Creosote.....715, 1056
Crepe rubber.....911
m-Cresol 1030-1032
o-Cresol 1030-1032
Cribs (wood piles) ...335, 518, 521, **523-524**, 527, 617, 931, 951
Crimping.....756, 765, 857
Critical ambient temperature ...370, 375, 381, 400, 425-426, 893, 965
Critical diameter 68, 188, 470-472, 481, 692-693, 695, 814, 833

Critical flux.....217-218, 260, 265, 291-292, 706, 726, 950, 962
Critical stacking temperature.....370, 375, 426
Crossing-point methods.....414-417
Crown fires.....504, 834, 835-840
Crude oil.....197, 217-218, 524, 562, **731**, 865-866, 1056
Crude oil tankers.....865
Crystal growth.....457, 469
CS 191-53.....321, 815, 818-819, 824, 936

Electrical insulators 553, 791, 806, 851
Electrical pruning 841
Electric appliances....728, 737, 740, 905, 918
Electric arcs 13, 19, 86, 175, 227, 313, 335, 466, 499, 507, 534, **540-548**, 571, 599, 601, 732, 747, 757, 773-774, 795, 823, 844, 854, 857, 861, 910, 941
Electric arcs: arc current..... 541-577, 745-746, 770-772
Electric arcs: arc power 542, 544-545, 772
Electric arcs: arc voltage..... 542-548, 770-772
Electric batteries 687, 739, **742-743**, 804, 925
Electric batteries, adventitious....553
Electric batteries, lithium....743
Electric blankets 740, 743-744
Electric cables 310, 312, 327, 332, 334, 766, **773-806**, 849
Electric cables: insulated distribution cables..... 772
Electric circuit interruption devices....744-746
Electric conduits....772-773
Electric condulets 773
Electric contacts 65, **70-73**, 74, 80-81, 466, 540-541, 546-551, 603, 725, 733, 740, 742, 745-746, 754, 756, 758-759, 762-763, 766, 769, 781, 788, 790, 793, 795, 804, 855
Electric current 14, 84, 402, 472, 480, 499, 534, **548-553**, 571, 756, 762-763, 782, 849, 960
Electric equipment....740-741
Electric equipment (*see also* specific equipment)
Electric fences 746
Electric heaters (*see* Heaters, electric)
Electric lamps, arc discharge....750-752
Electric lamps, fluorescent 739, 752, 755
Electric lamps, halogen 749, 750
Electric lamps, incandescent 709, 747-749, 755
Electric lamps, mercury vapor....750
Electric lamps, sodium 750-752
Electric matches 482, 701
Electric mattress pads....744
Electric motors 755
Electric outlets.....10, 643, 655, 658-662, 731, 738-739, **755-766**, 774, 779, 787, 794, 926
Electric outlets, backwired 660, 759-765
Electric outlets, duplex....643, 658-662, 759-765
Electric plugs....653, 655-658, 660, **755-766**
Electric panelboards 654, 664, **769-772**
Electric service drops 772-773
Electric service entrance....772-773
Electric sparks 14, 65, 118, 126, 145, 153, 170, 172, 175, 205, 210, 225, 273, 293-295, 298, 311, 331, 334, 446, 466-467, 514-515, **537-540**, 554, 625, 685, 752, 807, 825, 875, 877, 885, 933, 935
Electric squibs 472, 476, 482
Electric statistics....737-740
Electric switchboards 769-772
Electric switches....766
Electric transformers 766-769
Electric transmission and distribution systems....766-773
Electric wires..... 4, 304, 310, 534, 552, 568-569, 706, 728, 738, **773-806**, 815, 924
Electric wires, fire melted 795-796
Electrified houses 666, 782
Electrodes....71, 79-83, 127, 165-166, 170, 176, 313, 334-335, 467, 486, 534-536, 540-543, 545, 551, 554-556, 560, 566, 572, 602, 699-700, 770, 773, 783, 793, 848, 861, 909, 941
Electrodes, flanged 68, 69, 82, 83, 127, 104, 1023
Electromagnetic waves....571-574
Electromigration....763
Electronic ballasts 755, 784
Electronic components 806
Electronic equipment..... 327, 336, 374, 593, 740-741, 783,

784, 923, 926
Electronic equipment (*see also* specific equipment)
Electron tunneling....763
Electron volt....534
Electrostatic charging of granular materials 561-562
Electrostatic charging of liquids 562-567
Electrostatic charging of persons and apparel.... 559-561
Electrostatic charging of solids 557-559
Electrostatic discharge 146, 152-53, 166, 466, 476, 539-540, 554-555, 559, 561, 563-566, 592, 719, 736, 915, 917, 923
Electrostatic eliminators....592
Electrostatic sensitivity of explosives 466-467, 476, 486
Elements, ignition of 352-364
Elevators, grain....736
Elovich kinetics....714
Embers 2, 6, 152, 237, 292, 503, 629, 630, 695, 835, 860, 882, 951, 961, 967
Embers (*see also* Ashes)
Emissive power.... 305, 523-527, 529-530, 710
Emulsions 189, 454, 474, 694, 890
EN 50281-1-2 420
Encapsulation....600
Enclosures....18, 44, 96, 310, 327, 572, 600-601, 603, 610, 612, 727, 740-741, 772, 807, 918, 925-926
Endothermic compounds 445, 447
Endothermic reactions 14, 694, 911
Energy fluence 274-275, 291, 461, 463-465, 471, 477-478, 482, 574, 705, 709, 813, 821-822, 952
Energy of detonation....28, 814
Energy of explosion 28, 453, 814
Engine nacelles 211-212
Engines 26, 39, 55, 64, 124, 209-213, 223, 505-506, 517, 537-538, 691, 695, 730-731, 802, 806, 815, 834, 843, 865, 867, 877, 881-884, 918
Engines, diesel 806
Enkatherm....816
Enthalpy ... 25-27, 30-31, 255, 354, 356, 358, 376, 427, 447, 450, 455
Epichlorohydrin 1033-1035
Epoxidation....912
Epoxy....167, 218, 300, 323, 475, 509, 690, 725-726, 766, 898, 1067, 1072-1073
Equicylinders 379-381, 391, 475, 730
Equivalence ratio **29-30**, 50, 56, 61, 75-77, 81, 85, 89, 107, 116, 124, 147-148, 163, 190-191, 203-204, 211, 250, 538, 616, 688-689, 818
Era chrome brown....1066
Era chrome green....1066
Erbium 876
Erythrosine lake 1066
ESCA 21, 799
Essential oils 887
Esterification....451, 707
Ethane 15, 31, 55, 60, 62-63, 69, 76, 91, 109, 119, 121-122, 328, 767, 809, 864, 866, 928, 1036-1038
1,2-Ethanediamine 1036-1038
Ethanethiol....1036-1038
Ethanol.... 31, 59, 94, 101, 115, 119, 120, 122, 194, 196, 209, 506, 512, 562, 713, 717, 824, 851, 1036-1038
Ethanolamine 1036, 1037, 1038
Ether extraction 734
Ethers.... 109, 221, 562, **806**, 1059, 1061
Ethoxy ethane 1036-1038
2-Ethoxyethanol....1036-1038
2-Ethoxyethyl acetate 1036-1038
Ethyl acetate 31, 113, 115, 717, 1036-1038
Ethyl acetoacetate....1036-1038
Ethyl acetylene 1036-1038
Ethyl acrylate....1036-1038
Ethyl alcohol (*see* Ethanol)
Ethylamine....1036-1038
Ethylbenzene 119, 1036-1038
Ethyl benzoate 1036-1038
Ethyl bromide 1036-1038
2-Ethyl-1-butanol....1036-1038
Ethyl butyl ketone....1036-1038
Ethyl cellosolve 1036-1038
Ethyl cellulose 161, 1067
Ethyl chloride 1036-1038
Ethyl cyclobutane 1036-1038
Ethyl cyclohexane....1036-1038
Ethyl cyclopentane 1036-1038
Ethylene....28, 31, 53, 60, 64, 75-76, 87, 89, 101, 103-104, 113, 119, 121-122, 447, 508, 511, 513-514, 525, 572, 599, 620, 623, 717, 767, **807**, 850, 863, 888, 1027-1029
Ethylene chlorohydrin 1027-1029
Ethylene diamine....1036-1038
Ethylene dichloride....119, 1036-1038
Ethylenedinitramine.... 1036, 1037, 1038
Ethylene glycol.....64, 199-200, 225, 594, 695, **807**, 856, 890, 1027-1029
Ethylene glycol monobutyl ether....200, 1027-1029
Ethylene glycol monobutyl ether acetate....1036-1038
Ethylenimine....1036-1038
Ethylene oxide 53, 60, 87, 113, 122, 403, 447, 597, 619-620, 717, 806, **807-810**, 905, 909, 913, 1036-1038
Ethylene-propylene rubber 757, 784, 1067
Ethyl ethoxyacetate....1036-1038
Ethyl formate 1036-1038
Ethyl glycol mononitrate 454
2-Ethylhexaldehyde....904, 1036-1038
2-Ethyl hexanol 1036-1038
2-Ethylhexyl acrylate....1036-1038
Ethylidene chloride....1036-1038
Ethyl lactate 1036-1038
Ethyl mercaptan....1036-1038
Ethyl methacrylate....1036-1038
N-Ethylmorpholine....1036-1038
1-Ethylnaphthalene....1036-1038
Ethyl nitrate 447, 811, 1036-1038
Ethyl nitrite....1036-1038

Ethyl propionate 1036-1038
Ethyl propyl ether 1036-1038
Ethyl *sec*-amyl ketone 1039-1041
Ethyl selenide 1039-1041
Ethyl silicate 1039-1041
Eucalyptus 503, 843, 847, 951, 961
Europium 876
EVA 21, 246, 784, 786, 907, 917
Exhaust ducts 733
Exhaust manifolds 209, 210, 806, 837, 883-884
Exhaust particles 499, **505-506**, 843, 918
Exhaust systems 596, 826, 883-884
Exothermic reactions 6, 9, 14-15, 19, **44-46**, 47, 282, 288, 315, 353, 357, 369, 371, 394, 431, 445, 451-452, 455, 468, 480, 683, 689, 694, 696, 705, 809, 826-827, 891, 897, 913, 922-923, 963
Exploding bridgewires 21, 86, 472, 571
Exploding wires 21, 86, 472, 571
Explosion limits 15, 17, 20, 105
Explosion severity 598
Explosionproof equipment 96, 149, 205, 597-601, 603-604, 807
Explosions 6, 10, 13-15, 17, 20, 22, 24, 28, 36-37, 43-44, 73, 78, 96-99, 105-107, 120-123, 128, 142-146, 150-151, 153, 159-162, 167, 173-177, 184, 193, 205-206, 209, 215, 217, 223, 249, 319, 359-360, 364, 377, 405-406, 420-421, 428, 435, 445, 448, 450-457, 459-460, 463-464, 466, 468, 470, 472-473, 482-483, 486-488, 509, 512, 515, 526, 553-554, 564, 573-574, 595-598, 600-602, 604, 609-610, 612, 614-615, 617-622, 627, 683-686, 688-695, 709-710, 719-721, 724, 726-727, 730-732, 736, 739, 742-743, 748-750, 752, 766-769, 772, 778, 782-783, 789, 804, 806-815, 826-827, 847-850, 853, 863-865, 871, 875-876, 880, 885-886, 891, 894-895, 902-903, 913-915, 917-918, 920-923, 927, 939
Explosions, damages from 614-615
Explosions, heterogeneous 449
Explosions, manhole 772
Explosions, physical 9, 14, 620, 767-768, 847, 927
Explosions, primary 128, 144, 146
Explosions, secondary 144, 146
Explosions in buildings 609-612, 646-647
Explosives, chemistry of 455-456
Explosive substances 28, 425, 429, **445-490**, 692, 808-815, 1062
Extension cords 666, 738-739, 761, 773, 776, 779, 780-782, 788, 790, 793-794, 883
Extinguishers 719
Extractives 942, 962, 964
Extremely insensitive detonating substances 484
Extrusions 454
Fabrics 15, 268, 280, 301, 304, 310, 315, 317, 321-322, 337, 373, 502, 520, 559, 575, 591, 719, 733, **815-826**, 856, 926, 928-931, 933, 934-938, 967
Factory Mutual tests 227, 264, 332-333
Faraday cage 593
FAR Bunsen Burner Test 328
Farm machinery 826
Fecal matter 735, 787
Feedstuffs 826
Felt 826
Ferric hydrate 689
Ferric oxide 480, 863, 865, 868
Ferrosilicon 452
Ferrous sulfate 865, 1066
Fertilizers 371, 435, 687, **826-827**
FF 3-71 322
FF 4-72 938
FF 5-74 322
Fiber saturation point 835
Fiberboard 269, 293, 312, 316, 328, 337, 399-400, 410-413, 446, 468, 619, 701, 754, 788, 830, 919, 945, 947, 950, 952, 955, 959-960, **962-964**, 1067, 1073
Fiberglass 21, 171, 314, 513, 690, 699, 725, 855, 909, 919-920, 929, 931, 956-957, 1073, 1076
Fiber-reinforced plastics (*see* Fiberglass)
Fibers 154, 308, 319, 397, 404, 434-435, 560, 597, 619, 685, 701, 708, 711, 719, 730, 788, 816, 817, 820-821, 823, 825, 827-828, 832, 873, 887, 904-905, 909, 919, 922, 929, 962, 968
Fibers covered with oil 827-829
Filling stations 851-853, 924
Filter paper 253, 329, 485, **704-705**, 729, 826, 870, 899, 930
Filters 563-565, 688, 699, 736, 848, 896-897, 917
Finishing agents (for fabrics) 825
Fir 836, 838-840, 842, 897, 952, 954, 1074
Fire **15**
Fireballs 154, 456, **524-527**, 533, 536, 570, 574, 614-617, 619-620, 622-623, 641, 648-649, 687, 824, 892, 917
Firebrands 74, 240, 499, **500-505**, 507, 528, 596, 629, 650, 735, 842-844, 857, 862, 872, 934, 950-952
Firecrackers 482, 855, 915-916
Firedamp 83
Fire enclosures 727, 925
Fire extinguishers, carbon dioxide 719
Fire extinguishers, dry chemical 562
Fire guards 596
Fire hoses 829
Fireplaces 507, 596, 715, 858, 940, 967
Fire point 15-16, 18, 183, 192, **193-194**, 195, 198-199, 219, 225, 239, 247, 301, 618, 696, 702, 704, 856, 862, 890, 913
Fire retardants, effect of 308-309, 905, 908-909, 952-953, 1067-1070, 1072, 1074-1075
Fire spread, probability 6, 529, 844-845
Fire tetrahedron 7
Fire triangle 6-7, 10, 24, 105
Fire whirl 504
First fire 482, 960
Fishmeal 687, 826, **829**

FIST Test 332

Flame 6, 8, 14-16, 32, 43-45, 64-66, 74, 77, 84, 96, 105, 108, 120-121, 144, 152, 172, 206, 208-209, 237-240, 242, 244, 248, 250, 253, 266, 272, 286-287, 289, 293, 305, 307, 315, 320, 322-323, 326, 328-329, 332, 369-370, 457, 464, 470, 473, 518-524, 527-530, 532-533, 538, 574, 595, 612, 615-618, 620, 624-625, 631, 642, 683-684, 702-703, 716, 724, 728, 730, 741, 774, 777, 779, 786, 794, 803, 806-807, 818-819, 829, 833, 835, 837, 839, 848-849, 860, 866, 882-885, 900, 903, 912, 926, 928, 931, 938, 940, 948, 950-952, 963
Flame acceleration 121, 154, 619
Flame arresters 44, 594-596, 604, 940
Flame cap 65
Flame-ignition tests 329
Flame kernel 18, 66-67, 70, 79, 81-83, 95, 104, 120, 127, 203, 250, 254, 538-539, 555
Flames, as an ignition mechanism 73-74, 286-287, 289, 518-532
Flame speed 35-36
Flame stretch 32, 67, 107, 117
Flame traps 594
Flame velocity 17, 107, 207, 595
Flammability limits 104-120, 145-148
Flammability limits (*see also* specific substances)
Flammable atmospheres..... 10, 73, 85-86, 96-97, 147, 470, 473, 510, 512, 517, 538, 546, 555, 561, 565-567, 572, 596-604, 625, 686, 719, 752, 807, 853, 898, 927
Flammable atmospheres, equipment for 596-604
Flammable liquids.... 4, 14-18, 116, 184-186, 200, 206, 215, 506, 515, 564, 565, 697, 728, 810, 815, 861, 864, 967
Flammable solids 15, 322
Flammable Solids Test 322
Flanges 82-83, 98-100, 128, 149, 558, 600-601
Flannel 304, 505, 824
Flares 472, 479, 482, 527, 726, 810, 916, 918
Flashback 79, 127, 594, 596, 685, 686
Flash fires 142, 208, 615, 619, 939
Flashing..... 8, 15, 193, 201, 215, 223, 239, 244, 247, 253, 287, 288, 290, 309, 575, 621, 805, 836, 874, 905, 925
Flashlights 743
Flashover (combustion) 16, 307, 529, 532, 534, 615-616, 766, 802, 841, 925, 934
Flashover (electrical) 16, 773
Flash point 14-17, 21, 110, 114-115, 183-184, 187-188, **192-202**, 205-206, 210, 212-218, 223-225, 239, 246-247, 301, 338, 506, 631, 691, 695-698, 702-704, 731-732, 850, 861-862, 865-887, 890, 897, 903-904, 909, 913, 915, 921-924, 927, 968, 1023
Flash powder 153, 810, 915-916
Flash vaporization 623
Flax 736, 827, 887
Flea foggers 686
Flexible couplings 690
Flexible intermediate bulk containers 556
Flexing 731, 789, 927
Flints (cigarette lighter)..... 509, 513, **872**
Floating neutral 782-783
Flock 154, 166
Floor area, effect on ignition probability 4
Floor buffers 829
Floor coverings 292, 507, 640, **829-831**, 950
Flour 153, 167-168, 482, 515, 526, 687, 833, 907, 916, 923, 1064
Flower pots 901
Flow rate 35, 63, 74, 96, 126, 143, 209, 211-212, 227, 248, 250, 297-298, 311, 359, 370, 397, 562, 611, 704, 723, 825, 849, 851, 853, 871, 876, 909, 951
Flow velocity 36, 59-60, 79, 85-86, 89, 93, 97-98, 207, 211, 213, 252, 278, 281, 294, 297, 299, 337, 359-360, 409, 418, 538, 542, 563-564, 567, 594-595, 610, 873, 951
Flue-pipe ignitions 960
Flueric ignition 518
Flues **715**, 846, 858
Fluidic ignition 518
Fluorine..... 16, 452, **891**, 902
Fluoroethane 1060
Flux-time product 259
Flying brands 74, 37, 335, 499-500, 615, 629, 835
Flying brands (*see also* Firebrands)
FM Fire Propagation Apparatus 264, 332
Foam rubber 911
Foams 21, 206, 271, 310, 316, 908, **909-912**, 928-929, 931-934, 936
Fodder 687, 847
Fog 535, 618, 961
Food blue 1 1066
Food red 9 1066
Food red 14 1066
Foodstuffs 833
Food yellow 3 1066
Food yellow 4 1066
Forced ignition..... 18, 65, 239, 451
Forest materials 833-847
Forests 503, 531, 569, 629, 840
Formaldehyde 45, 111, 755, 759, 897, 910, 1039-1041
Formic acid 1039-1041
Forward smolder 316, 317, 319, 951
Foundry blacking 1066
Fourier number 283
Foxfire 903
FR-1 Test 327
Fractional distillation 186, 847
Frank-Kamenetskii (F-K) theory 93, 358, **374-383**, 394, 403, 406, 428, 457, 723, 905, 909, 966
Frank-Kamenetskii, David..... 47, 374
Frank-Kamenetskii number 379
Freon..... 686, 876, 1027-1029
Freon 142b..... 1027-1029
Fretting 769
Friction 6, 15, 20, 74, 152-153, 322, 353, 457, 459-461, 466, 472, 476, 482, 484-485, 488, 499, **507-516**, 553-554, 560, 570, 625-626, 693, 695, 700, 716, 721, 727,

729, 733, 736-737, 745, 811-813, 826, 829, 834, 868, 870, 882, 884, 895-896, 900, 912-915, 921, 927, 941
Friction coefficient 508, 626
Friction sensitivity tests 484, 813
Froths 206
Frozen liquid droplets 206
Fruit cereal 833
Fuel-air explosives 619
Fuel ash, pulverized 1066
Fuel concentration, effect of 56-57, 73, 76-77, 154, 161, 191, 211, 215-216
Fuel exhaustion 268
Fuel oil 187, 194, 206, 218-219, 225, 565, 683, 692-694, **847**, 848, 890, 1057
Fuel tanks 215-217, 594, 690, 698-699, 848, 882
Fuel type, effect of (*see* Molecular structure)
Fundamental flame speed 17, 35
Fungal growth 774-775, 965
Fungicides 864
2-Furaldehyde 1039-1041
Furan 806, 1039-1041
2-Furanmethanol 1039-1041
Furfural 1039-1041
Furfuryl alcohol 891, 1039-1041
Furnaces 91, 156, 190, 277, 364, 739, **847-849**, 858, 862, 940
Furniture 269, 271, 287, 503, 519-521, 527, 615-616, 703, 719, 726, 728, 730-731, 751, 756, 790, 794, 817, 829, 849, 859, 905, 909, 912, 921, 928-938
Fuse cord 482
Fused-wire ignition 94-96
Fuses 95, 321, 738, **744**, 768, 769, 772, 790
Fuses, expulsion type 652, 768, 841
Fusible pellet 742
Fusible plugs 685
Fypro 824
Fyrquel 220 hydraulic fluid 1057
Gadolinium 876
Galling 896
Gamma rays 574
Garages 734, 882-883, 939
Garbage 726, 826, 867
Gardening equipment 596
Gas connectors (*see* Gas lines, flexible)
Gas lines, flexible 665, 671, 782
Gas discharge 524, 534, 540, 555, 573, 753
Gas discharge tubes 593
Gases 43-128
Gas explosions, damages from 614
Gas jets 91, 97, 461, 479, 519-520, 527, 614
Gas leaks 834, 848
Gas meters 849
Gas oil 206, 732, 865, 1057
Gasoline 8, 45, 55, 84, 106, 119-120, 184, 193, 199, 209-210, 215-216, 219, 221, 239, 453, 506-508, 515, 523, 525, 562, 594, 596-597, 612-613, 620, 631, 683, 690, 692, 696-697, 702, 717, 733, 748, 750, **849-853**, 856, 858, 860-861, 865-866, 882-884, 890, 892, 913, 915, 926, 939-940, 1057
Gasoline containers 851-852
Gasoline filling stations 852-853
Gasoline filling station tanks 853
Gasoline spills 219, 613, 940
Gasoline substitutes 851
Gas piping 609, 782, 849
Gas regulators 849
Gear oil 1057
Gel candles 704
Gels 454, 474
Generators 571, 603, 738, 739, 884, 885, 895, 918
Germanes 921
Gerstein anomaly 201-202
GFCI devices 671, **853**, 855-856
Gibbs free energy 217
GIRCFF 816-817
Glass 59, 66, 82-83, 87, 95, 124-127, 195, 205, 219, 221-222, 421, 433, 460, 472, 485, 513, 527-528, 520, **533-534**, 559, 565, 571, 575, 576, 618, 628-631, 691, 693-694, 702, 709, 745, 747-752, 754, 806, 809, 868, 886, 905, 913, 934
Glass, Pyrex 559
Glass jugs 575
Glass wool 881, 891
Gloves 592, 912
Glow 8, 16, 45, 54, 91, 160, 172, 205, 225, 249, 301, 315, 320, 336, 534, 537, 547-548, 550-552, 555, 570, 573, 705, 741, 748, 752, 754, 759, 785, 795, 816, 868-869, 872, 876, 903, 908, 946, 951
Glow discharge 534, 537, 547-548, 570, 573-754, 795
Glowing combustion 299, 315, 337, 353, 503, 504-505, 761, 816-817
Glowing connections (*see* Overheating electrical connections)
Glowing ignition 91, 238, 245, 278, 297-298, 302, **315**, 575, 674, 704, 710, 729, 816, 818, 837, 841, 843, 877-878, 945-946
Glowing nests 153, 403
Glow-Wire Flammability Index 741
Glow-Wire Ignition Test 327, 336
Glycerides 887
Glycerin 194, 452, 481, 814, 892, 1039-1041
Glycerol (*see* Glycerin)
Glycols 45, 808-809, 890, 904, 1061
Godbert-Greenwald furnace 153, 156, **170-171**, 176, 419, 435, 598, 638, 923
Gold 84, 94, 353, 512, 517, 546, 553, 846, 879, 916, 923
Golden powder 475
Grain 143, 152-153, 318-319, 405, 461-463, 470-471, 479, 480, 502, 508, 516, 687, 734-736, 748, 795, 796, 814, 883, 914, 942, 946-950, 958, 962, 1064, 1076
Grain dust 152-153, 405, 508, 735-736, 748, 1064
Grain elevators 736
Grain orientation 948-950
Grain size 463, 470-471, 479, 480, 814, 914

Grandcamp (steamship) 692
Granular materials... 143, 315, 369, 373, 398, 410, 451, 467, 474, 561, 562
Graphite 25, 86, 144, 146, 306, **359-360**, 526, 690, 765, 805, 809, 874, 909, 917, 1063, 1065-1066, 1073
Grass 298, 318, 502, 506, 574, 630, 735, 746, 834, 835-837, 839-840, 844, 847, 884, 897, 920, 926, 1064, 1073
Grasslands....531, 629
Grass seed 1064
Gravity 64, 89, 113, 116, 191, 304, 539, 617, 883
Great Hakodate Fire....501
Grills 739
Grinding 152-153, 175, 205, 360, 475, 508-509, 511-512, 514-516, 561, 739, 817, 825, 850, 875-876, 886, 898, 918, 922, 927
Grinding wheels....509, 512, 515-516, 825, 898
Ground fault circuit interrupters (*see* GFCI devices)
Ground faults 18, 604, 728, 738, 740, 770-771, **781-783**, 849
Grounding 10, 16, 18, 562, 565, 567, 591, 688, 719, 782, 783, 852, 855, 856
GRS rubber 911
Guanidine nitrate....1066
Guano, bat....1065
Gum arabic..... 868, 917-918
Guncotton 453, **707-710**, 808, 810-811
Gunny sacks....824
Gunpowder (*see* Black powder)
GWIT ratings (UL) 336
Gypsum wallboard.....269, 312, 764, 802, **853-854**, 1073
Gypsum wallboard, Type X....1073
Hafnium 359, 1063, 1065
HAI ratings (UL) 334
Hailstones 557
Hairdresser chemicals 854
Hair dryers 653, **731**, 739-740, 794
Hair 335, 571, 614, 756, 832, **854**, 861, 902, 905
Half-time....393, 405, 420
Halogenated hydrocarbons....562, 870
Halogenated substances 7, 108, 111, 118, 125-126, 157, 168, 193, 200-201, 237, 240-241, 308-309, 331, 447, 562, 686, 870, 874, 876, 920
Halogenation....451, 876
Halogen fluorides....891
Halogens 16, 27, 59, 74, 110, 118, 157, 200, 323, 747, 749-750, 871, 891, 935
Halons....118, 920
Hammerscale 1066
Hand tools....152, 508, 515
Hardboard 242, 286, 293, 295, 312, **962**, 1073-1074
Hardeners....897, 902
Hardening 404, 888
Harmonic distortion 783-784
Hart heat flux calorimeter 428
Hartmann apparatus 160, 172, 638, 898
Hartmann bomb (*see* Hartmann apparatus)
Harvesters....834
Hastelloy alloys 626
Hay 238, 241, 289, 369, 371-373, 390, 399, 446, 540, 687, 716, 718, **833-847**, 883, 885, 956
Haystacks....371, 398, 845-846, 956
HDPE....559
Heart rimu....1076
Heat Accumulation Storage Test 422
Heat cables....744, **854-856**
Heated tube tests....124
Heaters, catalytic 856
Heaters, electric 222, 643, 738, 794, **856-858**, 951
Heaters, portable....858
Heat exchangers....6
Heat flux 16
Heat flux calorimeter 428
Heat flux density....16
Heat guns 854
Heating elements 59, 171, 719, 733, 744, 754, 802, 837, 856-858, 922, 928
Heating equipment..... 6, 736, 739-740, **858-859**
Heat of combustion.....25-28, 30, 39, 67, 110, 147, 196-197, 204, 227, 248, 255, 291, 353-354, 356, 404, 453, 475, 500, 512, 519, 524, 619, 701, 710, 719, 723, 849, 860-861, 873, 900, 925, 941, 943, 1023
Heat of condensation 399
Heat of decomposition....15, 354, 447-449
Heat of detonation 28
Heat of explosion....28, 447, 456
Heat of formation.....25-27, 74, 354, 356, 358, 445, 447, 763, 1023
Heat of sorption 399, 721, 846
Heat release rate....21, 35, 121, 155, 227, 291-292, 309-310, 326, 328, 330, 332, 445, 449, 458, 466, 476, 504, 518-525, 537, 567, 616, 631, 700-701, 727, 733, 740, 809, 832, 835, 858, 861, 869, 883, 889, 895, 897, 904, 925, 933, 938, 941, 949, 952, 959, 961, 964
Heat tapes 740, 744, **854-856**
Heat tracing 856
Heat transfer liquids....856
Hemicellulose 704, 942, 946, 961-962
Hemp 373, 687, 816, 827, **867**, 929
Hempseed oil 371, 867, 887, 889
Henkin Test 487-488
Heptane..... 31, 46, 53, 61-63, 86, 87, 104, 115, 119, 188, 190-191, 194, 196, 203, 208-209, 562, 563, 717, 719, 1039-1041
1-Heptanol 1039-1041
2-Heptanone 1039-1041
3-Heptanone 1036-1038
1-Heptene 1039-1041
2-Heptene 1039-1041
1-Heptyne 1039-1041
Herring meal....1066
Heterogeneous explosions 449
Heterogeneous reactions..... 315, 358, 396, 449, 476, 683
Hexaborane....701

Hexadecane 46, 187-191, 1039-1041
Hexamethyldisilazane 562, 563, 1039-1041
Hexamethyldisiloxane 1039-1041
Hexamethylenetetramine 864
Hexamethylene triamine trinitrate 454
Hexamethylenetriperoxidediamine 455, 808
Hexamethylnitratodialuminate salts 452
Hexane 31, 43, 56, 57, 85, 86, 88, 90, 113, 115, 119, 120, 122, 194, 196, 220, 305, 525, 562, 702, 717, 856, 1039-1041
Hexanitrosobenzene 455, 808
Hexanol 195, 1039-1041
2-Hexanone 1042-1044
1,3,5-Hexatriyne 686
1-Hexene 31, 1039-1041
Hexyl 808, 811
Hexyl ether 1039-1041
HIFT Test 332
High-Current Arc Ignition Test 334
High explosives 454, 470, 473, 571, 619, 622, 810
High Flyer (steamship) 692, 693
High-limit switches 651-652, 725, 731, 733, **741-742**, 752, 754, 848, 856-858, 922
High-temperature accelerants (*see* Accelerants, high temperature)
High-Voltage Arc Resistance Test 334
High-Voltage Arc-Tracking-Rate Test 334
High voltage insulators 773
HIPS 309-310, 905, 926, 1069
HMX 394, 458-461, 464, 469, 517, 808-809, 811-815, 885, 1039-1041, 1062
HNAB 808, 1062
HNS 808, 1062
Hobnails 513
Holland Tunnel fire 704
Holmium 876
Homogeneous ignition 190, 360-362, 396
Homogeneous reactions 448
Honeycomb 329, 594, 690
Hops 673, **859**
Hoses 518, 565, 627, 686, 829, 881, 939
Hot bodies, as an ignition mechanism 287-289, 465-466, 499-516
Hot bolts (lightning) 569
Hot Flaming Oil Test 327
Hot gases, as an ignition mechanism 96-101, 154
Hotplate tests ... 393, 401, 409, **418-419**, 724, 730, 824, 872, 922, 958, 966
Hot rivet tests 336
Hot spots 390-391, 402-403
Hot surface ignition 43, 65, **83-94**, 102, 124, 148, 153, 184, 207-213, 288, 289, 354, 598, 599, 699, 807, 824, 829, 862, 871, 884, 886, 907, 913
Hot surfaces 6, 13, 43, 87-88, 142, 153, 183, 184, 207, 209, 213, 288, 317, 332, 500, 598, 723-724, 731, 736, 835, 955
Hot work 387-389, 413-414
Houghto-Safe 271 ..... 1055, 1059
Houses 501-502, 575, 611, 629-631, 686, 762, 781-782, 928, 934, 953
HSE 6, 21, 59, 87, 99, 100, 128, 154, 227, 572, 602, 685, 921, 1023
HSE 20 mL Sphere Test 128
Human skin 823, 861-862
Humans, combustion of 561, 859-861
Humans, electrostatic charging of 559
Humidity 21, **302-304**, 399, 535, 557, 559, 591, 735, 763, 811, 818, 843-845, 852, 867, 898, 902, 920, 943, 951, 965
HVAC equipment 862
HVAR ratings (UL) 334
HVTR ratings (UL) 334
HWI ratings (UL) 336
Hybrid explosions 143, 151-152
Hydraulic diameter 595
Hydraulic fluids 193, 210, 212, 226, 227, 826, **862**, **1059**
Hydrazine 447, 452, 454, 476, 811, **862-863**, 891, 1039-1041
Hydrazoic acid 459, 1039-1041
Hydrocarbon gases 863
Hydrogen 25-26, 28, 38, 43, 53-54, 61, 66, 69, 76, 78-82, 84-87, 89, 91, 94, 97, 99-100, 102-105, 110-111, 115, 118-122, 145, 149, 152, 198, 294, 311, 319, 328, 359-361, 462, 476, 508-511, 513, 525, 536, 539, 542, 558, 560-561, 572-573, 594, 597, 599, 612, 619, 620, 623, 685, 690-691, 710, 719, 726, 732, 742-743, 752, 754, 767-768, 791, 807, 811, 851, 856, **863-864**, 870-871, 874-876, 898, 900, 920, 922, 1039-1041
Hydrogen, explosions due to adventitious presence 864
Hydrogenation 451
Hydrogen bonding dilution effect 851
Hydrogen chloride 27, 452, 758, 762-763, 775, 792, 797
Hydrogen cyanide 1039-1041
Hydrogen peroxide 206, 447, 452, 481, 554, 863, 902
Hydrogen selenide 1039-1041
Hydrogen sulfide 31, 53, 111, 119, 717, 1039-1041
Hydrolysis 399, 451, 700, 708-710, 912, 953, 958
Hydrotreating 6
Hydroxylamine 864
Hydroxyl-terminated polybutadiene (HTPB) 278, 475
Hypalon 784, 787, 1067
Hypergolic reactions 16, 24, 254, 434-435, 452, 476-477, 489, 499, 891
ICAL test (*see* ASTM E 1623)
ICBO Urban-Wildland Interface Code 631
IC-rated lighting fixtures 752, 793
Ideal Gas Law 37, 52, 114
Ideal mixtures 199

Phenol 759, 962, 1048-1050
Phenol formaldehyde (*see* Phenolic)
Phenolic (phenol formaldehyde) 169, 289, 291, 307, 313, 316, 323-334, 408, 482, 690, 725-726, 753, 824, 881, 906-908, 910, 917, 1064, 1067-1068, 1071-1074
Phenyl ether 1048-1050
Phenylhydrazine 1048-1050
PHI-TEC Adiabatic Calorimeter 428
Phlegmatizers 472
Phosphate ester hydraulic fluids 210, 862
Phosphine 717, 903, 1048-1050
Phosphines 452, 903
Phosphoric acid 713, 826, 869
Phosphorus 319, 352, 482, 801, 814, 826, **903**, 912, 914-915, 923
Phosphorus sesquisulfide 868
Photoflash mixture 453
Phthalic anhydride 110, 1048-1050
Physical damage 794, 855
Picoline 1045-1047
Picric acid 448, 454, 683, 808, 810-811, 813-814, 1048-1050, 1062
Piezoelectrification 553
Pigs 860-862
Pigtailing 765
Pile size, effect of 395-396
Pillows **903-904**, 911, 930, 937
Pilot, effect of 292-294
Piloted ignition 9, 13, 16, 43, **65-104**, 120, 217, 239, 241-242, 245-250, 252, 255, 259, 268, 276-277, 292-293, 295, 298-304, 308-309, 312, 333, 337-338, 445, 521, 530, 615-616, 628, 631, 690, 705, 726, 729, 731-732, 817, 821-822, 830-832, 836-837, 865, 883, 896, 899, 907, 910, 919, 926-927, 932-934, 945-950, 953-954, 962, 967
Piloted ignition temperature 16, 245, 277, 337-338, 899, 907, 927, 953
Pilot flames 16, 19-20, 65, **73-74**, 192-193, 195, 201, 205, 213, 215, 226, 239, 251, 293-294, 331, 337, 731, 837, 856, 908, 940
Pinane 1048-1050
Pine 241, 245, 292, 298-299, 328, 371, 501, 504, 574, 835-837, 840-844, 887, 943, 949-952, 954, 956-957, 962, 964-965, 1074, 1076
Pine oil 1058
Pinene 1048-1050
Pipe insulation 288, 371, 381, 383, 403, 809, **904-905**
Pipes, broken 614
Pistols 143
Pitch (*see* Asphalt)
Pittsburgh coal 170, 173-174, 395, 396, 401-402, 419, 598, 724, 1063
Plasma arc 941
Plastic explosives 454-455
Plasticizers 454, 791, 792, 897, 1069
Plastics 558, 725-726, 905-912, 1064, 1067-1076
Plastics (*see also* individual substances)
Plastics, fiber-reinforced 725-726
Plastics, laminates 726
Plastics, self-heating of 909-912
Plastics, sheets 558
Platinum 8, 38-39, 59, 83-84, 86, 89-91, 94, 96, 105, 124, 160, 176, 277, 334, 353-354, 480, 512, 546, 553, 683-684, 735, 856, 863, 923
Plexiglas G 1068
Plexol 201 1059
Plumbago 1066
Plumes 218, 246, 251, 253-254, 275, 315, 330, 353, 500, 504, 527-529, 610, 867, 887
Plutonium 356, 452, **876**
Plywood 271-274, 312, 328, 519, 521, 530, 560, 574, 715, 747, 750, 781, 912, 949, 952, 962, **964-965**, 1074
PMMA 21, 147, 157, 172, 239, 242, 244, 246-248, 250, 252, 265, 268-270, 273, 275-281, 289, 294-301, 305-307, 308-311, 323, 328, 484, 559, 693, 906-908, 1064, 1068, 1071, 1074-1075
Pneumatic transfer 561
Pockets 145, 509, 846
Point discharge 555, 569, 592
Point source radiation model 522, 527
Polarization 553
Pollution 38, 546, 773, 810, 851
Polonium 592
Polyacrylonitrile 164, 280, 313, 816, 824, 1064, 1068
Polyamide 334, 824, 1075
Polyamide-imide 1075
Polybenzimidazole 21, 326, 824-825
Polybutadiene-acrylic acid (PBAA) 281, 477
Polybutadiene rubber 910
Poly-1-butene 251
Polybutylene terephthalate 334
Polycarbonate 286, 290, 297, 307, 334, 461, 559, 628, 905-908, 1064, 1068, 1071, 1075
Polychloroprene 896, 910, 912, 1067-1068
Polychlorotrifluoroethylene (PCTFE) 21, 323, 559, 628
Polycondensation 881
Polyester 21, 161, 167, 289-290, 304, 309, 322, 328, 334, 559-560, 719, 725, 732, 734, 741, 786, 816-825, 831, 855, 861, 898, 903-905, 920, 931-934, 937, 1072
Polyester, glass reinforced 559, 1068, 1070
Polyester, unsaturated 1068
Polyester resin 873, 897, 906, 909
Polyetheretherketone 21, 628, 1075
Polyetheretherketone (*see also* PEEK)

Polyetherimide....628, 1068, 1075
Polyethersulfone....628, 1068
Polyethylene....21-22, 146, 148, 151, 157, 160-161, 168-169, 239, 246, 248, 251, 262-264, 270, 273, 286, 290, 297, 301, 307, 310, 313, 475, 526, 558, 561, 565, 614, 627-628, 688, 695, 699, 712, 744, 772, 780, 784-787, 792-793, 808, 851-853, 893, 895, 902-905, 907-908, 910-911, 957, 1064, 1067-1068, 1070-1072, 1075
Polyethylenenaphthalene....1075
Polyethylene terephthalate....21, 313, 628, 816, 1064, 1068
Polyisobutylene....215, 454, 809
Polyisocyanurate....21, 908
Polyisocyanurate foam....300, 910, 1075
Polymerization....8, 104, 369, 373, 448, 451, 683, 687, 808, 829, 888, 897, 902, 909, 913, 922
Polymer structure, effect of....308
Polymethylmethacrylate (*see* PMMA)
Poly-4-methyl-1-pentene....251
Polyoxymethylene....246, 248, 265, 270, 289, 307, 908, 1048-1050, 1067-1068, 1071
Polyphenylene oxide....307, 628, 784, 1071
Polyphenylenesulfide....1075
Polyphenylsulfone....326, 1075
Polypropylene....21, 238, 246, 248, 251, 270, 286, 287, 298-299, 307, 309, 559, 627-628, 725-726, 730, 786, 816, 821, 824, 829, 830-831, 849, 882, 891, 909, 1064, 1068, 1070-1073, 1075
Polysaccharides....707
Polystyrene....21-22, 163-165, 200, 246, 248, 270, 286, 289-290, 293, 299, 307, 309-310, 312-313, 323, 461, 475, 478, 506, 559, 628, 704, 718, 784, 849, 905-910, 922, 925-926, 934, 1064, 1069-1072, 1075
Polysulfide....304, 475
Polysulfone....1075
Polytetrafluoroethylene (*see* PTFE)
Poly(trifluorochloroethylene)....1069
Polyurethane....21, 269, 291, 307, 316-318, 454, 460-461, 475, 477, 506, 559, 594, 619, 628, 716, 730, 781, 806, 829, 849, 895, 903, 906, 908-912, 929-934, 936-938, 1069-070, 1072, 1075
Polyvinyl acetate....1064, 1069
Polyvinyl acetate alcohol....1064
Polyvinyl butyral....1064
Polyvinyl chloride (*see* PVC)
Polyvinyl ester....1072
Polyvinylidene chloride....825, 1064, 1066, 1069
POM (*see* Polyoxymethylene)
Ponderosa pine....242, 304, 836, 948, 954, 1076
Pools, liquid....213-215, 521-524
Poplar....242, 952, 1076
Poppyseed oil....889
Porosity....218, 308, 311, 316, 318, 359, 384, 394-396, 399, 410, 471, 618
Potash....826
Potassium....319, 353, 358, 400, 434, 460, 485, 512, 711, 814, 826, **876**, 886, 953
Potassium carbonyl....870
Potassium chlorate....452, 454, 472, 480-482, 811, 868, 894, **912-913**, 914-917, 921, 923
Potassium fluoride....474
Potassium hydride....870
Potassium nitrate....460, 475, 480-481, 526, 701, 811, 827, 868, 884-885, 915-917, 1048-1050
Potassium perchlorate....475, 480-482, 526, 913, 915-917, 1048-1050, 1066
Potassium permanganate....452, 481, 890
Potassium peroxide....902
Potassium superoxide....876
Potato starch....1064
Pouring....196, 485, 555, 561, 688, 702, 793, 852
Powder heap discharge....554, **556**, 644
Powdered metals....561, 871-879, 895
Powdered metals (*see also* specific metal)
Powdered milk....913
Power cables....402, 544, 780, 785, 719, 732, 739, 775, 779, 786, 790, 798, 802, 924
Power lines....572, 592-593, 840-841, 843-844
Power steering fluid....199, 881, 882, **913**, 1058
Praseodymium....509, 876
Pre-charring, effect of....310, 953, 958
Pre-flash 'halo'....194
Prescribed burns....833
Preservatives, effect of....953
Pressure, effect of....45, 49-52, 57, 63, 68-69, 78, 97, 99-100, 112-114, 120-123, 158, 162, 188-189, 191, 205, 208, 212, 289, 301-302, 447, 451, 464, 470, 476, 478, 504, 508-511, 517-518, 535, 625-628, 683-686, 689, 691, 693-694, 697-698. 789-790, 807-809, 850, 863, 873, 877, 879-880, 889-890, 903, 927-928, 940-941
Pressure, excessive....172, 849
Pressure gradient....78
Pressure limit....113, 117, 686, 691, 807, 849, 850
Pressure piling....**37**-**38**, 100, 611
Pressurized enclosures....603
Preventive measures....404-405, 576, **591**-**604**, 624
Primacord....472
Primary explosives....459, 461, 466, 468, 471, 488, 559, 574, 700
Primers....11, 372, 472, 482, 896-897, 962, 1073
Priming mix....482
Probabilistic aspects....9-10, 528, 759, 900
Probability level....98, 157, 170, 175, 462, 486, 572, 813
Proban....819
Process splices....791
Promethium....876
Proof Tracking Index....334
1,2-Propadiene....145, 1048-1050
Propagating brush discharge....554-557, 644
Propanal....1048-1050
Propane....28, 31, 38, 54-5, 62-63, 69, 74-77, 79, 81-82, 85, 87, 89-93, 103-104, 107-109, 111, 113, 116, 118-122, 152, 210, 227, 287, 331, 337, 447, 489, 508, 511, 513-

514, 519-599, 609-612, 619-624, 686, 717, 795, 848-849, 856, 866-867, 871, 881-882, 910, **913**, 919, 941, 1048-1050
1,2,3-Propanetriol 808, 1039-1041
Propanoic acid..... 1048-1050
Propanoic anhydride 1048-1050
1-Propanol..... 1048-1050
2-Propanol..... 103-104, 1048-1050
2-Propanone..... 1048-1050
Propargyl alcohol..... 1048-1050
Propargyl bromide 447, 1048-1050
Propargyl chloride..... 1048-1050
Propellants 290, 304, 453, 456, 458-461, 466-468, **475-479**, 686, 694, 695, 709, 811, 858, 884, 902, 923
Propene 1048-1050
2-Propenoic acid 808, 1024-1026
2-Propenol..... 1024-1026
Propiolactone 1048, 1049, 1050
Propionaldehyde 104, 691, 110, 1048-1050
Propionic acid 687, 967, 1048-1050
Propionic anhydride..... 1048-1050
Propionitrile 1048-1050
n-Propyl acetate 1048-1050
n-Propyl alcohol..... 1048-1050
Propylamine..... 1048-1050
Propyl benzene..... 1048-1050
Propyl bromide 1048-1050
n-Propyl chloride 1048-1050
Propylcyclopentane.....46
Propylene ...31, 47, 54, 89-90, 113, 119, 122, 620, 623, 686, 717, 863, 866, 1048-1050
Propylene chloride..... 1048-1050
Propylene dichloride..... 1048-1050
Propylene glycol 808, 890, 1048-1053, 1059
Propylene glycol monomethyl ether 1051-1053
Propylene glycol monomethyl ether acetate 1051-1053
Propylene oxide 110, 119, 122, 448, 507, 511, 597, 717, 806, **913**, 1051-1053
Propyl ether..... 1051-1053
n-Propyl nitrate 101, 1051-1053
Propyne (*see* Methyl acetylene)
2-Propyn-1-ol..... 1048-1050
Protective clothing 545
Prussian blue 897, 1066
PRV..... 21, 620-622, 624
PTC devices 673-674, 918-919
PTFE (polytetrafluoroethylene; Teflon) 21, 300, 302, 313-314, 323, 558-559, 627-628, 748, 784-786, 805, 816, 902, 907, 917, 1064, 1066, 1069
Puffing combustion.....617
Pumps 6, 851, 862, 896
Push-on connectors 662, 741, 762
Putty.....454
PVC.... 22, 152, 157, 237-238, 241, 286, 289, 293, 299-301, 307, 309, 311, 313, 323, 328, 475, 526, 559, 575, 614, 627-628, 657, 663, 665, 716, 726, 744, 757-759, 762-763, 773, 775-778, 780, 782, 784-793, 797-801, 804-805, 816, 821, 825, 830-831, 854-855, 906-908, 910, 912, 920, 923, 925, 931-934, 938, 1064, 1067, 1069, 1070, 1072-1075
Pydraul 150.....1059
Pydraul A-200 1059
Pydraul AC 1059
Pyrethrum 1065
Pyridine.....1051-1053
Pyrite 396, 400, 512, 514, 811, 864-865
Pyro aluminum 482
Pyrodex.....475
Pyroelectrification 554
Pyrofuze.....455, 480, 628
Pyrogard D.....1059
Pyrogen igniters.....476
Pyrolysates.....238, 252, 292, 295, 299-300, 330, 468, 617, 908, 927
Pyrolysis ... 7, 18-19, 144, 146-148, 150, 161, 185, 238-240, 249, 252, 257, 260, 277, 281, 283, 285, 287-288, 290, 292, 295, 299, 304, 317, 319, 360, 363, 369, 370, 412, 429, 453, 468, 500, 503, 617, 756, 772, 803, 822-823, 898, 927, 935, 942-943, 945-946, 958-959, 961
Pyrolysis, oxidative 7
Pyrophor bar 509, 512-514, **872**
'Pyrophoric carbon' 674, 955-960
Pyrophoric liquids.....485
Pyrophoric materials.....18-19, 354-355, 358, 373, 452, 484-485, 490, 499, 598, 695, 863-865, 869-878, 886, 890, 903, 920, 924, 955-960, 1023
Pyrotechnics 7, 9, 18, 28, 144, 238, 335, 452-453, 455, 472, 476, **479-482**, 489-490, 517, 526, 810, 912, **913-918**
Pyrotechnics, chemistry of.....480-481
Pyroxylin 707
Pyrrole 1051-1053
Quartz 59, 77, 86, 89, 305-306, 332, 510-511, 515-517, 747, 749-751, 821, 850, 899, 935
Quartz, fused.....513, 749-751
Quartzitic rocks 510-511, 513, 515-516
Quaternary mixtures 106-107
Quench layer height.....195, 196
Quenching distance or diameter 44, 65-66, 68-69, 74-75, 77-83, 97-100, 103-104, 117, 127, 145-146, 148-149, 151, 166, 196, 251, 370, 376, 395, 554, 594, 683, 743, 863, 1023
Quicklime 866
Quinoline 1051-1053
Quintiere's procedure 262-263
Radiant ignition of explosives and propellants.....465, 478-479
Radiant ignition of fabrics 821-823
Radiant ignition of liquids 217-219
Radiant ignition of plastics 905-910, 1071-1076
Radiant ignition of solids..... 250-277, 292-312
Radiant ignition of upholstery 932-934
Radiant ignition of vegetation 841-842
Radiant ignition of wood 946-950

Radiata pine (*see* Monterey pine)
Radiators 330, 532, 794, 956
Radio receivers 740, 864, **918**
Radio transmitters 469, 571-574
Rail cars 406, 507, 622, 624
Railroads 372-373, 520, 834, **918**
Rain 398-400, 557, 562, 570, 721, 792, 835, 965
Ramjet fuel 699, 701
Rangetops 727-728
Rapeseed oil 734, 828, 833, 886, 887, 897, 1058
Rapeseeds 687, 735
Rapid compression machines 64, 123-124
Rare earth elements 513, **876**
R134a refrigerant 885
Rats 666, 787-788
Rayon 321, 371, 373, 507, 574, 716, 816-817, 820, 822, 829-830, 918, 931, 933, 1064
RDX 389, 453-455, 458-460, 464-465, 471-472, 476, 478-479, 484, 808-815, 1051-1053, 1062
Reaction kinetics 24, **32-35**, 57, 64, 105, 108, 149, 283, 394, 430, 942
Reactive substances 452
Readily combustible solids 484
Receptacles, electrical (*see* Electric outlets)
Reclaimer pads 688
Reclosers 769
Rectangular brick 413
Red cedar 290, 292, 503, 948, 953, 956, 965, 1077
Red gum 480, 482, 916
Reduction reactions 18
Redundancy 10
Redwood 298, 502, 569, 947-950, 1076
Reflux heat flow calorimeter 428
Reforming 6
Reformulated gasoline 851
Refrigerants 1060
Refrigerants, flammable 885
Refrigerators 5, 674, 739, 740, 779, 882, 885, **918-919**
Reid vapor pressure 15, 17, 18, 22, 216, 696-697, 699, 702, 849, 851, 853
Re-ignition 311, 362, 618-619, 771, 876
Reina del Pacifico (explosion) 731
Rekindle **618-619**, 706
Relaxation time 127, 558, 561, 563, 564
Residence time 60, 83, 155-156, 170, 211, 219
Resins 480, 825, 897, 909, 957
Resins (*see also* Plastics)
Resistors 734, 773, 925
Resonance 518, 624
Resonant circuits 81, 548
Restricted breathing apparatus 600
Restrike voltage 548, 770-771
Retorts 710
Return stroke (lightning) 568, 592
Reverse smolder 316-317, 319-320, 951
RF initiation of explosives 469
Rice 739, 833, 919, 1064
Rice husks 919
Rinse-aid 732
Risk of house destruction 629-630
RJ-4 1058
RJ-5 1058
RJ-6 1058
Road tunnel dust 1063
Rock wool 403, 828, 881
Rodents 666, 769, 787
Rollout (of flames) 848, 940
Roofing materials 310, 502, 631, 919
Roof shingles 501, 631, 1075-1076
Roof tile 629, 631
Room fires 32, 264, 332, 532, **615-617**, 703, 803
Room fresheners 686
Rosin 708, 889, 917
Rosin oil 889
Rot 162, 940, 954
Roundrobin tests 173, 221, 334, 906, 931
RP-1 kerosene 476
Rubber (*see* Elastomers)
Rubber dust, from tires 1065
Rubber hammers 510
Rubber, chlorinated 559
Rubber, hard 559
Rubbish 5, 718, 923
Rubidium 358, 870, 876
Rugs (*see* Floor coverings)
Runaway exothermic reactions 451
Run-up distance 121
Rust 102-103, 328-329, 400, 480, 506, 509, 510, 512-514, 516, 572, 684-685, 688-691, 704, 720, 745, 809, 863, 865, 888, 892, 895, 898, 902, 921, 927, 960
Ruthenium 455
SADT 405-406, 422, 426-428, 433
SAE 5W-30 motor oil 1058
SAE 10 lubricating oil 688, 1057
SAE 30 motor oil 217, 218, 890, 1058
SAE 60 lubricating oil 1057
SAE J335 596
Safety film 709, 710
Safety fuses 472, 488
Safety matches 868, 934
Safety measures 113, 567, 903
Safflower oil 889
Sagebrush 840
Sakata City Fire 501
Salt water 775
Samarium 356, 509, 876
SAN 1064, 1070
Sand bomb test 488
Sanding dust 897
Sanding machines 919
Sandpaper 466, 486, 868
Sandstone 510-513, 515-516
Saponification 734

SASIN....469
Saturated vapor pressure....186, 192
Saunas....617, 920
Sauter mean diameter.... 150, 163, 203-204
Sawdust (*see* Wood dust)
Saws....834
SBR....314, 371, 910, 911, 938, 1070
School buses....934
Schramm-Zebrowski Incandescent Rod Test....336
Scintillations....312, 758, 759, 806
Screens.... 329, 533-534, 596, 630
Screw connections....756-759, 761-762, 764-765
Screwdrivers....508, 769
Scrim....507, 934
Scroll feed transfer....561
Sealed equipment....603
Seaweed....1066
Secondary explosives.... 459-460, 464, 466, 468, 470-472, 813
Seebeck coefficient.... 88-89
Seeds....35, 373, 687
Selenium....1066
Self-heating.... 9, 11, 14-15, 19-21, 36, 43, 54, 143, 237-238, 241, 243, 245, 249, 282, 288-289, 312, 318, 320, 335, 337, 353, 356, 360, 362, **369-436**, 446, 448-452, 457-500, 538, 618-619, 687-688, 692-694, 696, 700-702, 705, 707-714, 720-724, 726, 729-730, 732-736, 809, 814, 825-829, 833, 845-847, 859, 864-867, 872, 874, 881, 886-905, 909-914, 918-919, 921-924, 928, 942-943, 949, 953-968, 1062
Self-ignition.... 16, 18-19
Self-ignition temperature....16, 19
Semenov, Nikolai....47, 374
Semenov number....48, 393, 450
Semenov theory....**46-51**, 91, 149, 191, 220, 360, 375, 403, 420-421, 426, 428, 449-450
Semtex....454
Sensitivity....19, 82, 152, 167, 281, 337, 416, 422, 427-430, 433-434, 446-447, 455, 457, 459, 461-462, 466-469, 472-474, 476, 482-487, 489, 517, 574, 598, 602, 626, 692-693, 695, 709, 799-801, 811-813, 903-904, 915-917
Sensitizers....472, 694
Series arcs....546, 774, 788, 795
Service drops....772
Sesame oil....886, 1058
Setaflash Test.... 193, 224-226
Setaram C80 calorimeter....428
Setaram MS80 calorimeter....428
Setchkin flask Test.... 222-223
Setchkin furnace (*see* ASTM D 1929)
Sewage....726, 826, 1066
Sewage sludge....826, 1066
Shampoo....686
Shear....459, 460, 462
Sheep....860
Shellac....480, 917
Shingles....241, 290, 501-503, 629, 630, 919, 967
Shock....10, **64-65**, 66, 101, 281, 446, **461-465**, 476, 477, 484, 559, 561, 684, 719, 749, 752, 794, 813, 853, 903, 909, 912, 921, 928
Shock waves....14, 36, 38, 66, 68-69, 97, 219, 449, 451, 454, 457, 459, 461, 463-464, 469, 470, 472, 487, 517, 537, 544, 568, 571, 621, 627
Shoddy....827, 1066
Shoes....560, 592, 825, 918, 921
Short arcs....536, 540
Short circuits.... 13, 18, 334, 553, 569, 728, 740, 743, 746, 766-767, 774, 776-781, 788, 792-793, 795, 797, 799, 802, 882
Shrapnel....454, 474, 622-623
Shredded materials....920
Shrubs....630, 834, 841
Siding.... 241, 290, 310, 528, 631, 674, 781-782, 920, 951, 962, 1075
Sieving....170, 174, 561, 923
Silage....845, 847
Silane (or silanes)....452, 902, **920-921**, 1051-1053
Silica.... 187, 485, 878, 881, 1066
Silicon.... 104, 526, 750, 875, 920, **921**, 1063, 1065
Silicon carbide....91, 104, 336, 511
Silicone fluids....921
Silicone oil....210, 211, 856
Silicone polymers....921
Silk....373, 816-818, 825, 827
Silos....555-557, 561, 736, 845, 847, 913
Silver 59, 72, 83-84, 353-354, 512, 536, 546, 765, 772, 879
Silver acetylide....469, 810
Silver azide....459, 468, 700
Silver fulminate....468, 810, 915
Silver nitrate....452, 469, 875
Silver nitride....468, 886
SIMS....22, 797, 799-800
Single-base powder....475
Single-compartment model....611
Single-component explosives....453, 467
Siwek 20 L sphere....174
Skin effect (electricity)....549, 573, 593
Skins....921
Skydrol 500B....1059
Slab, infinite....260, 380-381, 383, 390
Sleeving....780
Slosh....116, 217, 697
Sludge....553, 767
Slurries....454, 459, 694
Smoke bombs....915
Smoke explosions....617-618, 647
Smokeless powder....335, 468, 470, 475, 708, 810-811, 813, 854
Smoldering....8-9, 19, 144, 175, 237-238, 284, 288, **315-320**, 335, 369, 376, 390, 395, 399, 401-403, 484, 499, 505, 516, 569, 596, 617-618, 630, 650, 695, 706-707, 712, 716-718, 724, 729-732, 735-736, 755, 761,

776, 788, 803, 824, 827, 839-842, 844, 854, 869, 874, 882, 887, 897, 899-902, 909, 910, 913, 919, 922, 924, 928-929, 931, 937-939, 941, 950-953, 963
Smoldering to flaming transition 319-320, 395, 929, 952
Smolder inhibitors 318-319
SMRE 70-72, 171, 512, 603, 939
Snakes 766, 769, 787
Snap caps 915
Soap 891, 921, 1065
Soap powder 1065
Sodium 353, 358, 400, 481, 696, 706, 711, 750-752, **876**, 895, 902, 923
Sodium azide 455, 700, 884
Sodium benzoate 475
Sodium bicarbonate 474, 562
Sodium bromate 854
Sodium carbonate 708, 881
Sodium chlorate 485, 811, 894, 895, 912, **921-922**
Sodium chloride 474, 878
Sodium chlorite 891, 921-922
Sodium dichloro-s-triazinetrione 894
Sodium dihydroxy naphthalene-disulfonic acid 1066
Sodium di-isobutyl sulfosuccinate 1066
Sodium dithionite 371, 387, 401, 419, **922**
Sodium hydride 870
Sodium hydroxide 452, 875, 908
Sodium nitrate 526, 712, 827, 885, 917
Sodium perborate 1066
Sodium peroxide 452
Sodium tetracarbonylferrate 870
Sodium trichloro ethyl phosphate 1066
Soil 316, 824, 834, 855, **900-901**, 923, 955, 1076
Soiling 533, 935
Solar heating 396
Solder 221, 796, 922, 924
Soldered joints 924
Soldering irons 922
Solids 237-338
Solvasol 1058
Solvents 151, 184, 201, 310, 709, 713, 829, 858, 870, 876, 880, 888, 942
Solvents (*see also* Chapter 15)
Solvents, chlorinated 200-202, 880
Soot films 690
Soots 689, 772, 922
Southern pine 964, 1074, 1077
Soybean meal 735, 826
Soybean oil 734, 886, 889, 1058
Soybeans 687, 922
Soy flour 833, 1064
Spalding B-number 151, 204, 227
Spandrel panels 528, 531
Spark arresters 506, 596
Spark duration, effect of 72, 80-81, 163-164, 205, 825
Spark gaps 79, 593
Spark guards 596
Sparklers 915-916
Sparks 2, 13-19, 43-44, 47, 54-55, 65-84, 95-96, 98, 101-104, 106, 114-115, 117-118, 120-121, 124-127, 146, 153, 159-161, 163-166, 170, 172, 192, 196, 202-207, 213-214, 216-217, 239, 252, 293-294, 296-297, 311-312, 322, 331, 334-335, 337, 467-468, 481, 506-516, 534, 536-540, 546-547, 551, 554-555, 557-563, 566, 572, 593-594, 596, 602-603, 614, 644, 683-684, 686, 690, 699-700, 727, 731, 736-737, 742-743, 754-755, 766, 788, 807, 811-813, 817, 825-826, 836, 844, 851-852, 871, 874, 876-877, 882, 898, 909, 915-916, 920, 922, 924, 933, 948-949, 1060, 1062
Spark Test Apparatus (STA) 216, 602
Spas 922
Specific gravity 197, 942
Specimen area, effect of 295-297
Specimen orientation, effect of 294
Spectral absorptivity 305-308, 821
Spectral emissive power 306
Spedding steel mill 509-510
Sperm oil 828
Spheres 45, 51-52, 54, 66-67, 69, 85, 91-92, 94, 99, 107, 117-118, 120, 125-128, 146, 159, 166-170, 173-176, 207, 288-289, 359, 378-381, 384-385, 388-392, 395, 402, 414, 416, 421, 425, 450, 467, 504-505, 538-539, 558, 570, 592, 699-700, 733, 777, 843, 879, 912, 957
Spills (of flammable liquids) 612-614
Splash loading 206, 565, 567
Sponge iron 372, 874
Spontaneous combustion 1, 4-7, 9, 11, 19, 36, 243, **369-436**, 687-688, 700, 708, 711-712, 720-721, 723, 726, 729, 734, 736, 826-829, 833, 845-847, 864-865, 881, 888, 892, 897, 899, 901, 903, 909, 911-912, 915, 918-919, 921, 923, 927, 956, 965-966
Spontaneous human combustion 372, 673, 859-861
Spontaneous ignition 16, 19-20, 43, 337, 485, 955, 959
Spontaneous ignition temperature 16, 19, 43
Spontaneous polymerization 448, 911
Spotting fires, spotting distances 503-505, 844-845
Spray electrification 565
Sprays 83, 190-192, 202, 204-207, 209, 211-212, 219, 226-227, 513, 565-566, 748, 850
Sprengel explosives 454
Spruce 242, 272-273, 840, 842, 847, 948, 965, 1077
Squibs 701
St. Elmo's fire 555, 569, 690
Stab igniters 472
Stability of explosives 457-459, 485-486
Stabilizers 400, 807, 910
Stab initiation 466
Staples, overdriven 668-669, 790
Starch 103, 516, 687, 712, 868
Starch paste 712
Starter mix 482, 916

UN Test O1 ..... 434, 485
UN Test O2 ..... 435, 485
UN Tests 405, 484
UN Test S1 ..... 435, 827
Upholstered furniture 287, 317, 331, 502, 519, 521, 619, 703, 716, 719, 730, 815, 817, 911, 921, **928-938**
Upper flammability limit 22, 44, 77, 110, 148, 1023
Upper flammability limit (*see also* specific substances)
Upper flash point 193, 201
Upper temperature limit 22, 114, 193
Uranium 358, 359, 452, 509, 870, **878**, 886, 1063
Uranium hydride 452, 870
Urea 753, 864, 897, 1054-1066
Urea formaldehyde 323, 658, 754, 759, 907, 1064, 1070
Urea nitrate 455
Urine 787, 935
UVCE (*see* Unconfined vapor cloud explosions)
n-Valeraldehyde 1048-1050
Valeric acid 1054-1055
Vacuum cleaners 938-939
Vapor-freeing 215
Vapor pressure 15, 17, 18, 22, **184-186**, 192, 216, 696-697, 699, 702, 849, 851, 853
Vapor recovery canister 881
Variable Confinement Cookoff Test 487
Varistors 593, 923
Varnishes 226, 373, 428, 482, 897, 962
Varsol 1058
VCHZ Synthesia 454
VDI 3673 175
Vegetable oil 369, 400, 519, 733, 828, 886-889, 921
Vegetation 238, 289, 302, 390, 500-506, 531, 540, 574, 596, 630-631, 687, 716, 735, 738, 746, **833-847**, 883-884, 915, 918, 956
Vehicles 4, 532, 700, 739, 804, 807, 834, 852, 881-885, 891
Veld grass 837
Vent Sizing Package (VSP) 428
Vermin infestation 666-667, 787
Versilube F-50 1059
Vessel size, effect of 58-59, 157
Vibration 457, 517-518, 548, 734, 762, 787, 795, 804, 856
Victorian ash 1077
Vinyl acetate 21, 246, 786, 909, 1054-1055
Vinyl acetylene 447, 686, 717, 1054-1055
Vinyl asbestos 1070
Vinyl bromide 1054-1055
Vinyl chloride 28, 119, 620, 717, 809, 1054-1055
Vinyl cyanide 1024, 1025, 1026
Vinyl epoxy adhesive 1070
Vinyl ether 806, 1033-1035
Vinylidene chloride 119, 1054-1055
Vinyl methyl ether 1054, 1055
Vinyl toluene 119, 1054-1055
Viscous flow 459
Vitamins 903
VM&P naphtha 856, 1058
Volatile content, effect on dust cloud explosions 146-147, 154-155
Volume resistivity 152, 167, 558
Volumetric decomposition 251
VW-1 Test 327, 334, 753
Waferboard 1076
Wall material, effect of 59, 79, 87-89, 221
Wardrobes 521
Washers, clothes (*see* Washing machines)
Washing machines 5, 686, **733-734**, 762, 739-740, 905
Wastebaskets 718, 899
Wastes 726, 833, 911, **939**, 956, 965-966
Water, acid rain 562
Water, deionized 562
Water, effect of 310
Waterfalls 565
Water gel 810
Water heaters 5, 612, 739, 848, 851, **939-941**
Water-reactive materials 452

Constants

e = 2.718 (base of Napierian logarithms)
$\varepsilon_o = 8.845\times10^{-12}$ F m^{-1} (electrical permittivity of a vacuum)
$\sigma = 5.67\times10^{-11}$ kW m^{-2} K^{-4} (Stefan-Boltzmann radiation constant)
R = 8.314 J mol^{-1} K^{-1} (universal gas constant)
R = 8.314 Pa m^3 mol^{-1} K^{-1} (universal gas constant, using alternate units)
$R = 82.1\times10^{-6}$ m^3 atm K^{-1} mol^{-1} (universal gas constant, using alternate units)
Molar volume = 22.414 L mol^{-1} (at 1 atm and 0°C)
Molar volume = 24.055 L mol^{-1} (at 1 atm and 20°C)
Molar mass of dry air = 28.96 g mol^{-1}
Density of air (kg m^{-3}) at 1 atm pressure = 353/T , where T = temperature (K)
Density of any gas (kg m^{-3}) at 1 atm pressure = 12.18 M/T,
where M = molar mass (g mol^{-1}), T = temperature (K)
Fraction of oxygen in dry air = 20.95 vol%

Volumes and areas

Sphere: $V = (4/3)\pi r^3$ $A = 4\pi r^2$
Cylinder: $V = \pi r^2 L$ $A = 2\pi r L$

Conversion factors

Density
1 PCF = 16.03 kg m^{-3}
Distance
1 in = 25.4 mm
1 ft = 0.3048 m
Electric charge
1 C = 1 A•s
Energy
1 J = 1 N•m = 1 kg m^2 s^{-2}
1 BTU = 1055 J
1 cal = 4.184 J
Power
1 BTU/h = 0.293 W
Mass
1 lb = 0.454 kg
Pressure
1 atm = 101,300 Pa = 101.3 kPa
1 psi = 0.068 atm = 6888 Pa = 6.888 kPa
1 bar = 100,000 Pa = 100 kPa = 0.987 atm
Surface weight
1 oz yard^{-2} = 33.93 g m^{-2}
Sprinkler density
1 GPM ft^{-2} = 679 g m^{-2} s^{-1} = 0.679 mm s^{-1} = 40.7 mm min^{-1}
Temperature
K = °C + 273
°F = (9/5)°C + 32
Volume
1 gallon (US) = 3.785 L
